Brown monkeys, *Silenus (Macacus) rhesus*, weighing about 20 lbs., were divided into three groups of 23 animals each. The monkeys of the first group were given the Kasauli 6 per cent sheep's brain carbolized vaccine in seven daily subcutaneous doses of 5 c.cm. each. On the seventh day the monkeys of the second group were given one dose of the proprietary vaccine. The third group of monkeys received no treatment. One hundred days after completion of this treatment all the 69 monkeys had injected into the deep muscles of the neck 2 c.cm. of a 2 per cent emulsion of the brain of a rabbit which was completely paralysed 15 days after intracerebral infection with the brain substance of a dog which had died of naturally acquired

rabies. Negri bodies were present in the brains of both dog and rabbit. The results of this experiment are shown in the table, the monkeys having been observed for a period of 98 days after the test dose of street virus was administered. In all cases of death from rabies the diagnosis was confirmed histologically.

TABLE

Prophylactic treatment employed	Number of monkeys tested	DIED	
		'Other causes'	Rabies
Kasauli vaccine ..	23	Nil	1
Proprietary vaccine ..	23	Nil	15
No treatment (controls)	23	1	13

It appears reasonable to conclude that the course of Kasauli animal vaccine affords better protection against street virus infection than the proprietary vaccine given by the 'one-shot' method. Repeated doses of the latter might give better results but the 'one-shot' method is popular in India and it appears desirable to report that this may not be adequate. No attempt is made to compare the two vaccines in terms of equal dosage of brain substance nor to assess the value of vaccine treatment after exposure to infection has occurred. This note merely contrasts the possible protective value, before infection, of two methods of prophylactic treatment which are in general use in India. The experimental results should be of interest to dog owners and to persons responsible for planning anti-rabic vaccine campaigns among dogs.

For several years an attempt has been made to collect figures regarding the anti-rabic treatment of dogs with Kasauli vaccine. Reports have, however, been received in respect of less than 60 per cent of the dogs inoculated. The consolidated figures for the three years 1936 to 1938 are as follows :—

Reports received in response to enquiries made  
six months after completion of inoculation

Total inoculated	DOGS INOCULATED AFTER EXPOSURE TO INFECTION		DOGS INOCULATED PROPHYLACTICALLY	
	Number	Deaths believed to be due to rabies	Number	Deaths believed to be due to rabies
4,349	767	18	1,838	1

## WHEREIN LIES THE ACTIVITY OF SULPHANILAMIDE ?

By U. P. BASU, D.Sc., P.R.S.

(From the Bengal Immunity Research Laboratory, Barnagore, Calcutta)

SINCE the development of modern 'Chemotherapy' by Paul Ehrlich, various synthetic compounds have been offered to clinicians for treatment of disease. Amongst these the compound—hydrochloride of 4'-sulphonamido-2,4-diaminoazobenzene—with which Domagk (1935) experimented was a remarkable advance because it extended Ehrlich's chemotherapy to the treatment of infections as yet not influenced by any chemical. Subsequent researches in this direction further show that, for the major portion of the bactericidal effect of the azo dye, the sulphanilamide grouping present is mainly responsible. Of course, there is now considerable difference of opinion as to whether sulphanilamide itself is or is not the sole active agent in this new therapy. Still, in view of the great therapeutic significance of sulphanilamide, extensive investigations have been carried out to discover its mode of action on the one hand, and to obtain a more effective but less toxic substitute on the other.

At the outset, it may be pointed out that the active radical common to all the drugs now in

use is  $N \text{—} \text{—} \text{—} S$ . But this does not mean

that the presence of nitrogen or sulphur is absolutely essential for the development of the chemotherapeutic activity, as Levaditi, Girard and Vaisman (1938) noticed an activity in dihydroxy diphenyl sulphone,— $(HO.C_6H_4)_2SO_2$ —, and Mayer and Oechslein (1939) in p-nitrobenzoic acid,  $p\text{-NO}_2.C_6H_4.COOH$ . The replacement of the amino group from the para to the other positions, or, the addition of amino or sulphonamido group in p-amino benzene sulphonamide molecule, however, lowers the efficacy of the drug. The substitution of the amino hydrogen of the p-amino group in sulphanilamide might either increase the solubility, lessen the toxicity, or both, but would not have any influence on the efficacy or the range of activity of the drug. The replacement of the amide hydrogen of the sulphonamido group by other radical or nucleus has again afforded a number of products that are equally, if not more, effective against infections affected by sulphanilamide itself, and in addition possess certain advantages over them in gonococcal and pneumococcal infections. The recent observations of Climenko, Crossley and Northey (1939) on the efficacy of the sodium salt of disulphanilamide in mice infected with a strain of human influenza virus, is of more than theoretical interest as it raises the possibility of influencing virus diseases with this group of drugs.

The question how and in which way the sulphanilamide or any of its derivatives produces

the therapeutic effect in bacterial infections, still remains unsolved. From general considerations the compound may exert its characteristic effect by being a simple disinfectant, by stimulating the natural defences of the body or by acting by a combination of these two factors. But unlike the well-known germicides such as acriflavine, brilliant green and others, sulphanilamide is neither instantly bactericidal nor even instantly bacteriostatic. The effect of sulphanilamide on the growth of micro-organisms is more pronounced in ordinary infusion broth in comparison with that in rabbit serum (Gay *et al.*, 1939). A review of the whole literature shows that the drug is bactericidal by some adjuvant factors [Nitti, Bovet and Depierre (1937), Finklestone-Sayliss, Paine and Patrick (1937), Lockwood (1938) and others]. The bacteriostatic as well as the bactericidal activity varies, not only with the type of culture, but also with the nature of the substrate. Sulphanilamide is active against streptococci *in vivo* but ineffective in peptone-containing broth at ordinary temperature. The activity in the latter medium may be restored by raising the temperature to 39 to 40°C. [White and Parker (1938), Weld and Mitchell (1939)]. The observation of Britton (1938), that it is active against pneumococcus type I in peptone-containing broth but practically inactive *in vivo*, makes the problem more complex.

One of the necessary conditions for its therapeutic action is that the organism and the drug should actually meet in the body of the host (Browning, 1939), as it does not set up any permanent anti-bacterial condition within the body. It may be mentioned that antiseptics like acriflavine are fixed by streptococci whereas the drugs of this group are neither changed nor fixed by contact *in vitro* with large masses of the bacteria. Still there exists a quantitative relationship between the concentration of the drug and the number of bacteria (McIntosh and Whitby, 1939). A higher concentration of the drug is effective against a greater number of organisms and a lower one against the smaller number. In all cases, however, a definite bacterial multiplication takes place at least for the first few hours. This feature—a 'lag' phenomenon—is invariably noticed in experiments whether carried out *in vitro* or *in vivo*. What is the cause of this delayed action? Is it due to the time required for a chemical transformation of the drug in the body or is the drug gradually entering into some chemical combination with the bacterial protein? That the drug does not act directly upon the micro-organisms is also evident from the observation of Levaditi and Vaisman (1938) that sulphanilamide is more potent when absorbed *via* the gastro-intestinal tract than when locally applied, or, when injected directly into the peritoneum for immediate contact with the infectious agent. Levaditi and Vaisman (1938a), from their study on the effect of the drug on bacterial endotoxins, have also suggested that the drug has to undergo a change

*in vivo* in order to exert its neutralizing action on the endotoxin. This is very difficult to reconcile with the conception advanced by Barron and Jacobs (1937) as well as by Chu and Hastings (1938) that the drug behaves in such a way that the organisms are unable to utilize the nutriment from the body of the host. Evidence is also lacking to show that the production of toxin by the bacteria is inhibited, or, if formed, then it is inactivated by the drug [Osgood and Powell (1938), Gross *et al.* (1938), Gay *et al.* (1939)]. Even the virulence of the micro-organism is in no way impaired by contact with the drug in a concentration as high as 1 in 2,000 (Browning, 1939).

The other point that may be considered is whether the drug has any stimulating action on the natural defences of the body. In clinical study, leucocyte counts do not show any variation other than the usual daily fluctuation, and consequently the drug does not stimulate leucocytosis [Gay and Clark (1937), Mellon *et al.* (1937)]. Osgood and Powell (1938) and Gay *et al.* (1939) have again observed no evidence of any marked opsonic action of the drug. The general belief now is that the production of antibodies is not stimulated and there is no direct action upon the phagocytic mechanism in the body of the host [Reid (1939), Traut and Logan (1939), McIntosh and Whitby (1939)]. It seems therefore that the drug, by one or other change, inhibits the growth of bacteria, and this necessarily causes a suppression of their aggressive character. Under such circumstances, the natural body defences may easily play their part and ultimately help in the immunity mechanism.

What, then, is the factor that contributes to the remarkable chemotherapeutic action of a group of drugs otherwise possessing a weak antibacterial property *in vitro*? It was Mayer (1937) who first suggested that the antistreptococcal effect of sulphanilamide might be due to some other substance produced from the drug *in vivo*, and considering the first product of oxidation of an aromatic amine to be the hydroxylamine, he pointed out that p-hydroxylaminobenzene sulphonamide is the active substance in this therapy. A rider to this hypothesis was further added by Locke, Main and Mellon (1938) from their belief that such an oxidation would enhance the anticatalase activity which sulphanilamide and several allied compounds were found to possess (Main *et al.*, 1938, Shinn *et al.*, 1938). Whether the hydroxylamino derivative is sufficiently stable or not in the system, its presence, though in very low concentration, is indicated from the recent experiments of Rosenthal and Bauer (1939) with urine of patients. But the anticatalase activity alone cannot truly explain the mode of action of this group of compounds (Long and Bliss, 1939). Harris and Michel (1939), from their clinical observations, have deduced that sulphanilamide is partially converted by the body into some

active agent which, functioning as an oxidant, is supposed to be responsible for the occurrence of methæmoglobinæmia in patients receiving therapeutic doses of the drug. As this formation of methæmoglobin is frequent both in adults and children, irrespective of the sex, it would not be unnatural to postulate that in its formation lies the factor on which the activity of the drug depends. In other words, is this oxidizing agent then simultaneously accounting for the toxic symptoms as well as for the therapeutic effectiveness of the drug? (Shaffer, 1939).

The most common toxic effects that have been reported following the use of this group of drugs have been nausea, vomiting, depression, dizziness, fever, headache, acidosis, cyanosis, decrease in hæmoglobin and red blood corpuscles. But the majority of these are not of such a nature as to contra-indicate the use of the drug. The most serious types of toxic manifestation are acute hæmolytic anæmia and agranulocytosis; but these rarely occur. Sulphanilamide causes an acidosis due to alkali deficit occurring from the loss of excess of sodium and potassium in the urine. It produces a decrease in pH of the blood and increase in the pH of urine (Long and Bliss, 1937 and 1937a). The administration of sodium bicarbonate prevents the occurrence of any clinical acidosis. But the most common symptom in patients receiving therapeutic amounts of sulphanilamide or, retaining 4 mgm. of sulphanilamide per 100 c.cm. of their blood, is the development of cyanosis, or, blueness of the skin (Wendel, 1938, Bensley and Wilen, 1939). It is invariably associated with the formation of methæmoglobin [Hartmann, Perley and Barnett (1938), Evelyn and Malloy (1938), Wendel (1938)] and occasionally with that of sulphæmoglobin (Colebrook and Purdie, 1937). Marshall and Walzal (1937), however, suggest that the cyanosis may not be due to any change in the condition of the blood pigment but may be due to the formation of an oxidation product of sulphanilamide (Ottenberg and Fox, 1938). The observations of Harris and Michel (1939) that the intensity of methæmoglobinæmia is proportional to the concentration of the drug, tends to show that the methæmoglobin formation during treatment is a definite action of the drug. Sulphanilamide itself cannot oxidize hæmoglobin *in vitro*, whereas in contact with body tissues it undergoes a change that is responsible for the production of methæmoglobin (Harris, 1939). Very recently Wendel, Wendel and Cox (1939), from their spectrophotometric and simultaneous gasometric analyses of fully oxygenated blood from cyanotic patients, have expressed the opinion that the pigmentation during sulphanilamide therapy is for the most part due to the formation of methæmoglobin.

Such a phenomenon is not a new one as various substances, *e.g.*, aniline, acetanilide, nitrobenzene, etc., have been found to cause cyanosis and methæmoglobinæmia *in vivo*, though they have no action on hæmoglobin

*in vitro* (McElroy, 1919, Scott and Hanzlik, 1920). Considerable differences of opinion exist regarding its mechanism, but the general belief now is that p-amino phenol formed in the system from the above aniline bodies is mainly responsible for this cyanosis [Heuhner and Schwedtke (1936), Schwedtke (1938), Michel *et al.* (1937), Harrop and Waterfield (1930)]. The p-amino-phenol (I) is readily oxidizable to p-iminoquinone (II) and this transformation being reversible, a small amount of either agent would produce many molecules of methæmoglobin.

In *in vitro* experiments sulphanilamide can be oxidized to quinone (III), when it would not be unreasonable to expect that an oxidation in *in vivo* may lead at least to the formation of p-iminoquinone (II). If this latter product be once formed in the body, it would establish an oxidation-reduction equilibrium with p-amino-phenol (I) and, as such, may be the cause of the oxidation of hæmoglobin to methæmoglobin (Rimington, 1939). On this basis, the formation of methæmoglobin would first depend on the ease of oxidation of sulphanilamide drugs to p-iminoquinone. In clinical practice, too, the rate of formation of methæmoglobin is found to be much lower in 2-(p-aminobenzene sulphonamido)-pyridine (IV) and p-benzylamino benzene sulphonamide (V), two products less susceptible to decomposition from chemical consideration [Harris and Michel (1939), Finland (1939)]. Acidosis, by interfering with absorption of alkalis in renal tubes, and an increase in the urinary excretion of porphyrin, are two other common physiological disorders during this chemotherapeutic treatment (Rimington and Hemmings, 1938). The two effects are again minimum in the case of compounds (IV) and (V), indicating thereby that the various toxic manifestations depend on one and the same factor. The injection of methylene blue (0.1 to 0.2 c.cm. per kilogramme of body-weight of a one per cent aqueous solution) removes the methæmoglobin from the circulating erythrocytes without any injurious effect on the host, and thereby restores the oxygen-carrying capacity of the blood (Wendel, 1939). This seems to be logical as this readily reducible dye, by disturbing the reversible reduction-oxidation equilibrium between the above two agents, would then inhibit the formation of any further quantity of methæmoglobin. Any conjugation of sulphanilamide would make it more resistant to

oxidation and this would in turn lessen the probability of any change in the hæmoglobin molecule. Such a conjugation has been actually found by Bensley (1940) to reduce the formation of methæmoglobin. All these then point to an alteration in the composition of sulphanilamide in the body. Further, the fact that the concentration of both free and acetylated sulphanilamide is invariably higher in the corpuscles than in the plasma, again indicates an existence of a close relationship between blood corpuscle and sulphanilamide (Hansen, 1939). It really suggests a sort of combination between something within, or on the surface of the corpuscle and the drug. As the method of estimation of distribution of the drug has been traced by means of diazo (colour) reaction with the p-amino grouping of the drug and no consideration is being made for the sulphonamido—SO<sub>2</sub>NH<sub>2</sub>—grouping, so the question remains unsolved whether the product that tends to be associated with the red blood corpuscles is the sulphanilamide molecule itself, or some product at least in part derived from it. The problem now is whether in such transformation lies the anti-bacterial activity of the drug in question. P-iminoquinone (quinoneimine) has been recently found by Bernheim *et al.* (1938) to inhibit the oxygen uptake of body tissues and the xanthine oxidase of liver. The action is dependent on the formation of a quinoneimine-enzyme complex. Does this also inactivate the bacterial enzymes (McIntosh and Whitby, 1939)? The mode of action of this group of drugs should then depend on the formation of p-iminoquinone and its subsequent conversion in such a way as to inactivate the invasive character of the micro-organisms. But the presence of such p-iminoquinone in the system will have to be demonstrated. The idea would not, however, preclude any sulphanilamide drug exerting its own characteristic pharmacological effects—whether therapeutic or toxic—depending on its ability to penetrate through the cell membrane and subsequent ease of oxidation to p-iminoquinone inside the cell.

It would be of much interest to study the exact chemical nature of the drug that is being daily excreted in the urine, circulated in the blood and more particularly remaining associated with the red blood corpuscles. The next point of importance seems to be a study on the effect of the drug on endotoxin *in vitro* in the presence of several body tissues under various conditions, and then to note the effect of such a mixture on treated and untreated animals. An investigation on the change, if any, in the constitution of the drug seems also to be essential. All these might bring forth a clue to the mechanism by which this group of drugs exert their characteristic pharmacological action, or, at least might throw light on the problem whether the oxidant that is invariably formed, exerts any influence on the anti-bacterial action of the drug. For such a study team work from

chemists, bacteriologists, biologists and clinicians is essential.

## A Mirror of Hospital Practice

### A CASE OF CEREBRO-SPINAL FEVER CURED BY SULPHANILAMIDE\*

By BABU RAM GARG

Muzaffarnagar, U. P.

A boy aged 14 had an attack of 'fever' and headache on 16th March accompanied by frequent liquid stools. The temperature increased but was not recorded as a thermometer was not available.

I first saw him the following morning and found his axillary temperature 103.5°F., pulse 120 and respiration 20 per minute, sighing in character.

The patient was deeply unconscious—pupils fully dilated, equal and did not react to light, and reflexes were absent. There was no stiffness of the neck nor head retraction but pressure over the spine caused twitching of the face muscles indicating that it was painful.

Diagnosis was doubtful as at the time I had no needle to do a lumbar puncture and there were no similar cases in the village.

The boy could swallow liquids so he was given six doses of a hexamine mixture and six powders (half gramme each) of Septalium, Glaxo (a sulphanilamide product).

On 18th March, the condition was unchanged except that one pupil was now smaller than the other. The parents refused permission to do a lumbar puncture.

\* Rearranged by Editor.

The same treatment as on the previous day was continued with the addition of an intravenous injection of 5 c.cm. of 'Aktisol', a sulphanilamide drug.

On 19th March the boy was brought to my dispensary and on lumbar puncture 23 c.cm. of opalescent fluid under pressure was allowed to escape. Microscopically it contained large numbers of intracellular diplococci. The left pupil was more nearly normal and reacted slightly to light.

He was distinctly better on the 20th, consciousness was returning and the pupils were normal in size and reaction.

On the 21st, the boy was fully conscious. Lumbar puncture was again performed and 50 c.cm. of clear fluid evacuated under slight pressure. Diplococci in smaller numbers could still be seen. Reflexes were now obtainable.

The treatment was continued and there was steady improvement. On 23rd March 15 c.cm. of cerebro-spinal fluid was withdrawn and only very scanty diplococci could be seen. Progress was maintained and on 27th March 35 c.cm. of fluid was withdrawn; and no micro-organism could be found in it. The temperature was normal. Intravenous medication was stopped but Septalinum by mouth was continued. All treatment was stopped on 30th March and the boy was discharged as cured.

**Conclusion.**—An obviously severe case of cerebro-spinal meningitis was cured by means of sulphanilamide drugs.

## A METHOD OF REMOVING A TIGHT RING FROM A FINGER

By Y. M. BHAVE, M.B., B.S.

Sir J. J. Hospital, Byculla, Bombay

It is not infrequently that the general practitioner comes across a patient with a ring impacted on one of the fingers. The following is a useful method of removing such a ring with the least amount of trauma to the tissues involved.

**Anæsthesia.**—It is better to block the digital nerves with 2 per cent novocaine or in the case of children just to give a little general anæsthetic, to keep them quiet. As a general rule very

Fig. 1.

little pain is felt during the manipulations. The adrenalin content of the local anæsthetic reduces the congestion and makes the proceedings easier.

**Technique.**—First clean the part with rectified spirit. Starting at the tip of the finger (figure 1) a strong thread (twine would suffice) is

wound round the fingers, the strands touching each other without overlapping, till the strands reach in the vicinity of the ring. The free end of the thread is now manipulated under or preferably threaded through the ring with a vaselined aneurism needle, so as to come out at the proximal edge of the ring (figure 2). Any space,

Fig. 2.

between the most proximal strand of the thread and ring, left uncovered is covered by continuing the winding, the loose proximal end of the thread being pulled so as to leave no loop between the ring and the fingers. Sterile vaseline is now applied to the ring and all the strands of the thread. The thread is now unwound, from the proximal end, a little force being usually necessary to do this (figure 3).

Fig. 3.

The ring will be found to move very slowly forward till it slips off the finger, when the whole thread is unwound. Thick cat-gut can be used but only if a sufficiently long strand is available, to enable the proceedings to be finished with only one winding and unwinding.

**Mechanism.**—This method works both by relief of congestion brought about by direct pressure of the thread, and by the screw-like action when the thread is unwound.

### ERRATUM

Our attention has been drawn to an error on p. 179 of the March number.

From 'Calcium diuretin' to 'Citobaryum' the names should be lowered one line to correspond with the correct particulars in columns two and three of the table.

# A Tonic and Reconstructive of Exceptional Efficiency

**Fresh Liver  
& Spleen**  
for bloodbuilding

**Cod Liver Oil**  
for its food value

**Malt Extract**  
for its nutritive influence

**Hypophosphites**  
for remineralization

Waterbury's Compound is the preparation of choice as a tonic and reconstructive at every age period and at every season of the year. Its unusual palatability appeals to all—there is no oily taste or odour.

## WATERBURY'S COMPOUND

Supplied PLAIN, or with Creosote and Guaiacol.  
A bottle of each form is at your service.  
May we send them?

**MARTIN & HARRIS LTD.,**  
Mercantile Buildings, Lall Bazar, CALCUTTA.  
*Also at Bombay, Madras, Karachi and Rangoon.*

*Made by Waterbury Chemical Co. Inc., New York and St. Louis, U.S.A.*

## KEEPS FALSE TEETH CLEAN

### Steradent

REGD TRADE MARK

"I really think in all my experience that 'Steradent' is the finest product I have used" writes a leading dentist. It is widely acknowledged by the Dental Profession to be the most efficient preparation for cleaning and sterilising dentures. It removes mucin film, tartar, stains, tarnish and all unsanitary accumulations. It is harmless to gold, platinum, stainless steel, etc. Patients should immerse their dentures overnight in a glass of warm water in which 'Steradent' has been dissolved. Then take out and rinse.

*Samples and literature will gladly be sent on application to*

**ATLANTIS (EAST) LTD.,**  
20/1, CHETLA ROAD, CALCUTTA.

## In Nutritional Macrocytic Anæmias

Nutritional macrocytic anæmias are stated to be due primarily to a deficiency of Castle's extrinsic factor. It is logical, therefore, to assume that they will respond to the exhibition of Anahæmin—the product of interaction of intrinsic and extrinsic factors.

Convincing evidence of the value of Anahæmin in nutritional anæmias is provided in a report (Response of Nutritional Macrocytic Anæmia to Anahæmin, *Lancet*, August 12th, 1939, p. 360), in which it is shown that Anahæmin is at least as active in its curative effect as less highly-purified preparations of liver.

In other words, Anahæmin is of high and unvarying activity, not only in pernicious anæmia which is due to lack of intrinsic factor, but to nutritional anæmias which are due to lack of extrinsic factor. This latter fact accounts for the restorative effect produced upon patients after operation or who for one reason or another are maintained on a restricted dietary.

*Stocks of Anahæmin B.D.H. are held by leading chemists, and full particulars are obtainable from :*

### THE PROBLEM OF DRUG ADDICTION

Drugs of addiction are those which are liable, in the course of time, to take control of the individual who has become habituated to their use inasmuch as all his social and business obligations become subservient to obtaining a regular supply of his pet narcotic, and their continued use, generally in increasing quantities, to obtain the desired effect eventually leads to complete moral and physical degeneration and even death. This practice of taking drugs, not for the cure of disease but for their euphoric and stimulating effects, is one of importance as well as of considerable interest on account of the numerous problems involved.

The habit is so ancient and so widespread throughout the human race that it almost seems that man has an innate need for stimulo-sedatives of some kind. This is suggested by the fact that when European explorers first made contact with races who had been, as far as we know, completely out of touch with other races for immeasurably long periods of time, most of them were found to be using regularly some form of narcotic or stimulant drug. For example the natives of the South American jungles were accustomed to use cocaine in a crude form, and even in remote Australia the primitive and widely scattered nomads inhabiting this country had a plant of similar nature, which although very mild in its action was greatly prized and was of high trade value between parts of the country where it grew and those places where it was not found, so that it was passed from tribe to tribe over many hundreds of miles of sparsely populated country. In large parts of Asia and Africa Indian hemp has been used from as far back as records go, and it is probable that the practice began in the earliest stages of man's social development in these countries. Elsewhere in this issue there is a full summary of the subject of hemp drug addiction in this country, which embraces the earliest historical records of its use and traces it right up to the present day. This report is only an account of part of the general study of the use and abuse of drugs of addiction in India, which has been carried out by Colonel Chopra and his collaborators over many years, under a grant from the Indian Research Fund Association.

World communications have improved so much and trade ramifications have spread so widely that, now in times of peace, every country or state trades with every other one in the world, and all world products are obtainable almost

everywhere. This applies to narcotic drugs as well as to other commodities and manufactured articles, and those which were originally used almost exclusively in one country or area are now obtainable anywhere. The prevention of the traffic in narcotics is a large and important problem in most countries and one on which governments are compelled to spend vast sums of money. One of the most important countries in this respect is Egypt, which on account of its geographical situation, is a suitable clearing-house for drugs between Europe and Asia, quite apart from having a serious local problem of drug addiction of its own. As is always the case the demand has created the supply and one of the most active narcotic preventive services in the world exists in Egypt, and the work of this bureau is of great value outside its own borders because it has been able to indicate the source of origin of much of the drugs seized in that country. The world effort to limit the international traffic in dangerous drugs is greatly assisted by the League of Nations whose organization is well fitted for operations of this nature.

Before the days of rapid and frequent inter-communication throughout the world, in which every country now participates, different countries were prone to use one type of stimulo-sedative to the almost total exclusion of others. For instance, speaking in the broadest sense, Europe used alcohol, Asia used Indian hemp and later opium, North America used tobacco, South America used cocaine and so on. But with the free interchange of narcotic drugs as well as other products the people of Europe began to make use of cocaine and opium, and the highly potent distilled spirits of Europe were introduced to primitive races, where they began to supplant the mild fermented liquors they had been using for centuries. These fermented drinks of native origin have recently been shown in some cases to be the main source of necessary vitamins (notably the vitamin B complex) in an otherwise deficient diet, so that the change in type of alcohol used, or attempts to prohibit the local product, may cause the appearance of vitamin deficiency diseases as well as the harmful effects of the immoderate use of potent spirits.

In one respect these drugs of addiction resemble an infectious disease, in that their prolonged use by a people eventually leads to a decrease in the number of persons whose excessive consumption of the drug causes serious mental and physical deterioration, and instead the majority are found to be still using the drug, but in such moderation as not to give rise to serious symptoms. Examples illustrating this can be found almost everywhere, for instance in Europe drunkenness is almost unknown among the Mediterranean peoples who have been using wines for very prolonged periods, whereas in the more northern countries whose general use of alcohol is a more recent acquisition and whose inhabitants are inclined to drink the more potent distilled spirits more freely, as well as fermented

beverages, drunkenness is still all too frequent. Other examples arise to the mind such as that of the Sikhs in India who take their one or two opium pills a day and appear to derive benefit therefrom, but amongst whom excessive use of opium is of the rarest occurrence, and the aboriginal natives of South America make use of cocaine in the same way and benefit by its use, but never give way to its abuse. Then let us look at the other side of the picture and see the effect of the sudden introduction to races, of a type of narcotic to which they were not hitherto accustomed. The ravages of distilled spirits among the native races of Africa, North America and the South Sea Islands after their introduction by Europeans are well known, and cocaine and opium or its alkaloids claimed and still claim many more victims in Europe and other countries, into which they were introduced relatively recently, than they do in their countries of origin where they have been used for hundreds of years. To sum up this paragraph, narcotics appear to establish some kind of immunity or resistance to their abuse in races that have used them for a long time.

Consideration of these facts raises the question as to the best method of dealing with the drug menace. While there is no doubt that preventing the introduction of new narcotics into countries not accustomed to them is of prime importance, it is doubtful if the long view would not be preferable regarding the control of narcotics that have already been in use for centuries. By this we mean that limited official efforts at restriction with the hope of the eventual disappearance of the dangerous aspect of drug addiction would perhaps be preferable to the sudden stoppage of supplies in the attempt to stamp out completely and at once the use of a certain drug. The failure of prohibition in the United States of America with its tremendous

increase in crime and excesses of all kinds as secondary effects to the attempt to stop the use of alcohol altogether, as well as the rise in the clandestine consumption of poisonous trade spirit as a drink, is a striking indictment against this method of control. Another difficulty regarding the absolute prohibition of these drugs is that their cultivation and manufacture cannot be totally prohibited because large amounts are necessary for their legitimate use, the treatment and cure of disease.

Addicts to any drug can be treated, and often successfully, to overcome their craving. A striking example is the success of the lecithin and glucose treatment of opium addiction practised in recent years at the Calcutta School of Tropical Medicine. This is also a complicated problem, because although it is agreed that a great deal can be done in freeing a slave to the habit from the influence of a drug, it is now considered by those with experience in this matter that a large number are bound to relapse. Although such reasons as the example of companions, business worry, prolonged painful illness, etc., are given and accepted as explanations of beginning the habit, it is now stated that, in addition to one of these causes, there is an inherent weakness in the individual which is the basic cause of his subordinating his own initiative to the power of a drug. Even if he is relieved of this influence by treatment and the craving disappears for a time, the weakness is still there and is likely again to become manifest by a relapse into his former habit of excessive drug taking.

A short article of this kind is not the place for the discussion of preventive measures in detail as the problem is much too vast, so we have confined ourselves to the statement of a few aspects of the subject to indicate in some slight degree its complexity and difficulty.

### USE OF HEMP DRUGS IN INDIA\*

By R. N. CHOPRA, C.I.E., M.A., M.D., SC.D. (Cantab.),  
F.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S. (Retd.)

(From the School of Tropical Medicine, Calcutta)

#### Historical and General

*Introductory.*—The habitual use of drugs of a stimulative and restorative character was prevalent in India probably long before any of the other countries of the modern world. The juice of the Soma plant was a favourite drink of the Aryan settlers and was regularly taken by them many centuries before the Christian era. What

exactly was the Soma plant is not known, though a number of plants such as *Cannabis sativa*, *Ephedra vulgaris*, *Asclepias acida*, etc., have been implicated. During the Hindu period, i.e., up to the 8th or 9th century A.D., alcoholic beverages were used by the people as well as the preparations made from hemp drugs. These produced not only a sedative effect, but also brought about euphoria in the form of pleasant dreams, forgetfulness and, it would also appear from the writings of that period, voluptuous satisfaction. Opium and poppy were introduced on the west coast about the 9th century A.D. by the advent of the Mohammedan traders and opiates soon came into use. A study of the records shows that during the period of the Moghul Empire alcoholic beverages, opiates and hemp drugs were freely used. A

\* Being a lecture delivered at the Royal Asiatic Society of Bengal on the 29th of March 1940.

decoction made from poppy capsules known as 'koknar' was extensively used all over India. A beverage containing wine, opium, Indian hemp and poppy capsules, known as 'Chaharbargha' (four-leaved), was drunk by the well-to-do classes in the time of Akbar (1556 to 1605) and later. Opium on account of its stronger effects appears to have taken a great hold on the people, and poppy was extensively cultivated all over the country during this period and was indulged in by all classes.

The hemp drugs commonly used in India are derived from the flowers, fruits, leaves (and the resinous matter derived from the leaves), young twigs, and bark of the stem of the plant known as *Cannabis sativa* Linn. The plant belongs to the family *Cannabaceae* and has been found growing in a state of nature to the south of the Caspian Sea, in Siberia, in the desert of Kirghiz in Russian Turkestan, in Central and Southern Russia and along the southern lower slopes of the Caucasus mountains. In China, where probably it is indigenous on the lower mountain tracts, it has been known since the 6th century B.C. It grows in almost a wild state in Iran and in the Western Himalayas and Kashmir, and it extends to the east of Assam.

For some time the European form of the plant was supposed to be distinct from the Asiatic, the chief value of the latter consisting in its narcotic properties; but this distinction has now disappeared from the literature on the subject. *Cannabis indica* Lamk., the Indian plant, has thus been reduced to *C. sativa* Linn.

The hemp drugs are used in India in three principal forms, *ganja*, *charas*, and *bhanga*. *Ganja* is the female flowering tops and twigs covered with resinous exudation, *charas* is the resinous exudation found on the leaves, young twigs, bark of the stem, and even on the young fruits; *bhanga* is composed of the mature leaves and in some parts of India of the fruits also.

*Early historical references.* (a) *In Hindu medicine.*—Mention of hemp drugs is found in the classical literature as well as in the works on medicine of many countries old in the world. The plant is referred to in the ancient Sanskrit literature under the three names: 'bhanga', 'indracana' and 'vijaya' or 'jaya'. The earliest mention of the word 'bhanga' occurs in the Atharva Veda which, according to Western scholars, dates from 2000 to 1400 B.C.

The first mention of 'bhanga' as a medicine occurs in the works of Susruta (6th to 7th century A.D.) where it is described along with a number of other drugs as an antiphlegmatic. In the 10th century A.D., the intoxicating properties of the plant seem to have been already recognized. In the 14th century, the intoxicating properties of 'bhanga' were certainly well known as it is mentioned in some of the dramatic literature of that period.

In Sarangadhara Samhita, a medical work written about 1500 A.D., it is described as an excitant and is mentioned along with opium in the same passage. In the Bhavaprakash (about 1600 A.D.), a number of important properties of the hemp drugs are given with special stress on its digestive and stimulant effects on biliary secretions.

(b) *In Arabian and Persian medicine.*—Hemp is frequently mentioned in the early Arabic and Persian literature. The oldest work in which it is noticed is

a treatise by Hassan (658 A.D.). In the Arabian Nights, frequent references to hemp have been made under the old name 'benj'. The Arabic name 'benj' and the Persian name 'beng' are so closely related phonetically to the Sanskrit 'bhanga' that there is a strong presumption of their origin from the latter source.

(c) *In European literature.*—Hemp is also frequently mentioned in the early classical literature of Europe. The ancient Scythians seem to have been acquainted with the narcotic properties of the plant as well as with its fibre. They used to induce a state of excitement amongst themselves by inhaling its vapour. More recently, hemp was brought to the notice of European medicine through the accounts of Sylvestre-de-lacy in 1809 and Rouyer in 1810. These authors were attached to Napoleon's expeditionary forces in Egypt and during their stay there, collected a large amount of information regarding hemp drugs and published their findings and observations.

#### PRODUCTION OF HEMP DRUGS IN INDIA

(a) *Wild growth.*—As has been already stated, hemp grows wild over extensive tracts in northern India and along the slopes of the Himalayas. It is interesting to note that hemp seems to have the capacity for growing with equal luxuriance under almost any climatic conditions. With the change of climate, and the consequent alteration in the conditions of growth, however, some of the important characters of the plant are changed or modified. Thus, in Europe, hemp produces a valuable fibre, while showing little or no tendency to produce the narcotic principle, which in Asia constitutes its chief value. On the mountain tracts of upper India, hemp yields a fairly good fibre, but in Kashmir and Ladakh, its narcotic principles become much more predominant. When hemp is cultivated in the plains of India, the resin (*charas*) is not generally secreted but the young female flowers and shoots show a tendency to develop the narcotic principle (*ganja*) instead. In other parts of India again, the narcotic property is often not developed until the fruits are mature.

The plant grows wild throughout the Himalayas from Kashmir to the east of Assam at an altitude up to 10,000 feet above sea-level. It extends down the southern slopes of the mountains and from there into the Punjab and the Gangetic plain for a limited distance. It is found in the hill tracts of Assam whence it spreads to the mountainous tracts of East Bengal. The southern boundary of this area begins approximately at Peshawar and runs through the middle of the Punjab and the United Provinces, from where it follows the course of the Ganges. In this region, the plant propagates itself from self-sown seeds but it is possible that the growth on the lower slopes of the Himalayas and in the Terai is to a large extent accounted for by the aerial dissemination of seeds from the mountains. The plant appears to be very hardy once it is well established. The soil need not be rich, but it should be well drained and permeable.

(b) *Cultivation.*—Though hemp grows wild in many parts of India, it has to be properly

cultivated in order to obtain, for commercial purposes, its fibre or its narcotic principle as the case may be. For a good growth of hemp a rich soil as well as elaborate methods of cultivation are required.

*Present extent of hemp cultivation.*—The Indian Hemp Drug Commission (1893-1894) obtained statistics of the area under cultivation and found that after deducting the area under fibre cultivation (which yields little or no narcotic principle), the total area under cultivation for narcotic purposes did not exceed 6,000 acres. At present cultivation of hemp drugs for the production of ganja and bhang by the wholesale vendors is only permitted under licence and is considerably less than 2,000 acres.

The cultivation of the hemp plant for intoxicating purposes is absolutely prohibited in Assam, United Provinces, and in the minor provinces of Delhi, Baluchistan, Coorg and Ajmere-Merwara, while in some of the major provinces, it is permitted, for the production of ganja only, in limited areas and subject to careful restrictions. Thus, in the Bombay Presidency the cultivation is allowed in four villages of Nagar taluk in Ahmednagar district. In Bihar and Orissa, ganja is cultivated in Bhagalpore district. In the Madras Presidency, ganja is cultivated only in the village of Santaravur. In the Central Provinces and Berar, cultivation of the plant is restricted to a small area in Khandwa district. These areas are only able to meet the actual demand for their respective provinces. The main supply of ganja, however, comes from a place called Naogaon in the Rajshahi district of Bengal. This small area supplies ganja to the whole of the Bengal Presidency and also to other provinces, Indian States, and foreign territories where cultivation is prohibited.

If we compare the present figures with those published by the Indian Hemp Drug Commission in 1893-94, we are struck with the progressive decline of hemp-drug cultivation in India. For years together, the Government of India has followed a policy of gradually cutting down the area of hemp under cultivation and the total yearly outturn with the idea of reducing the hemp-drug addiction to a minimum. Hemp is not cultivated in this country for the production of charas and therefore these remarks do not apply to this form of the drug.

(c) *Manufacture of bhang, ganja and charas.*—Hemp drugs that are obtained by cultivation or from spontaneous growth require further treatment at the hands of experts before they are fit for consumption as narcotics.

1. *Manufacture of bhang* (synonyms 'siddhi', 'subzi', 'putti', 'sawi').—Bhang consists of specially dried leaves and flowering shoots of both female and male plants, wild or cultivated. The inclusion of male plants and male flower heads in the manufacture of bhang is not considered of special advantage as the male flowers are believed to contain very little of the active principle. Recent work has thrown doubt on this belief.

The narcotic principle in hemp develops only when the plant matures, reaching its maximum about the time of flowering and then it gradually begins to disappear when the leaves and the flowers turn yellow. Therefore, for the manufacture of good bhang, the leaves should be separated when they are just mature and when there are no signs of decay or withering. The usual time for gathering leaves varies in different localities but generally it is done during the months of May and June in the plains and during July and early August in the hills.

2. *Manufacture of ganja.*—Ganja ['ganja yala' (Tamil) and 'bhangaku' (Telugu)] consists of dried flowering tops of the cultivated hemp plant which become coated with a resinous exudation, chiefly from the glandular hairs, in consequence of being deprived

of the opportunity of setting seeds. To secure these results, the male plants are removed from the field at an early date. As the female plants begin to form ganja, all the large leaves on the stem and branches are also removed. The smaller leaves and the brackets of inflorescence become agglutinated into a mass called ganja. Fresh excise ganja has a rusty green colour with a characteristic odour. The colour and the smell are considered to be features of merit but as a rule ganja which has least mixture of leaf is regarded as the best. The plants thus collected require further treatment to form the ganja of commerce sold by the excise vendors. In Bengal the entire plant is cut, while in Bombay the flowering tops are generally pulled off by hand.

3. *Manufacture of charas.*—Charas is the name given to the resinous matter collected from the leaves and flowering tops of the plant and constitutes the active principle of hemp. Charas, as sold in this country, is a greenish mass, with a peculiar and characteristic odour. When kept for some time, it becomes hard and friable and acquires a brownish-grey colour, thereby losing most of its narcotic properties.

Although the hemp plant, when cultivated in tropical countries such as India, Africa and Malaya, becomes rich in narcotic principles, it seldom yields enough resin to be collected as charas. On the plateaux of Central Asia and southern Himalayas (Nepal) charas is sometimes collected, but it is poor both in quality and yield. The best quality and the maximum amount of resin is obtained from plants grown in Yarkand in Chinese Turkestan in Central Asia.

*Manufacture of charas in Chinese Turkestan.*—In Chinese Turkestan at an altitude of 3,000 to 5,000 feet above sea-level, *Cannabis sativa* grows extensively in a state of nature. It is also cultivated along with other field crops. The plant flourishes well in these plateaux often attaining a height of 8 to 10 feet. It matures during the month of September or October when big tufts of flowers appear at the top of each plant, which can be collected and used in the preparation of finished charas. The method of charas manufacture in these areas is entirely different from that in use in India. The female flower heads are first dried, then broken and crushed between the hands into a powder, which is passed through sieves so that it attains the fineness and consistency of sand or saw dust. This powder, which is still green, is stored in bags made of raw hide for four or five months during the winter. With the onset of the hot weather the material is taken out and exposed to the sun for a short time, sufficient to allow the resin to melt. It is stored again in hide bags of 10 lb. to 14 lb. capacity. After a few days, the agglutinated mass is again taken out and kneaded well by means of wooden rods so that a certain amount of oily matter appears on its surface. The process of kneading is repeated till each bag yields about one to two lb. of oil. At this stage charas is transferred into fresh hide bags and is ready for sale and distribution.

*Trade and traffic in charas.*—Charas forms one of the most important articles of trade between Central Asia and India. It is usually brought down from Yarkand in the month of August when the mountain passes are opened and it reaches Leh in Kashmir by September or October. The payment for charas is usually made in kind and not in currency. All forms of piece-goods which are apparently in great demand in Central Asia are generally accepted as barter.

The traffic in charas has always been carefully regulated by the Punjab Government; the charas bundles are checked at Panamik and again at Leh in Kashmir State to ensure that any bundle which reached Leh (where the Punjab Government has established a warehouse and maintains a special staff) was again accounted for either in Kashmir State or in one of the Punjab warehouses. Each bundle of charas, which ordinarily weighs about 50 seers (100 lb.), is recorded in Leh and forwarded either to Kulu or to Rawalpindi, or is consumed locally under the control of Kashmir State authorities in the State. There are four warehouses in the Punjab, at Sultanpur (in Kulu),

Hoshiarpur, Amritsar, and Rawalpindi. The Government of Chinese Turkestan have now totally stopped the import of charas into India.

*Illicit traffic in charas and measures to combat it.*—Contraband charas comes into India nowadays mostly through Chitral and to a certain extent through independent tribal territories. It is also brought across the Indus river principally to the neighbourhood of Peshawar. The drug is mainly smuggled by travellers who carry small quantities at a time upon their persons. Very often it is said to be exchanged for smuggled cocaine from Calcutta and other parts. In fact, it has been stated that the practice of charas smuggling in the Punjab and the North-West Frontier Province has been responsible for the introduction of the cocaine habit in those areas.

In parts of India where the consumption of the drug is totally prohibited, there is reason to believe that illicit charas is still being sold to a certain extent. In other parts where the consumption is permitted but the duty is high our inquiries reveal that smuggling is far from being checked and the drug is frequently obtainable through illicit sources.

#### THE NARCOTIC PRINCIPLES OF HEMP DRUGS

An interesting feature about the formation and development of the narcotic principle is that this process is generally found to be associated, and sometimes runs parallel with some distinct morphological modification of the plant anatomy. In some plants, the leaves are the chief organs where the narcotic resin is found; in others, the flowering tops assume the important rôle of storing and secreting the resin; while in a third group, the fruits and the surfaces of stems take upon themselves the secretory function. The first group of plants where the narcotic is primarily stored in the leaves yields the bhang of commerce, the second group affords ganja, and third group is considered particularly suitable for the production of charas. The factor or factors which are responsible for such modifications in the physiology of the hemp plant are not known.

The resinous substance contained in hemp is considered the most important principle responsible for the physiological activity of the drug. The resin as obtained from the plant apparently contains a number of compounds, one of which is *cannabinol* (Cahn) and which is probably the active principle. There is no satisfactory evidence to show that the other constituents are physiologically active.

*Deterioration of the narcotic principle.*—The narcotic principle of the hemp drugs deteriorates with age, though it is difficult to give the precise period during which a preparation can retain its activity under ordinary conditions of storage. The popular impression is that hemp drugs retain their activity for a period of at least two years without appreciable loss. Some authorities consider that the potency remains intact for a much longer period. The experience of the excise authorities in the plains of India is that ganja retains most of its activity for one year and during the second year it begins gradually to lose its potency until it becomes quite useless and unsaleable at the end of two years. It must be realized, however, that the retention of physiological activity of the three different types of hemp drugs, like that of many other medicinal products, largely depends on the climate and also on the care exercised during its storage. Bhang is not as susceptible to deterioration as ganja and may keep in fairly good condition for three to four years, if not

directly exposed to sun and air. This comparatively slow deterioration of bhang is supported to a certain extent by the subjective symptoms complained of by the bhang addicts.

With regard to the keeping properties of charas, it is still more difficult to make any definite statements. However, the general opinion of dealers in this drug is that charas is very potent during the first year, after which it gradually loses its activity until the fourth year, when it becomes practically inert and useless.

#### MODES OF CONSUMPTION

Ganja and charas are mostly smoked, while bhang is taken by the mouth in the form of a beverage or a confection. The latter method, eating of hemp for narcotic purposes, would appear to be a much older method of indulgence than smoking.

1. *Hemp drinking and eating.*—The beverage made from bhang is known by different names in different parts of India. It is called 'thandai', 'siddhi', 'sardai', 'sawi', and 'sukha' in the Punjab and United Provinces; in Bombay and Central Provinces, it is known as 'bhanga' or 'ghota' or 'pang'; in Bengal, it is called 'siddhi'; in Rajputana and Central India, 'dudhii'; in South India hemp beverages are known as 'ramras' or 'ram-rasam' and correspond to 'dudhii' and 'siddhi' of upper India.

The simplest form of consumption consists of a drink made from bhang leaves by pounding them together with a little black pepper and sugar and adding enough water to reach the desired strength. Various kinds of special beverages are prepared by the middle and well-to-do classes by the addition of almond kernels, sugar, iced milk, curds, etc. A number of other ingredients are at times added to improve the taste and possibly with the idea of enhancing the euphoric effects produced by these drugs. Amongst these, aniseed, ajowan, cucumber, melon and poppy seeds, rose petals, saffron, cloves, cardamoms, musk and essence of rose are the most common. Besides their common use as a beverage, bhang leaves are sometimes chewed for their sedative effects. This is done at times when it is not convenient for the individual to prepare the beverage, for instance during travelling, and also during the winter season when the system does not require large quantities of fluid.

A number of preparations containing bhang are made in different parts of India. Sweetmeats containing bhang are sold and even ice cream containing powdered leaves is available in some towns.

2. *Hemp smoking.*—Ganja and charas are usually consumed by smoking. Different kinds of apparatus have been improvised in various parts of the country for smoking hemp drugs, the one commonly used being an earthenware 'chillum' (used for smoking tobacco) with an elongated neck. The ordinary 'chillum' used for smoking ganja and charas resembles a funnel with a long neck and a somewhat wide base.

The method of smoking is simple. Ganja is first moistened with a little water to render it soft. The mass is then kneaded till it changes to a pulpy mass. A small amount of tobacco (almost equal in amount to the ganja taken) is then placed in the 'chillum' and the 'prepared ganja' is placed on the top of it. The usual practice is to place the prepared mass of ganja (or charas as the case may be) between two thin pieces of broken earthenware pottery. After the 'chillum' is prepared, a piece of glowing charcoal or a piece of

smouldering cow-dung cake is placed in it. The smoke is inhaled into the lungs by powerful inspiratory efforts and the narcotic principles are at once taken into the blood. The smoke is retained in the lungs as long as possible and is then allowed to escape slowly through the nostrils, the mouth being kept shut. The longer the smoke is retained inside the lungs the better the effects obtained. Apart from the 'chillum' method just described ganja and charas are also smoked by the ordinary 'hooka', the smoke being allowed to pass through water before it is inhaled. This is the common method employed in the north-western districts of the Punjab and the North-West Frontier Province, but it has not become popular in other provinces in India where smoking of hemp drugs is prevalent. Recently, cigarettes containing bhang have been used in certain towns. Both bhang and charas are occasionally smoked in an ordinary tobacco pipe, but this method has not become very popular.

Unlike opium smoking, which is indulged in by the smoker alone and away from his friends, hemp smoking is always preferred and enjoyed in the company of others. The smokers, usually two to five in number, sit down in a small circle and the prepared 'chillum' is passed round from one to the other so that each can take two or three deep pulls at it. Ganja or charas worth at least four to six pice (1 or 1½ penny) is required for preparing a full 'chillum'. The quantity of hemp procurable at this price is usually sufficient to produce narcotic effects of a mild degree on three to five persons.

Charas is smoked more or less in the same way as ganja but there is some difference in the initial preparation of the drug. Charas is usually warmed a little in the early stages and is mixed with approximately double its quantity of tobacco before being put in the 'chillum'. Charas is generally considered to be a stronger preparation and, therefore, a smaller quantity of the drug is used.

Besides ganja and charas, bhang leaves are also smoked at times. 'Sirkali' or the flowering tops of the hemp plant are sometimes cut and dried and smoked in a 'chillum' alone or mixed with tobacco.

#### USES OF HEMP DRUGS IN INDIA

Hemp drugs have been used in India from very early times in order to overcome fatigue and worry, for production of euphoria, and to give courage to warriors during times of stress. The present use of these drugs may be conveniently considered under three main headings:

(i) use in connection with religious and social customs, (ii) medicinal uses, and (iii) employment for narcotic and euphoric purposes.

(i) *Uses in connection with religious and social customs.*—The use of hemp drugs in connection with religious and social practices is still met with in almost all the provinces of India, though to a much smaller extent than in the past.

In Bengal, for instance, the custom of offering a beverage prepared from the leaves of the hemp plant to the members of the family and to the guests present on the last day of the Durga Puja (Bijaya Dasami) still persists. In Tarakeshwar Temple in Bengal ganja is used as an offering on the Shivaratri (Shiva's night). Less commonly, it is used in other religious festivals such as Trinath Puja, a religious ceremony observed also by certain Mohammedan sects in slightly different form. In Puri (Orissa) ganja and bhang are largely used by the attendants and worshippers of Jagannath. In the United Provinces where Durga Puja is observed in a manner similar to that in Bengal, the use of bhang is not so much in vogue. It is, however, taken by certain classes on the occasion of the Holi and Dewali festivals, marriage ceremonies

and other family festivities. Among the Sikhs, the use of bhang as a beverage was quite common 20 or 30 years ago and these beverages were freely distributed to devotees attending some of their religious places and shrines. Drinking of bhang is also in vogue in Rajputana at the festival of Kama (Indian cupid) by the Rajputs of Bondil. In the Central Provinces 'ghota' is used among the lower classes at the time of different festivals. In Bombay, worshippers of Shiva generally use ganja, while the Marwaris and merchant classes who belong to religious sects such as Jains use bhang on festive occasions. In Madras, the use of hemp drugs in religious and social life is less common than in other provinces. Assam is the only province where bhang is used practically not at all at the present time, probably because of the prevalence of the use of opium in that province.

It may be pointed out that charas, which is a foreign product and which has been comparatively recently introduced into India, is not in any way connected with religious worship or observances.

From the foregoing description it is evident that the use of hemp drugs in social and religious customs is still in vogue though it has considerably decreased during the last two or three decades. Even to-day a religious mendicant smoking ganja is not only tolerated but is looked upon with some veneration and is even considered to possess supernatural powers of healing disease and infirmities, by some of the illiterate classes. Sects of 'sanyasis', 'mahantas', 'mantra-data gurus' or religious preceptors are held in great respect although they indulge freely in hemp drugs. In fact, offering of hemp to them is considered to be an act of piety.

(ii) *Medicinal uses.* (a) *Indian hemp in Hindu medicine.*—In the Ayurvedic medicine, the first mention of the hemp plant occurs in the work of Susruta written before the 8th century A.D. In this work hemp leaves are recommended along with a number of other drugs as antiphlegmatic, as a remedy for catarrh accompanied with diarrhoea and as a cure for fever arising from excess of 'bile' and 'phlegm'. The hemp plant was believed by the ancient Aryans to possess cooling and febrifuge properties. On account of its narcotic properties it was probably also used as an anæsthetic by the ancient Indian and Chinese surgeons.

(b) *Indian hemp in Mohammedan or Unani medicine.*—Rumphius (1095 A.D.) in the *Herbarium amboinense* states that the Mohammedans frequently used the male hemp plant in the treatment of gonorrhoea, asthma, and also in the treatment of a condition, popularly called 'stitch in the side'. He also adds that the powdered hemp leaves are stomachic and check diarrhoea and excessive biliary secretion. He mentions the use of hemp as an enema in strangulated hernia, and as an antidote in poisoning with orpiment. In *Makhzanul aldawaiya*, the well-known Arabic book on materia medica, the author dwells on the wonderful properties of the hemp plant. It is said to be a cordial, a bile absorber, an appetizer, and that its moderate use prolongs life. The powdered bark is recommended as an external application to fresh wounds and sores. A poultice made by boiling the roots and leaves of the hemp plant is prescribed for application to inflamed parts as a cure for erysipelas and for allaying neuralgic pains. The oil expressed from the hemp seeds is known as 'kandiryak' and is used in Kashmir as well as in certain parts of the Punjab as an application for rheumatic pains.

(c) *Indian hemp in western medicine.*—The introduction of Indian hemp into western medicine may be traced back to the period when Napoleon's expeditionary forces occupied Egypt. In India, O'Shaughnessy in 1839 tried Indian hemp as a sedative of the central

nervous system in such diseases as tetanus, hydrophobia, rheumatism, chorea, and convulsions in children. Christison also carried out clinical trials in Indian patients and considered it to be an anodyne, hypnotic, and antispasmodic next only to opium. Later, Aaronson used it on some of his patients undergoing surgical operations and they testified that the drug subsequently had some pain-relieving properties. During the period that followed the report of these early workers, Indian hemp was used for its analgesic and hypnotic properties in such affections as asthma, neuralgia, neuritis, migraine, sciatica, myodynia, gastrodynia, enteralgia, tinnitus, dysmenorrhoea, muscular and joint pains, etc. It was also used to relieve the lightning pains of tabes, fornication, numbness, paresthesia, convulsions, etc. On account of its diuretic and sedative properties a decoction of hemp leaves has also been used in cystitis and urethritis.

(d) *Indian hemp in veterinary medicine.*—For diseases of cattle, hemp leaves are frequently used mixed with such ingredients as spices, salt or sugar candy. The smoke produced by the burning hemp plant is considered to be a disinfectant for sheep folds. Ganja is considered to be a good remedy against intestinal worms and in 'foot sore' disease. Bhang is sometimes used to increase the flow of milk in cows. Bhang mixed with salt is often administered to cattle as a preventive against diarrhoea, which is of common occurrence in India during the mousoon months. The use of these drugs is chiefly based on hearsay and tradition.

(e) *Indian hemp as a household remedy.*—The hemp drugs are popularly used as household remedies in the amelioration of many minor ailments. A mild beverage made from bhang leaves is believed to sharpen appetite and help digestion. Indian hemp is commonly used as a smoke and as a drink for its supposed prophylactic value against malaria in malarious tracts. Bhang beverages form one of the popular household remedies for gonorrhoea and dysuria. On account of their mild diuretic and sedative properties these drinks probably give a certain amount of symptomatic relief. Likewise, the use of bhang in dysmenorrhoea, asthma, and other spasmodic conditions is not uncommon. A poultice made from fresh leaves is a common household remedy for painful affections of the eyes, conjunctivitis, swollen joints, orchitis, and other acute inflammatory conditions.

(iii) *Use of hemp for euphoric, intoxicating and aphrodisiac purposes.*—The habitual use of hemp drugs for the production of euphoria and intoxication is widespread not only in India but throughout Asia and Africa. According to reports in published literature, it is a fairly common habit in the southern states of the United States of America where it is generally known as 'marihuana'. The rapid development of its use since 1935–1936 and widespread traffic in it has been the source of very great concern to the Bureau of Narcotics. Particularly disturbing is the fact that the victims comprise for the most part members of the younger generations and even boys and girls of school age are not excepted.

These drugs are said to alleviate fatigue and also to increase the 'staying power' in severe physical stress. In India, fishermen, boatmen, washermen, and cultivators who have to spend long hours of the day in rivers, tanks and water-logged fields often resort to hemp drugs in some form or other in the belief that these will give them a certain amount of protection against catching cold. Mendicants who roam about aimlessly in different parts of India and pilgrims who have to do long marches often use hemp drugs habitually. Sadhus and fakirs visiting religious shrines usually carry some bhang or ganja with them and often indulge in them. It is not an uncommon sight to see them sitting in a circle and enjoying a smoke of ganja in the vicinity of a temple or a mosque. Labourers who have to do hard physical work use hemp drugs in small quantities to alleviate the sense of fatigue, depression and sometimes hunger. A common practice amongst labourers engaged on building or excavation work is to have a few pulls at a ganja pipe or to drink

a glass of bhang towards the evening. This produces a sense of well-being, relieves fatigue, stimulates the appetite, and induces a feeling of mild stimulation, which enables the worker to bear the strain and perhaps the monotony of his daily routine of life more cheerfully. The low cost and easy availability of these drugs are important factors in their use by the working classes, whose economic condition is low in this country. Hemp drugs are perhaps the only narcotic drugs which fall comfortably within their means and they make use of them as occasion arises. A dose worth two to four pice ( $\frac{1}{2}$  to 1 penny) is often sufficient for producing the desired effect in a few individuals.

Hemp drugs are also sometimes used to induce a state of intoxication which will excite emotion and give a sense of bravado so that daring acts may be committed. As has been said the Rajput warriors, during their frequent encounters with the Mohammedan invaders in the old days, used to indulge in bhang so that any nervousness present might be banished, and a feeling of determination created either to win or die on the field of battle. This practice is seen even in these days in connection with wrestling contests and athletic sports and games needing great physical effort and endurance. Indulgence in hemp drugs, unlike alcohol, rarely brings the habitué into a state of extreme intoxication where he loses entire control over himself. As a rule, the intoxication produced is of a mild nature and those who indulge habitually can carry on their ordinary vocations for long periods and do not become a burden to society or even a social nuisance.

Another purpose for which hemp drugs are largely used in this country is for their aphrodisiac effect. The belief regarding their stimulant effects on the sexual organs has been in existence for a very long time. According to the physiological data obtained it is possible that hemp drugs by their action on the higher centres of the brain, may excite ideas and delusions of a sexual nature, but no experimental data are available to show that they have any specific action on the lower sexual centres in the cord or directly on the organs.

The use of hemp drugs for euphoric, intoxicant, and aphrodisiac purposes, although quite common 20 to 30 years ago, has gradually declined and at the present time it is almost entirely confined to the lower strata of society. Amongst the upper and middle classes, the use of hemp drugs is nowadays considered to be derogatory, in spite of the fact that the practice was held in great esteem in ancient India, and early literature is full of references to the virtues of this drug.

This change in outlook with regard to indulgence in them is not difficult to understand. One reason is that hemp drugs are popular with the lower strata of society which contain a large number of undesirable and criminal elements, and the well-to-do and respectable classes are giving them up on account of this association. Another and perhaps a more important reason for the decline of the use of hemp drugs is probably traceable to the peculiar blunting of the sense of relativity in which the idea of time and space may be lost. By affecting the higher nervous pathways concerned in the balanced co-ordination of time and space, the use of Indian hemp, unlike other drugs which produce euphoria, is more likely to place the habitué in an awkward position and bring him into ridicule. Behaviour problems are also known to arise commonly with them. These lapses naturally become immediately apparent in social and club life and make the company of such persons undesirable. The upper and middle classes, therefore, abstain from the use of these drugs as far as possible. Whatever may be the reasons for the decline in the use of hemp drugs, statistical data undoubtedly show a marked decrease in their consumption during recent years, especially among the upper classes.

#### ABUSES OF HEMP DRUGS

The hemp drugs are rarely employed to produce a state of intoxication which is so intense that the

individual may lose all control over himself. Although their habitual use is common, these drugs are not often indulged in to such an extent as to constitute a definite abuse. The deliberate abuse of bhang is met with among certain classes of religious mendicants in this country, their main purpose being to get into a state of frenzy which, according to their traditional ideas, is conducive to mental concentration and communion with God. Such a frenzied state is used as a cloak for creating belief in the minds of the credulous illiterate masses. A large number of religious fanatics in temples and in places of pilgrimage undoubtedly are hemp-drug addicts of long standing.

Another class of people who are prone to abuse hemp drugs are some of the nomadic classes who have no fixed home and who move about from place to place living in small camps by the roadside exposed to all sorts of inclement weather.

It is commonly believed that bhang drinking is comparatively less harmful than the practice of smoking ganja and charas. There appears to be a good deal of truth in this popular belief. Although the use of bhang as a cooling beverage is encountered in many parts of India and cases of excessive indulgence are not frequently met with, instances of frank abuse and harmful effects following therefrom are as a rule uncommon. This, of course, does not mean that bhang does not produce any deleterious effects on the system. Impairment of digestion is a common occurrence with bhang drinkers of long standing, who take excessive quantities. This naturally results in injury to their general health and vitality. There is definite and demonstrable stimulation of the higher cerebral and medullary centres, but this is seldom intense and, therefore, the harm done is comparatively small. The smoking of ganja and charas on the other hand, although it affects the digestion to a lesser extent, brings about a state of intense intoxication as a result of action on the higher centres in the brain and, if the abuse is continued for a considerable time, it may lead to mental derangement, behaviour problems, crime and insanity. These habits, therefore, constitute an important social problem. Moreover, ganja and charas are possibly more likely to produce intense addiction than bhang. Habitual use of bhang can be discontinued without much trouble but the withdrawal from the ganja and charas habits is accompanied by unpleasant symptoms and is much more difficult, though negligible compared to those associated with drugs like opium or cocaine.

#### PRESENT EXTENT OF HEMP-DRUG ADDICTION

*Total consumption of hemp drugs.*—The total consumption of hemp drugs, according to excise returns of 1934-35, amounted to 1,031,496 lb. in British India and this works out approximately at 4.24 lb. per 1,000 of population per annum (census of 1931). The consumption of these drugs in British India in 1912-13 worked out at 15 lb. per 1,000 of population per annum. It will be seen therefore that, during the last 20 years, the use of these drugs has been reduced to nearly a quarter of what it was. When the three preparations, bhang, ganja, and charas, are considered individually, the amounts consumed in 1934-35 were as follows:—

		Seers or	lb.
Bhang	..	292,166	584,332
Ganja	..	162,153	324,306
Charas	..	61,429	122,858
TOTALS	..	515,748	1,031,496

The United Provinces consume the largest amount of hemp drugs, the total consumption in that province being 287,926 lb. during 1934-35; next in order come the Punjab, Bengal, Bombay, and Central Provinces.

As regards the incidence of the hemp-drug habit,

Sindh shows the highest incidence with a consumption of 35.12 lb. per 1,000 of population per annum, then comes Delhi with 23.84 lb., Ajmere-Merwara 14.6 lb., Baluchistan 8.22 lb., the Punjab 7.6 lb., North-West Frontier Province 5.94 lb., United Provinces 5.94 lb., Bombay 4.4 lb., Assam 2.18 lb., Bihar and Orissa 2.2 lb., Bengal 1.6 lb., and Central Provinces and Berar 1.6 lb., respectively.

It is very difficult to form an accurate idea of the number of persons addicted to the three forms of hemp drugs as there are many occasional consumers, and there is no system of registration of addicts. It is only possible therefore to form a very rough estimate of the number of addicts from the total amount of the three preparations consumed and the average dose taken.

The average daily dose of bhang, ganja, and charas has been carefully worked out by us in more than 1,500 addicts. This is approximately as follows:—

	Grains daily
Bhang .. ..	20
Ganja .. ..	18
Charas .. ..	15

Assuming that the whole amount was used for euphoric purposes and for habitual consumption (the amount used for medicinal purposes being negligible), the number of hemp-drug addicts in the whole of British India at the present time works out to be 855,844, provided only the amount issued by the excise authorities is considered. From the knowledge we have of the situation all over the country, we are inclined to believe that the actual amount is a good deal higher, as considerable amounts of the drugs are obtained from illicit sources, for example by smuggling or from the spontaneous growth, which can be easily utilized.

The hemp drugs are the narcotics most extensively employed by the poorer classes throughout the country because they are cheap and easily available. Extensive work in the field has enabled us to estimate that the incidence of hemp-drug addiction ranges between 0.5 and 1.0 per cent of the total population in British India. The largest number of addicts are in the United Provinces and next comes Sindh. In these areas the use of hemp drugs is not restricted to any particular community and extends even among the middle classes. Charas is not used in Madras, Assam, Bihar and Orissa, and Central Provinces excepting in a few industrial towns such as Ahmedabad and Jubbulpur. Ganja is used to a comparatively small extent in Sindh, eastern districts of the United Provinces and in N.-W. F. Province and Punjab where it is prohibited.

From our investigations in the field, we conclude that a large number of the inhabitants of this vast country take hemp drugs habitually at the present time, that the habit is on the whole declining and it certainly is not on the increase anywhere, that there is reason to believe that during the last 15 years the use of hemp drugs has more rapidly declined than in the previous similar period; the cause of this decline appears to be the tightening of control by government by reducing the area under cultivation and increasing the price by enhancement of excise duty.

The localities in each province where the incidence of hemp-drug addiction is high are urban and not rural areas. Large industrial towns or large agricultural centres, as a rule, have large labour populations in low economic circumstances. They have to work very hard and they usually indulge in these drugs as cheap euphorics. Thus, in towns such as Calcutta, Bombay, Madras, Ahmedabad, Cawnpore, the consumption is high on account of this large industrial population. The mining areas also show a high incidence, due to the preponderance of labour forces. Burdwan district in Bengal with its large mining industries shows a comparatively higher incidence than other parts of Bengal, with the exception of Calcutta.

Religious centres and important places of pilgrimage also show a high incidence of the use of hemp drugs. This is due to the presence of hordes of mendicants who collect at such places.

## HEMP-DRUG ADDICTION IN DIFFERENT PROVINCES IN INDIA

**Bengal.**—During 1936-37 the consumption of different forms of hemp drugs in Bengal, according to the Excise Reports, was as follows: ganja 64,974 lb., bhang 16,736 lb., and charas 1,452 lb.

The incidence of the use of different forms of hemp drugs is high chiefly in the western zone, composed of Iwan, Birbhum, Midnapore, and

The high consumption in these to large labour forces engaged in various industries such as jute and cotton mills, iron and steel works, coal fields, etc., which abound in this area.

In most of the districts of East Bengal, the demand for bhang as an intoxicant is very small, but it should be remembered that in these districts bhang grows wild, and it is believed to be extensively used as an illicit substitute for ganja. Further, it will be seen that the consumption is highest in Calcutta and its suburbs. The reason of this is that in the city of Calcutta and its suburbs there is a large labour population engaged in different industrial occupations, whose hygienic and economic conditions are such as to lead to the use and abuse of narcotic and euphoric drugs.

Taking the Presidency as a whole the incidence of the use of these drugs is not very high, being only 1.6 lb. per 1,000 of population per annum for all hemp drugs and 1.4 lb., 0.4 lb., and 0.02 lb., for ganja, bhang, and charas, separately. There is no doubt that there is a further decline in these figures.

**Bihar and Orissa.**—In 1936-37, 57,726 lb. of ganja and 14,470 lb. of bhang were consumed in Bihar. Minor rises occur in the consumption of bhang in the districts of Gaya and Patna, in all probability because of their having places of pilgrimage to which people from other parts of India come in large numbers. The consumption of ganja keeps at a fairly high level throughout the province. The incidence of consumption of total hemp drugs per 1,000 population was 2.2 lb. per annum.

The types of people who use hemp drugs in these provinces are similar to those in Bengal, the only difference being that the incidence of addiction among the middle classes is higher than that in Bengal, particularly in the western districts which adjoin the United Provinces.

**Assam.**—Cultivation of hemp drugs is not allowed in this province, the supply of ganja being obtained from Rajshahi in Bengal and of bhang from Bhagalpore in Bihar. The amount of ganja consumed in Assam during the year 1935-36 amounted to 20,245 lb. The incidence per 1,000 population works out to be 2.2 lb. The consumption appears to have increased during the last year throughout the province except in Cachar, Sylhet, the Khasi Hills, Jaintia Hills, and the Garo Hills.

The consumption of bhang amounted to 60 lb. during 1935-36 which is very small as compared with other provinces. There are only two bhang shops, one in Cachar and another in Sylhet, but the consumption from excise sources is gradually decreasing, due to smuggling from Manipur and the Naga Hills. Permits are also issued to 47 druggists and Kavirajas who are allowed to store the drug for medicinal purposes. Those addicted to hemp drugs are mostly working class coolies and labourers.

**United Provinces of Agra and Oudh.**—The total consumption of all these drugs in the United Provinces was 287,942 lb. during 1934-35. Of this amount 228,724 lb. was bhang, 42,752 lb. charas, and 16,466 lb. ganja. As regards the incidence per 1,000 population per annum is concerned, it works out to be 5.8 lb. of all hemp drugs and 5 lb., 1 lb., and 0.4 lb. for bhang, charas, and ganja, separately.

**Punjab.**—Only bhang and charas are used in the Punjab, the sale of ganja being strictly prohibited. Total consumption of hemp drugs in this province during 1935-36 amounted to 179,408 lb. out of which 34,502 lb. was charas and 144,906 lb. was bhang.

The total incidence for the two drugs worked out at 7.6 lb. per 1,000 of population per annum and 1.4 lb. and 6.0 lb. for charas and bhang separately.

**Delhi province.**—As this province adjoins the Punjab and western districts of the United Provinces, the problem of hemp-drug addiction is very similar to these provinces. Bhang and charas are almost entirely used and the supply is obtained from the Punjab. Total consumption of these drugs during 1934-35 was 15,130 lb. out of which 5,702 was charas and 9,428 was bhang. The average consumption per 1,000 population per annum works out at 23.8 lb. and the province stands second in India with regard to the incidence of consumption.

**North-West Frontier Province.**—The problem of hemp-drug addiction in this province is similar to that in the adjoining provinces of the Punjab and Sindh. Bhang and charas are the only two preparations which are used in this province for addiction purposes. Indian hemp grows spontaneously almost everywhere and can be collected without restriction up to the legal limit of 2 lb. per person. During 1935-36, 6,768 lb. of charas were consumed in this province which gives the incidence of 4.2 lb. per 1,000 population per annum. The drug is used by all classes, who are chiefly Mohammedans.

Bhang is mainly consumed in Bannu and Dera Ismail Khan districts. This is probably because these areas lie on the border of western Punjab districts and Sindh which are both heavy bhang-consuming areas. The total consumption of bhang during the year 1935-36 was 12,242 lb. which gives an incidence of 1 lb. per 1,000 population per annum. The incidence of both forms worked out at 5.2 lb. per 1,000 population.

**Sindh.**—During 1934-35, 136,480 lb. of hemp drugs were consumed of which 118,660 lb. was bhang, 17,504 lb. charas, and 316 lb. ganja. The consumption of bhang is rather high throughout the province, and works out at 35.12 lb. per 1,000 population per annum.

**Baluchistan.**—The total consumption of hemp drugs during 1935 amounted to 3,352 lb., of which 2,164 lb. was charas, 1,186 lb. bhang, and only 2 lb. ganja. The average consumption of all the hemp drugs put together was 8.2 lb. per 1,000 of population per annum.

**Bombay Presidency.**—The total consumption of hemp drugs in the Bombay Presidency proper during the year 1936-37 was 79,646 lb., of which 16,214 were bhang, 12,476 lb. charas and 50,956 lb. ganja. Ganja is however the drug of choice, bhang is in little demand and is only used by the Marwari community and people from northern India. The use of charas is prohibited all over the province except in the towns of Bombay and Ahmedabad.

In this province, taken as a whole, it has been roughly estimated that about 1 per cent of the population use hemp drugs habitually in some form or other at the present time. The incidence of all drugs works out approximately to 4.4 lb. per 1,000 of population per annum. That for ganja, bhang, and charas is 8.4 lb., 2.8 lb., and 0.8 lb., respectively. There appears to be no doubt that, on the whole, habitual indulgence has considerably declined during recent years.

**Central Provinces and Berar.**—The total consumption of hemp drugs in this province works out at 1.6 lb. per 1,000 population per annum and that of bhang and ganja to 1.2 lb., and 2 lb.

**Coorg.**—The amount of ganja consumed during 1935-36 was 318 lb. and the incidence of hemp-drug addiction worked out at 1.8 lb. per 1,000 population per annum.

**Madras Presidency.**—The population of southern Madras uses hemp drugs to a lesser extent than that of northern parts. During 1934-35 the total consumption of ganja and bhang amounted to 89,172 lb., out of which only 12,158 lb. was bhang, the rest being ganja. The total average consumption amounted to 1.8 lb. per 1,000 population per annum. The incidence is somewhat high in Madras and Salem districts, in the former on account of its being an industrial centre and in the latter because it is a rich agricultural centre. The consumption of both ganja and bhang is low in all other districts. The use of charas is practically unknown. There are altogether 544 licensed shops in the presidency.

### EFFECT OF HEMP-DRUG ADDICTION ON GENERAL HEALTH

From an analysis of the statements of addicts (1,238) as to whether the general health is affected in any way, we have observed that in about 52.10 per cent no ill effects were admitted. In 24.47 per cent health was believed to be affected to a minor degree and in 14.78 per cent to a marked degree. There were, on the other hand, 8.64 per cent who stated that they had improved in their general health since they took to indulgence in hemp drugs. The last group of persons were mostly those addicted to the use of bhang and who were in the habit of taking small doses in the neighbourhood of 10 grains a day. It is also evident that the evil effects were admitted more frequently in the case of ganja and charas addicts than in the case of bhang addicts, in 65.02 per cent as compared with 23.7 per cent, in this series. Further analysis showed that with increased dosage, the adverse effects were admitted to be more pronounced.

It will thus be seen that the general health may not suffer when hemp drugs are consumed in doses below 20 grains daily; further increase in the dosage is attended with deleterious effects and consumption exceeding 180 grains a day may damage the health seriously and rapidly.

#### *Physical effects*

Moderate habitual use of ganja or charas may or may not be attended with harmful effects, and in the case of bhang there is evidence that no apparent harm may result if it is taken in moderate quantities. Of all the preparations of Indian hemp, bhang is popularly believed to be the least harmful. According to the Indian Hemp Drug Commission (1893-1894) it is the refreshing beverage of the people, corresponding to beer in England and moderate indulgence in it is attended with less injurious consequences than similar consumption of alcohol in Europe. This view has been corroborated by our own experience in the field.

Bhang drinkers, unlike other drug addicts, are robust and physically well-built individuals. Its moderate habitual use does not lead to malnutrition, on the other hand appetite is said to be stimulated. The cases, in which loss in weight occurs, are probably those who are at the same time addicted to some other pernicious drugs such as opium, cocaine, or alcohol. In a certain number of our cases from the well-to-do and priestly classes, an atonic condition of the voluntary muscles of the body was commonly met with. These individuals were flabby and therefore had a tendency to become obese. The appearance of bhang addicts taking excessive doses is generally sleepy and they often have a vacant look. In about 60 per cent of those indulging in Indian hemp, the conjunctivæ are congested and have a yellowish-red tinge which becomes intense when the dose is repeated.

The confirmed ganja and charas addicts, especially those taking large doses, often exhibit signs of deterioration of general health. The excessive smokers are thin, emaciated persons with a sallow or muddy complexion, and dull grey eyes. Excessive smoking also produces chronic catarrhal laryngitis and considerable bronchial irritation may result.

The daily repeated dosage of these drugs overburdens the alimentary and excretory systems, the appetite declines and food is not properly assimilated. The addicts lose weight rapidly and may suffer from general cachexia; the skin becomes pale and dry and is often covered with scales; the nails, teeth and hair, which are often affected, become dry and lose their lustre. The general bodily nutrition suffers, because the money, which should be spent for the purpose of procuring wholesome and nutritious food, is used to buy the drug itself. Impairment of vitality is thus produced, which renders the system incapable of resisting an intercurrent disease. Addicts are generally more sensitive to the vicissitudes of weather than ordinary individuals.

#### EFFECTS ON THE CENTRAL NERVOUS SYSTEM

The main effect of hemp-drug addiction is on the central nervous system. These effects can be grouped under two headings:—

A. Temporary effects, i.e., those that are only present when the person is actually under the influence of the drug.

B. Permanent effects, i.e., the sequelæ of the prolonged use of these drugs.

##### *A. Temporary effects*

Soon after taking a moderate dose by mouth the pulse increases somewhat in fullness and frequency, the face becomes flushed, and there is a feeling of warmth all over the body; the appetite becomes sharpened and there is a tendency to talk. In rare instances aphrodisiac sensations are experienced. The sensation of pain is definitely dulled and there is a feeling of partial anæsthesia all over the body. The pupils are slightly dilated.

With larger doses the above symptoms become more pronounced; the pulse becomes rapid and sometimes irregular at first and slows afterwards. The temperature varies according to whether the individual is excited or depressed. This stage is usually followed by drowsiness and deep sleep.

*Ganja and charas smoking.*—The immediate effects of moderate doses in a habitual consumer is the initial feeling of anxiety and restlessness, which is followed by a refreshing and stimulating feeling. The sense of fatigue is alleviated, pleasurable sensations are produced so that the consumer is happy, and congenial towards everybody. Restlessness is removed and there is a quietening effect on the nervous system, which induces a sense of forgetfulness of all mental worries.

The effects in many cases are attended with hallucinations of sight, hearing, and general sensibility. The senses become hyper-acute and more subtle. Disturbance of the sensations of taste and smell may also occur during the later stages. Deep sleep generally follows in the majority of cases an hour or more after indulgence.

There are individuals amongst ganja and charas smokers on whom the effect of intoxication is quite different from that ordinarily obtained. They lose all sense of proportion and become irresponsible.

*Bhang or 'siddhi' drinking or hemp eating.*—Bhang is somewhat extensively used for occasional indulgence and for religious purposes; its symptomatology therefore deserves special mention. The effects produced by this drug are more lasting than those produced by smoking ganja and charas. With moderate doses the individual feels cheerful. The appetite is sharpened. With some there is a sensation of forgetfulness and relief from worries and troubles of life, others get good sleep after the day's hard work, still others feel active and interested in life and their surroundings, after taking a dose.

Most bhang addicts, after a regular dose, become reflex and emotional; the control of the higher centres is lost and the sense of judgment is impaired to an appreciable degree. The stage of intoxication generally lasts from three to five hours and then sleep supervenes. The addict on waking next morning does not experience any marked nausea or vomiting nor are the bowels affected (constipated) as in the case of other intoxicants. Some of the addicts complain of slight dizziness and congestion of the eyes and feeling of heaviness in the head on waking next morning.

*Duration of effects. Ganja and charas smoking.*—Smoking produces its effects more rapidly than consumption by the mouth because by the latter method the absorption of the resin, which is combined with large quantities of colloidal matter, is considerably delayed from the gastro-intestinal tract. With pure resin absorption is of course much quicker. According to Russell, in the case of ganja smoking the mental effects appear within three to five minutes while in the case of charas they may appear with the first pull from the pipe ('chillum'). In the case of ganja, the effects last from half to one hour or even longer, in the case of charas from 15 to 20 minutes. With bhang the symptoms may set in from 20 to 30 minutes or may be delayed and may last from two to twelve hours.

#### B. Permanent effects

*Mental effects.*—Mental injury is more likely to occur in the case of those individuals who take large doses and for prolonged periods.

The effects of different preparations are interesting. Emotional character and judgment are affected more in the case of bhang, while memory

and sleep are more disturbed in the case of ganja and charas. Bhang habitués were also more peevish and hypochondriacal than those indulging in ganja and charas. The incidence of gross injuries to the central nervous system such as insanity and moral depravity appears to be more frequent amongst the ganja and charas habitués than the bhang drinkers. Epileptic fits are, on the other hand, more frequent amongst the bhang habitués.

*Effects on sleep.*—We are inclined to believe that sleep is disturbed more in the case of ganja and charas addicts and little or not at all in the case of those addicted to bhang. This may be due to the fact that bhang as a sedative has a mild and prolonged action, while ganja and charas have rapid and intense effects in which euphoria and stimulation are more pronounced.

*Use of the hemp drugs in relation to mental disorders and crime.*—We have come across a few instances of insanity resulting from the abuse of bhang or charas or ganja. The testimony of many of the competent medical authorities in this country also sponsors this belief. The abuse of hemp drugs injures the constitution in the same manner as an excessive indulgence in any other narcotic drug. It does not necessarily produce insanity, except perhaps in those who have predisposition to it. It may, however, lead to rough manners and apathy and extraordinary behaviour on the part of the individual. Those who smoke ganja and charas excessively are often quarrelsome and do not heed the consequences of their deeds. We have examined records of murder and crime cases in jails and mental hospitals and have found that only in a very few instances (1 to 2 per cent) the temporary or the permanent mental derangement induced by hemp drugs was directly responsible for a crime.

As regards the relationship between hemp-drug addiction and crime, there are instances where the addicts committed criminal acts under the effect of these drugs, especially after smoking ganja or charas, under grave provocation or in cold blood and with premeditation. Such instances do not necessarily prove any definite relationship between hemp drugs and crime. Indulgence in alcohol undoubtedly gives rise to a feeling of bravado and courage by depressing the higher controlling cerebral centres, and there are many instances in which it has led to crime of a very grave nature. With regard to hemp drugs, however, the situation may be viewed from a different angle. Hemp drugs are cheap and are generally used by the poorer classes, who belong to the lower strata of society, to which most of the criminals in this country belong. This may be an explanation of the fact that proportionately more consumers of hemp drugs, especially ganja and charas smokers, are found among bad characters than among the population in general. Moreover the associated poverty of the addicts may lead them to commit thefts and other petty offences, but

this does not throw the entire responsibility on the hemp drugs.

So far as premeditated crime is concerned, especially that of a violent nature, hemp drugs in some cases may not only not lead to it, but they may actually act as deterrents. The result of continued and excessive use of these drugs, in our opinion, is to make the individual timid rather than to lead him to commit a crime of violent nature. Our opinion in this respect, based on the study of a large series of addicts, is that the tendency of the drug appears to be to develop or bring into play the natural disposition of the consumer and to emphasize his true character and peculiarities.

#### TYPES OF HEMP-DRUG ADDICTS

There is nothing inherent in the make-up of a normal individual which draws him towards the habitual use of narcotic drugs. The basic factor underlying addiction is always some defect or abnormality in the mental make-up of the individual. The causes leading to drug addiction are almost identical all over the world. The reasons for which the habit is started are psychological and are sufficiently convincing to the addict himself and he intentionally carries on the habit in spite of being aware of its dire consequences. The addicts in this country can be divided into four main groups :—

Group I.—Persons belonging to poorer classes, such as day labourers, or domestic servants. These people are the principal consumers of ganja and charas. They keep to small doses and as a rule suffer from little or no injury to their general health.

Group II.—Those individuals who use these drugs in the same way as opium, for their narcotic effects. The members of this group are idlers and persons below average mental equilibrium. Ganja and charas are mostly used by this group and the damage to their health is more perceptible than in the case of group I.

Group III.—Those who use hemp drugs in order to obtain stimulant effects combined with intoxicating effects in the same way as from alcohol. This practice exists mostly amongst the idle rich.

Group IV.—Mostly religious mendicants (sadhus and fakirs) and the priestly classes. Hemp drugs are used in all forms by them in order to overcome the feeling of hunger and in order to help them to concentrate on religious and meditational objectives, and also sometimes by the unaccustomed to excite passion and emotion.

#### SUMMARY AND CONCLUSION

(1) The hemp plant grows wild over extensive tracts in northern India along the southern slopes of the Himalayas, coming well down into the plains. Its cultivation for narcotic purposes is strictly controlled and is confined to selected areas under careful supervision of the excise authorities.

(2) The resinous substance contained in the hemp plant is the active principle responsible for its physiological activity. The resin, as obtained from the plant, contains a number of compounds, one of these being *Cannabinol* which is probably the active principle. The potency of hemp drugs deteriorates with age.

(3) *Charas* and *ganja* are preparations from the same plant and differ in the amount of the narcotic principles they contain; the physiological effects produced by them are similar, differing in degree. Ganja and charas are mostly smoked, while bhang is usually taken by the mouth in the form of a beverage.

(4) The present use of hemp drugs in India may be considered under three main headings:—(i) use in connection with religious and social customs; (ii) medicinal uses; and (iii) use for narcotic and euphoric purposes.

(5) The use of hemp drugs in order to produce euphoria and mild stimulation, although still common, is gradually declining. It exists mostly at the present time among the lower and working classes.

(6) As euphorics, hemp drugs, unlike alcohol, rarely produce severe intoxication, especially in those who take them habitually. Abuse of these drugs sufficient to produce intoxication of a pronounced type exists only amongst the idle and vicious classes in the cities and towns.

(7) The total consumption of hemp drugs in British India during the year 1934-35 amounted to 1,031,496 lb., which works out approximately at 4.24 lb. per 1,000 of population per annum (according to the census figures of 1931) as compared with 15 lb. during 1912-13. The United Provinces are the largest consumers of hemp drugs, next in order come the Punjab, Bengal, Bombay, and Central Provinces and Berar, respectively.

Charas is mostly used in the northern and western parts of India, i.e., the North-West Frontier Province, the Punjab and the western districts of the United Provinces. In Sindh, Rajputana, and western districts of the Punjab and the United Provinces, bhang is more commonly used in the form of a cooling and refreshing beverage suitable for the hot and dry summer months. In the rest of India, i.e., Bengal, Bihar and Orissa, Bombay, Madras, etc., ganja is the drug of choice.

From the survey we have carried out and from the total consumption of hemp drugs and daily dosage of addicts we have roughly estimated that there are at least between 855,844 and 1,000,000 hemp-drug addicts in this country, i.e., approximately 0.3 to 0.5 per cent of the population of this vast country take hemp drugs habitually at the present time.

(8) The moderate use of ganja and charas may or may not be attended with harmful effects, while in the case of bhang there is definite evidence that no harm may result to the general health with moderate doses. On the other hand confirmed ganja and charas addicts, especially

those taking large doses, often exhibit signs of deterioration of general health. The daily repeated-doses, especially if large, overburden the digestive and the excretory systems with the result that the appetite is lost and food is not properly assimilated.

(9) Hemp drugs are, even at the present time, used as sexual stimulants by the lower classes. They lead to temporary stimulation of the psychic areas, and the mental excitement thus resulting gives the semblance of aphrodisiac effects, especially in those individuals who are sexually inclined.

The incidence of sterile marriages amongst hemp-drug addicts worked out to nearly twice that of the normal population.

(10) Effects on the central nervous system can be divided into two stages: (a) an initial stage of stimulation and exhilaration, and (b) a stage of depression when the sedative effects become more marked. The effects during each stage are largely influenced by racial and personal idiosyncrasy and may be entirely modified by the individual temperament.

(11) From a careful study of a series of 1,238 addicts we are inclined to believe that continued

and excessive indulgence in these drugs tends to impair the normal functioning of the nervous system, renders the addict incapable of mental exertion, and causes general debility and premature decay.

(12) We have come across a few instances of insanity resulting from the abuse of bhang or charas or ganja. The abuse of hemp drugs injures the constitution in the same manner as an excessive indulgence in any other narcotic drug. It does not necessarily produce insanity except perhaps in those who have predisposition to it.

## Medical News

### BOMBAY MEDICAL COUNCIL

SUMMARY of the proceedings of the meeting of the Bombay Medical Council held on the 9th February, 1940.

The Council proceeded to consider the complaint by Dr. V. B. Mankad, M.B., B.S., and five other medical practitioners of Ahmedabad against Dr. Ganpatram Gokaldas Patel, M.B., B.S., D.O.M.S. (Lond.), in respect of the charges, *viz*,

(a) of directly or indirectly procuring, or sanctioning or acquiescing in the publication and free distribution among patients of a handbill or leaflet in Gujarati, the said handbill or leaflet commending or directing attention to the professional skill, services, popularity, amiable temper, the care and caution had by Dr. Patel in the treatment of eye diseases; it was alleged that the mention of Surya Bhuwan Hospital was intended to be an advertisement to solicit more practice;

(b) issuing cards or tickets containing not only the number and name of the patient thereon but also the name and address, etc., of Dr. Patel which, it was alleged, constitute an advertisement;

(c) under the cloak of a semi-charitable eye-clinic, it was alleged, he was carrying on private practice charging only one anna to every out-door patient of the Surya Bhuwan Eye Hospital.

These acts appear, it was alleged, to contravene the provision of clauses (a) and (m) of rule 1 in Section II of the Code of Medical Ethics and clause (a) of section 6 of the Warning Notice.

Mr. C. C. Parikh, Advocate from Ahmedabad, was allowed to appear for Dr. V. B. Mankad, Dr. D. E. Anklesaria, Dr. M. M. Parikh and Dr. M. D. Anklesaria, four of the complainants herein, as a special case.

Mr. G. C. O'Gorman, Bar-at-Law, and Mr. H. R. Pardiwalla, Bar-at-Law, instructed by Messrs. Majumdar and Dalal, Solicitors, appeared for Dr. G. G. Patel, the practitioner.

Upon the conclusion of the deliberations, the following resolution was put from the chair:—

'That the facts alleged against Dr. G. G. Patel, M.B., B.S., D.O.M.S. (Lond.), in the Notice of Inquiry have been proved to the satisfaction of the Council.'

The said resolution was declared lost, as a result whereof Dr. Patel was held not guilty of the charges preferred against him in the Notice of Inquiry.

The Council then proceeded to consider the question of amendment of rules 61 and 64 of the Rules of the Council relating to travelling allowance and passed a resolution approving of the amendments recommended by the executive committee in regard to the said rules.

The Council then proceeded to consider the question of recognition of the D.O.M.S. of the College of Physicians and Surgeons of Bombay as an additional registrable qualification and decided to grant recognition to the D.O.M.S. of the College for registration as an additional qualification and further resolved that the same be included in Table (G) of the Bombay Medical Register.

The Council then proceeded to consider the application of Dr. J. N. DeSylva, L.M. & S., for restoration of his name to the Bombay Medical Register and resolved that the consideration of his application be adjourned *sine die* and that he be asked to submit certified copy of the judgment in the proceedings now pending against him.

The Council then proceeded to consider a letter dated the 7th August, 1939, from the Secretary, Medical Council of India, forwarding therewith a copy of letter dated the 4th July, 1939, from the Registrar, South African Medical Council, Pretoria, and decided to accept the recommendation of the executive committee that any person whose name is erased from the Register of South Africa where he was formerly a registered medical practitioner for infamous conduct in a professional respect should not be entitled to have his name entered in the list of the Bombay Medical Register, provided the Medical Council of the said country

notifies to this Council the name of such a medical practitioner, until such time as the registering Council shall otherwise intimate and that this rule be laid down by the Council provided that the South African Medical Council is also prepared and willing to reciprocate with this Council in the like manner.

### INDIGENOUS DRUGS INQUIRY

ADVANCE in knowledge of the pharmacopœia and allied drugs produced in India and development of local drug manufacture, bringing prices within easy reach of large masses in India are some of the achievements claimed for the study, of a large number of Indian medicinal plants under the Indigenous Drugs Enquiry, financed by the Indian Research Fund Association. The study ranged over a wide field from the isolation of the active principles to tests of action on animals and, in suitable preparations, on patients.

A number of manufacturing firms have come into existence and instead of concentrated extracts which were formerly imported, practically all kinds of galenical preparations, powders, etc., are now being manufactured in India, in many cases, from material locally produced. The growth of the pharmaceutical industry has, in its turn, stimulated the manufacture of solvents such as alcohol, chloroform, ether, benzene and many coal-tar products used in medicine.

There is now greater demand for indigenous raw material and with this increase in demand, there has been an increase in the area under drug cultivation. Belladonna, digitalis, hyoseyamus, squills, colchicum gentian, artemisia, juniper, valerian, podophyllum, colocynth, ephedra, pyrethrum, etc., are a few of the drugs which have come into more extensive use. Raw products of good quality are now more easily available at reasonable prices and the export of crude drugs such as belladonna, ephedra, podophyllum, chaulmoogra, castor oil seeds, etc., has gone up considerably.

Attempts are being made to grow the plants in such a manner that the maximum quantity of active principles can be obtained, while to overcome difficulties in identification, a herbarium of medicinal plants is being got ready. Digitalis, ipecacuanha, pyrethrum are some of the important drugs, the cultivation of which is being thus encouraged. It is hoped that with proper development, India will not only be able to meet her requirements of medicinal herbs and drugs but also have a large residue for export.

The researches have done much to prove or disprove, by the application of modern methods, the therapeutic value of many drugs used in indigenous medicine. Of the drugs, the efficacy of which has been proved, Isabgul (*Plantago ovata*), Kurchi (*Holarrhena antidysenterica*), Sarpagandha (*Rauwolfia serpentina*), Babchi (*Psoralea corulifolia*), Kuth root (*Saussurea lappa*), cobra venom, are a few which may now be admitted into the Indian Addendum to the Pharmacopœia and, later, into the Indian Pharmacopœia. On the other hand, a number of drugs, which were in the old addendum, have been shown to be worthless.

As a natural corollary to work on the medicinal plants, a systematic study has been undertaken of the poisonous plants growing in India. The work is of importance not merely to the medical profession, but also to the veterinarian and to those interested in livestock. The toxic effects of plants in common use, such as aconite, barringtonia, calotropis, nerium, etc., have been worked out, and steps taken to warn people against their indiscriminate use by unqualified practitioners.

Some common food poisons, such as Khesari dal (*Lathyrus sativus*), Indian millet (*Sorghum vulgare*), Sialkanta seeds (*Argemone mexicana*), which have been responsible for serious outbreaks of poisoning in men and animals, have also been studied. Only the fringe, however, of this vast problem of poisonous plants and food poisons have so far been touched.

Investigations have also been made on the diagnosis and treatment of such diseases as malaria, amœbic dysentery, kala-azar, filariasis, diabetes, etc. In order to find out whether climatic factors and variability of

the strains of parasites make any difference in the effectiveness of drugs, indigenous drugs as well as drugs and synthetic preparations manufactured in India and abroad have been subjected to careful tests. The minimum effective doses of antimalarial and other drugs, required to bring about disinfection of the patient in a reasonably short time, are being worked out, so that treatment may be carried out with the minimum of expense.

The Indian Indigenous Drugs Enquiry was started in 1926 at the School of Tropical Medicine, Calcutta, with its well-equipped pharmacological and chemical laboratories, where the chemical composition of crude drugs could be determined and their biological action on living tissues evaluated. The clinical testing of drugs were carried out at the Carmichael Hospital for Tropical Diseases which is attached to the Tropical School as its research hospital, the only one of its kind in the East.

The main objects which the enquiry had in view, were to make India, as far as possible, self-supporting in her supply of drugs by making possible the utilization of indigenous drugs in a form suitable for administration; to discover remedies suitable for application by exponents of Western medicine from among those claimed to be of high value by Ayurvedic, Tibbi and other indigenous systems of medicine; to find means by which efficacious remedies could be brought within the reach even of the poor, and finally to prepare an Indian Pharmacopœia.

The Indigenous Drugs Enquiry brought to light the true state of affairs with regard to the quality of drugs on the market in India and, eventually, led to the appointment of the Drugs Enquiry Committee and finally to the establishment of the Biochemical Standardization Laboratory of the Government of India.

The pioneer work of the Indian Research Fund Association has also given an impetus to research on Indian medicinal plants in many places in India. Investigations have been started in the universities and colleges at centres such as Calcutta, Bombay, Dacca, Patna, Allahabad, Lahore, Madras and Trivandrum.

### MEETINGS OF THE UNITED PROVINCES MEDICAL COUNCIL HELD ON 17TH NOVEMBER, 1939, AND 18TH MARCH, 1940

THE Delhi Medical Association's resolution, dated the 11th March, 1939, regarding immigration of foreign medical practitioners into this country, was considered and the council passed the following resolution:—

'The United Provinces Medical Council strongly protests against the immigration into this province of foreign medical practitioners, not registrable anywhere in the Empire—much less in these provinces, also against the fact that no bar has so far been placed against their practising medicine and surgery.

This council unanimously recommends to the Government to take early steps in the shape of adequate legislation to (i) prevent unrestricted immigration of such practitioners for the purpose of practice into this province, and (ii) to prevent them from practising in the United Provinces since they are neither registered nor possess any registrable qualification.

In this connection, the council brings to the notice of the Government the fact that Indian Nationals are not allowed to practise in their countries of origin even if they have qualified as doctors in those very countries.

Further, this council views with great disfavour the association or covering of unregistered foreign medical practitioners by the medical practitioners registered under the United Provinces Medical Act.

In view of the influx of many men who practise medicine and surgery and about whose qualifications nothing is known, the question as to what constitutes an unqualified person was considered.

The question of restoration of the name of Dr. Kanhaiya Lal, L.M.P. (Reg. no. 2957) was considered and it was resolved that his name be restored free of charge and without any affidavit.

The question of restoration of the name of Dr. Ram Saran Das Bejal, L.M.R. (Reg. no. 729) was considered and it was resolved that his name be restored provided he submitted an affidavit to the effect that he was the person who was originally registered under certificate no. 729, but no affidavit to the effect that to his knowledge no proceedings for removal of his name were ever taken against him be obtained. It was further resolved that this practice be followed in similar cases in future.

Resolved that the name of Dr. Ram Saran Das Bejal (Reg. no. 729) be restored to the medical register, free of charge and without obtaining any declaration, as the case is known to Captain Bagchi. Resolved further that no rules on the point are necessary but in future each such case be referred to the council to be judged on its merits, while the Bengal procedure be followed in the restoration of names removed for want of address. Rest of the minutes be confirmed.

Resolved that the name of Dr. Ivy Keess, W.M.S. (Reg. no. 1963), be restored without obtaining a declaration and free of charge, as she is known to Dr. Caul.

The action of the President in requesting Government to prosecute, under the Indian Medical Degrees Act, (i) Midwife Mrs. Bala Saxena (*née* S. Dass) and (ii) Mr. S. S. Singhal, Director, The Indian Medical Society, Aligarh, was confirmed, and it was resolved that that it may be pointed out to Government that this council has no powers to deal with the case of Mr. Singhal in the manner suggested and that Government should be requested to take further action in the matter.

Resolved that the State Medical Faculty be informed that this council is prepared to restore the name of Mr. Mahmud Ali (late Reg. no. 840) to its medical register if the State Medical Faculty restore his diploma. Mr. Mahmud Ali may then be asked to comply with the formalities.

The report of the Standing Committee, which met on 28th February, 1940, was considered to approve their recommendations.

*Recommendation no. 1* was accepted subject to the following changes and it was decided that the Bombay Medical Council be informed:

(i) *Delete* the following paragraph from the footnote proposed to be added to item 1(c) of the Code of Medical Ethics, *viz*:

'The United Provinces Medical Council takes a similar view of the association of a medical practitioner with any system or method of treatment which is not under medical control and which is advertised in the public press.'

(ii) The last paragraph of the proposed footnote should read as follows:—

'In the above findings the United Provinces Medical Council does not pretend to interfere with the right of a medical practitioner to be associated (save as above) with any legitimate business enterprise but if such enterprise concerns the sale of a medicine or food the practitioner should not allow his name, professional status or qualifications to be used for advertising purposes outside the medical press.'

Resolved that this council recommends to the Government and the Agra University that while constituting the Agra Medical College they should consider the desirability of affording opportunities to the Licentiates for obtaining the M.B., B.S. degree. This council should be given an opportunity to submit its proposals on this point before their arriving at a final decision.

## ST. JOHN AMBULANCE AND RED CROSS

THE ANNUAL GENERAL MEETING OF THE ST. JOHN AMBULANCE ASSOCIATION AND INDIAN RED CROSS SOCIETY, HELD ON 26TH MARCH AT THE VICEROY'S HOUSE

THE Viceroy said 'India has not escaped the infection of the discords and rivalries which have disfigured the world's history and retarded its progress of late.

Amidst all these, and in contrast to them, it is heartening to see two Societies, both of which had their beginnings in the strong desire to relieve the toll of suffering caused by war, going steadfastly forward, hand in hand without competition, confusion or discouragement, jointly dedicated to the service of humanity, which so sorely stands in need of it to-day.

The work which your Societies have done in peace is admirable, but, inevitably, it is in time of war that the test and the strain is heaviest. It was therefore with particular attention that I read the reports and listened to the interesting summaries which have just been presented to us by Sir Ernest Burdon and by General Jolly of the work that has been accomplished during a year in which we have been living partly under the shadow of imminent war and partly in a state of war itself.

There is every cause for satisfaction with the work that these reports reveal, and especially the report of the Central Joint War Committee. It was no small task to bring the Mobilization Plan so smoothly into operation, and those responsible for it, both at Headquarters and on the Provincial Committees, fully deserve the compliments which have been paid to them in the speeches we have heard. I am happy to feel that the work so well prepared and begun is continuing with the smooth efficiency we should expect under the able guidance of the Red Cross Commissioner.

The work of the Joint War Committee involves a close co-operation with Army Headquarters, and it was in that sphere that the willing help and counsel of General Tabuteau, whose loss we mourn to-day, made itself particularly felt. I will not add to the tributes you have already heard paid to him, except to say that no one more richly deserved the honour recently conferred upon him of admission to the rank of Commander of the Order of St. John.

It is a matter of regret to all of us that this is the last Annual General Meeting which Sir Ernest Burdon will be attending. Three years ago, the first of these meetings over which I presided, was also the first at which Sir Ernest was present as Chairman of the St. John Ambulance Association and as a Knight of Grace. His energy, his balanced judgment and his ripe experience have combined to make him the ideal Chairman and Chief Commissioner. We shall miss him very much.

Mr. Badenoch, whom I have nominated to succeed him as Chairman, needs no introduction either to you or to the work and responsibilities which await him. As Honorary Treasurer of both organizations he has already to his credit much valuable work, and I am sure that he will prove an able successor to Sir Ernest Burdon.

I feel sure, too, that you would wish me to welcome to-day, on your behalf, General Jolly, to this his first General Meeting as Chairman of the Indian Red Cross Society.

Dealing, first, with the St. John Ambulance Association and Brigade, I was delighted to hear that 1939 had been a record year of achievement, both in the field of instruction in First Aid and Home Nursing, and in increase of membership of the Brigade. Eight thousand members does not sound a large number in this country of hundreds of millions, but it represents a leap forward in membership by 60 per cent in one year. For this the war is no doubt responsible, but war or no war, let us hope that this increase will have set the standard for the years to come, for India has and will always have need of as many trained workers, as she can get, of the type that are found in the St. John Ambulance Brigade. It is a matter of great satisfaction that the organization of the Brigade on a territorial basis coinciding with Provinces, under the control of heads of Civil Medical Departments, has been completed. This arrangement, I am sure, will greatly assist to maintain the efficiency of the Brigade in India.

We may hope that there will be no call in India to put into practice A. R. P. and anti-gas training provided by St. John Ambulance, but the importance of having

ready a supply of volunteers skilled in such measures needs no emphasis from me.

The Mobilization Plan and the formation of the Joint War Committee made it inevitable and proper that the Red Cross and St. John Ambulance should share the burden of and the credit for much that has been accomplished during the past year. In particular I would like to mention the Women's Auxiliary Corps in Bombay the numerous work parties that have been formed up and down the country, typical of which is the party that works so zealously here in Delhi under the guidance of Lady Cassels, and the organization of a Voluntary Aid Service of Nurses to supplement the Nursing Branch of the Army Medical Services. These are all solid achievements of great value, within the scope of both organizations.

Let me mention now some matters which pertain more particularly to the Indian Red Cross Society. I was most interested to hear of a Blood Transfusion Service in Bengal. This is an example which I hope will spread.

I hope, too, that the donation from the British National Institute for the Blind, which has been spent upon education work on the prevention of blindness, is a seed that will multiply a hundredfold. My appeal for funds for St. Dunstan's Hostel, and Sir Clutha Mackenzie's recent tour of India (though St. Dunstan's, of course, works only for the war blinded) have, I think, roused interest in the grave problem of blindness in this country and have perhaps inspired the hope that much might be done here by way of prevention, cure and after-care, in co-operation with the great institutions which already exist outside India for the purpose.

It is gratifying to note that the Society in India has been able to extend help to other parts of the world, which stood in need of it, and that two nurses in India have been awarded by the International Red Cross Committee the distinction of the Florence Nightingale Medal. This, and the fact that the war has not yet curtailed the normal peace-time activities of the Red Cross in India, betokens good organization and reserves of strength. But there is no doubt that those reserves still need most urgently to be built up both in members and in funds, against a severer testing time which may yet be in store. The response by the public to my appeal for funds for the Red Cross and St. John Ambulance—which was greatly assisted by the willing co-operation of the Press—has been generous, especially considering the claims of other War Funds. But there can never be too much generosity in such a cause, and I feel sure that if and when the greater need arises it will be found that the springs of public support in India have barely yet been tapped.

War is an evil thing, but out of war have arisen such symbols as the Red Cross of Geneva and the eight-pointed White Cross of St. John of Jerusalem, the arms of which represent the virtues of prudence, temperance, justice and fortitude. These are ancient symbols, and they have undoubtedly helped to lead the world along the paths of humanity and progress. The shadow of another symbol, not so humane, is now brooding over our civilization. When it has passed, mankind will still need the services of those who work under the Red Cross and the Cross of St. John; they will not be found wanting, and they will come to their work, I know, with strength renewed and with their chivalry untarnished.

## Current Topics

### The Use of Colloidal Aluminium Hydroxide in the Treatment of Peptic Ulcer

By JOHN F. McINTOSH

and

COLIN G. SUTHERLAND

(Abstracted from the *Canadian Medical Association Journal*, Vol. XLII, February 1940, p. 140)

In recent years there has been a tendency to avoid the use of absorbable alkalis in the treatment of peptic ulcer, and to search for antacid substances which do not affect the acidbase equilibrium of the body as a whole. Among these newer substances may be mentioned mucin, magnesium trisilicate and colloidal suspensions of aluminium hydroxide.

The use of aluminium hydroxide in the treatment of peptic ulcer was introduced in 1922 by Roch, who reported favourably on its clinical use. Since this time a considerable number of clinical articles have been published. All of these have been favourable, and all attest to its value in relief of symptoms. Careful studies of its mode of action have also been made. The direct effect of the drug in controlling the acidity of the stomach has been studied by several authors. A recent paper by Bennett and Gill presents clear-cut evidence that the free hydrochloric acid of the gastric secretion can be completely and continuously neutralized by its use. It is well established that aluminium is not absorbed from the alimentary tract. It has been shown that its use does not lead to alkalosis or other disturbance of the acid-base balance of the body. By inference one would expect that its ingestion would not be followed by 'rebound' acidity or hypersecretion of acid, and it is generally agreed that such is the case. Indeed, Babkin found an inhibition of gastric secretion in dogs as an after-effect, rather than an increase. Similarly Einsel has presented evidence that prolonged ingestion of aluminium

hydroxide cream by ulcer patients leads to a marked diminution in titratable gastric acidity after alcohol stimulation in comparison with acidity curves determined before treatment was begun. Woldman and Rowland have introduced a method of administration through a nasal catheter which has considerably increased its effectiveness in intractable cases and in hæmorrhage.

The present report is based upon the clinical use of an aluminium hydroxide preparation in 38 cases of peptic ulcer, some of them from the Out-patient Services, the others from the medical wards. The group comprises all the cases which came under observation during a certain period, and in which the drug was used in adequate dosage for at least a week. Cases in which the diagnosis of peptic ulcer was in reasonable doubt have been excluded, as have cases in which ulcer was established but in which there was reason for attributing the symptoms to some associated condition, such as permanent pyloric obstruction or gall-bladder disease. A synopsis of the groups of cases and results of treatment is given in table I.

TABLE I

Group		Success-ful	Unsuccess-ful	Total
1	Out-patients ..	7	0	7
2	Ward cases, uncomplicated.	18	1	19
3	Cases with gross hæmorrhage.	9	1	10
4	Cases complicated by infection.	0	2	2
	TOTALS ..	34	4	38

**Group 1. Out-patients.**—This group of cases, seven in number, comprises six cases of duodenal ulcer without complications, and one of jejunal ulcer, all proved by x-ray examination and showing evidence of active ulceration. The patients were allowed to follow their usual occupations throughout the course of treatment. In some cases frequent feedings were advised, with milk freely used as an 'interval' feeding; as improvement occurred, three regular meals were instituted, with restrictions. Aluminium hydroxide was prescribed, usually as two drachm doses, at first six times a day, later two or three times a day, as improvement occurred. All of these did well.

Several points of interest arise from the consideration of this small group of ambulatory cases. The patients took the preparation readily, and, even when due allowance is made for the possible effects of suggestion, seemed to experience marked symptomatic benefit. Five of the seven cases were re-examined after treatment had been continued for several months, and in none of these did an ulcer crater persist. In one case, in which an exploratory operation was carried out some time later, there was operative proof of cure. Only one complaint arose from the use of aluminium hydroxide. Several complained that it caused constipation. This was not sufficient to interfere with continuation of treatment, and was easily controlled by mineral oil. The literature makes frequent mention of this effect of the drug.

**Group 2. Ward cases, uncomplicated.**—This group of 19 comprises 15 cases of duodenal and 4 of gastric ulcer. Five were recent but the majority were of long standing. The average duration of the 14 chronic cases was ten years. Cases with intestinal obstruction or permanent pyloric obstruction have been eliminated, although six which showed some degree of gastric delay have been included. These cases on the average are more severe and intractable than the ambulatory cases in group 1. Hospital stay varied from one to ten weeks though two to three weeks was the usual duration, not long enough to reach an opinion as to the final outcome of treatment. Some have been followed as out-patients and others by questionnaire, so that further information is available in ten cases.

The diet and dosage of aluminium hydroxide used in this group will be discussed below, along with the other groups of hospital cases. As to the immediate effect of treatment this was very satisfactory. Pain was relieved usually in the first two or three days, and usually without the use of atropine or other drugs. It is difficult to apportion the benefit from bed rest, diet, and medication in judging this group of cases, except as a matter of personal judgment. With this qualification we may say that the immediate effect of the drug was very satisfactory indeed and compared favourably with any other form of medical treatment. On discharge all the patients were considered improved.

In eight of the ten cases in which follow-up information is available, progress has been satisfactory, although only one patient has been able to give up treatment altogether. One, under observation in the out-patient department, has suffered a recurrence of symptoms. She has stopped taking aluminium hydroxide on account of constipation, preferring an antacid which has a laxative effect. The tenth case must be regarded as a failure of medical treatment although the immediate effect was considered to be good.

**Group 3. Cases with gross hæmorrhage.**—This group comprises nine cases of duodenal and one of gastric ulcer. One patient had no symptoms before the hæmorrhage which caused his admission. Like the previous group, the average duration of the chronic cases was ten years, and the usual hospital stay two or three weeks. Two of the cases were given Meulengracht's diet, the others 'bland', or Sippy diets. Aluminium hydroxide was given by mouth usually every two hours, in one or two drachm doses. With one exception all the patients in this group did well.

Hæmorrhage ceased, pain when present was relieved, and all were able to leave hospital improved.

This series of ten cases is too small to reach a final conclusion as to the value of aluminium hydroxide given orally in the treatment of gastric and duodenal hæmorrhage. Woldman has reviewed the mortality rates reported in eight recent series of cases of hæmorrhage, and in these the fatalities have ranged from 10.7 to 22.6 per cent. In his own control series of 38 cases there were 11 deaths—a mortality of 28.9 per cent. Hence among our cases one to three deaths might have been expected, although none occurred.

Until recently medical treatment of hæmorrhage in peptic ulcer comprised starvation—withholding all solids and giving only ice-water by mouth, in order to avoid dislodging the clot by food or peristalsis. Meulengracht deserves great credit for breaking with this tradition, and allowing liberal meals to his cases of hæmorrhage; by so doing he reduced the mortality rate in his wards from 7.9 to 1.5 per cent. Alvarez and Carlson suggest that the food neutralizes the acid of the gastric juice, and so protects the clot in the aperture of the bleeding vessel from digestion. Woldman points out that the optimum acidity for peptic digestion is between pH 2 and 3; about pH 5 the power of pepsin to digest protein disappears; and that blood clot placed in a test-tube with fresh gastric juice is protected from digestion by colloidal aluminium hydroxide, even at body temperature. This is the basis for the 'drip method' which he introduced, which aims at complete and continuous neutralization of gastric acidity. In 21 cases of gross hæmorrhage treated in this manner he was able to report complete recovery in every instance. Comparing his results with those of our series, it would appear that Woldman's method is to be preferred to oral administration in cases of peptic ulcer which present this complication.

**Group 4. Cases complicated by infection.**—The two cases in this group were very much alike. Both were in males in the fourth decade suffering from duodenal ulcer; one was complicated by chronic otitis media, the other by chronic pansinusitis. Aluminium hydroxide treatment over a period of months was unsuccessful in both instances. The experience with these two cases is in sharp contrast with the outcome in the preceding groups. It is well known that manifest infection of this type is a serious obstacle to healing, and calls for vigorous attention. In retrospect it seems that it was a mistake to attempt ambulatory treatment in these two cases, and that bed rest should have been advised, along with aluminium hydroxide administered by Woldman's 'drip method'.

#### DISCUSSION

The dosage of aluminium hydroxide used in these cases was either one or two drachms. Statistical examination shows that there is no advantage in the larger dose. It is difficult to generalize about the frequency of dosage. Thrice daily seems often enough to control symptoms and promote healing in some cases. In others it seems wise to begin with six doses a day, or even a dose every two hours. On the other hand there is an advantage in cutting down dosage as soon as the symptoms are under control, in order to avoid any tendency to constipation.

The difference in the properties of aluminium hydroxide and the readily soluble alkalies makes it important to consider the time of administration. The latter are commonly given about an hour after the meal, in order to control the peak of acidity. Aluminium hydroxide reacts rather slowly with acids, and much of its efficacy is lost if given an hour after food. Some of the patients discovered this fact for themselves, and preferred to take it immediately after eating. It is probably still better to give it half an hour before the meal, as advised by Kreis. Ivy has called attention to the fact that the aluminium combines with the gastric mucus to form a flaky precipitate, which adheres to the mucosa of the stomach and duodenum. A film of this nature would serve as a physical protection to the mucosa and exert an antacid action as well. Hence it seems logical that

the drug would have its best effect when given on an empty stomach.

No definite conclusion can be drawn from these cases as to the type of diet best given in conjunction with aluminium hydroxide, as failures were equally distributed between diets of the Sippy type, and the hospital 'bland' diet. It is fair to raise the question whether there is any need for diets of the Sippy type and the undernutrition incidental to their use, when the gastric secretion is modified by the presence of aluminium hydroxide.

From studies of the chemical composition of the blood it is clear that there is no tendency to alkalosis or nitrogen retention, such as sometimes follows the use of soluble alkalis. If alkalosis is already present the carbon dioxide combining power tends to fall towards normal. Bennett and Gill have been able to put this preparation to a more rigorous test than it received in our cases. They were able to give two ounces daily to a patient with renal failure, without increase in the alkali reserve.

In this series of cases the symptomatic effect of aluminium hydroxide has been highly satisfactory, and bears out the claims made for it in the literature. Its curative effect is probably measured fairly well by its value in relieving symptoms. If this is true it is fair to ask why so many patients state that they cannot give up its use, when they claim to be symptom-free. It is probable that fear accounts for the desire to continue its use. For this fear, of course, there is good basis, and occasional doses after dietary indiscretions or warning symptoms are probably of value in preventing relapse.

In this series there have been four definite failures in 38 cases (10.5 per cent). Einsel reported nine failures in 110 cases (8.1 per cent), while Jones reported one failure in a group of 24 cases (4 per cent). In the cases recorded as failures, symptomatic relief was usually not satisfactory from the first. It is possible that some of these would have responded better to Woldman's method. It seems reasonable to consider that cases which have severe symptoms and long histories, and cases with radiographic or other evidence of penetrating ulcers should be treated in this manner, as well as cases with severe hæmorrhage.

#### CONCLUSIONS

It seems justified to conclude that aluminium hydroxide offers many advantages over the older remedies in the treatment of peptic ulcer and that its properties are such as to call for reconsideration of the principles involved. Hitherto, conventional treatment has been based upon a regimen of small meals, frequent feedings, the use of absorbable alkalis to control acidity and of atropine to control secretion. Each of these measures has its disadvantage. There is good evidence that frequent feedings are an undesirable stimulus to gastric secretion, and that absorbable alkalis lead to 'rebound' acidity. It is fair to say that treatment by conventional methods has been a disagreeable ordeal, frequently made worse by hunger, deficiency states, and the symptoms of atropine poisoning.

It is evident that aluminium hydroxide has proved itself to be a highly effective antacid without danger of 'rebound' activity. Although it may be used in conjunction with frequent feedings, these are no longer required to control acidity, and one may safely dispense with them if sufficient hydroxide is given. There is evidence that the drug has a tendency to inhibit gastric secretion when given over a considerable time. Finally its use is compatible with the present-day tendency to give more generous meals during treatment.

#### Treatment of Infected Burns

By B. C. MURLESS, M.B., B.Ch., F.R.C.S. (Edin.),  
M.R.C.O.G.

(From the *Brit. Med. Journ.*, Vol. I, 13th January, 1940, p. 51)

THE literature on the treatment of burns is legion. A great number of publications followed the introduction

of the use of tannic acid by E. C. Davidson of the Henry Ford Hospital, Detroit, in 1925, which has revolutionized this branch of surgery. Many writers since have published modifications of the original technique described, with reports showing excellent results. It is therefore with some trepidation that I venture to add to a subject so extensively investigated. The tremendous increase of burns in war-time surgery may, however, render this short article of interest now, and the somewhat rare opportunity of treating and watching the progress of eighteen cases of severe burns from one of His Majesty's ships seems worth recording.

#### THE USE OF TANNIC ACID

The functions of tannic acid are twofold. First, in the early stages it prevents the absorption of toxins by combining with proteins and their metabolites to form a coagulum; and, secondly, the coagulum formed exercises a protective action. Suffering and shock are prevented by the protection of exposed nerve endings, but equally important is the effect of the coagulum in rendering the surface free from outside disturbance and guiding the growth of the new epithelium.

For practical purposes a burn may be considered like any flesh wound, healing proceeding most rapidly in the absence of bacterial infection. Such conditions are of course ideal for tannic acid treatment, the burnt area being rendered aseptic by cleaning before the tannic acid is applied. In war time the difficulties of thoroughly cleansing burns are many, and delay must often occur. Severe shock may contra-indicate anaesthesia or any active treatment; transport difficulties are bound to delay the arrival of cases at the theatre. Consequently, though they may have received preliminary treatment, many burns met with under war-time conditions must be of the septic variety, and it is with such cases that this article is concerned.

#### TANNIC ACID IN SEPTIC CASES

Burns which have been left for forty-eight hours or more may be considered septic, as no amount of treatment with ether or spirit will render them surgically clean. Difference of opinion exists as to the use of tannic acid in septic cases. Some surgeons prefer picric acid dressings unless the burn has been cleaned within forty-eight hours. Hamilton Bailey states that tannic acid treatment may be instituted as late as seventy-two hours. The cases reviewed here may help to support the contention that there is no time limit after which tannic acid treatment should be abandoned, and that good results may be obtained by its use where sepsis is fully established.

When applied to a septic surface tannic acid will form a coagulum more readily than on a surgically clean area. A crust soon dries which, if it stays in place and can be kept hard, will supply the rest and protection essential for the healing of the inflamed tissues beneath. Such treatment may be compared with that adopted by Winnett Orr for open fractures and by Dr. J. Trueta for infected wounds in Spain. The essential advantages of this method are that the surface remains undisturbed, the covering allowing epithelium to grow in from the edges, at the same time preventing the formation of fibrous tissue and piled-up granulations, which are nearly always seen when infected burns have been treated by constantly changed dressings. The speed of epithelization with such treatment is infinitely greater than when the surface is disturbed daily, and the saving of pain and discomfort to the patient beyond estimation.

#### PUS FORMATION

Pus will usually collect beneath the crust and may form in patches, or almost the whole crust may be slightly raised and fluctuation may be present. The usual teaching of removal of or incision into the coagulum under such circumstances was not adopted in these cases. If an expectant attitude is taken, within twelve hours the pus will always find its way out at some point. It may come through cracks in the coagulum, especially at joint flexures, or may ooze out

at the edges. After discharging for a short time suppuration will cease, and any part of the crust which has become softened may be resprayed with tannic acid and dried. Not unnaturally the smell during the suppurative phase is somewhat unpleasant, but it is not nearly so bad as that encountered in the closed treatment of infected fractures.

#### FEVER AND PAIN

Nearly all cases register a rise in temperature during this treatment. It may reach as high as 104°, but this should not cause undue anxiety, and should not be considered an indication for removal of the coagulum. In most cases the fever subsides in from two to three days.

The absence of pain during tannic acid treatment is well known to be remarkable, and the same fact applies when it is used for septic burns. Following the first application and drying little pain is experienced. A feeling of tenseness and heat sometimes exists for a few hours during the suppurative phase, before the pus has found its way through the coagulum, but this is soon relieved. The agonizing pain, for which anaesthesia may be necessary, when infected burns are treated by daily dressings is thus avoided, and the general condition of the patient will benefit accordingly.

#### USE OF ANTISEPTICS

When sepsis is established the use of antiseptics in combination with the tannic acid therapy cannot render the area aseptic. Any strong antiseptic is in fact contra-indicated, as it may produce further tissue damage and prevent healing. Weak solutions of dye substances may, however, be used with the object of preventing undue bacterial growth. For these cases the tannic acid was made up in flavine solution and used in conjunction with a weak solution of methylene-blue and brilliant-green. Healing was very rapid, and it is possible that these dyes also help by stimulating epithelial growth.

The danger of softening the coagulum by using a watery solution and setting free toxins, which is very real in some early cases, is not great where sepsis is present at the beginning of treatment. If, however, the electric drier is used after each application of the dye solution softening need not be anticipated.

#### DESCRIPTION OF CASES

Eighteen cases of severe burns from cordite explosions were treated in this series. All these patients were healthy men of ages varying between 18 and 40 years. In nearly all cases the hands and face were burnt. In order of severity the sites involved were: (1) dorsal surfaces of hands and forearm, (2) feet and legs, (3) face, (4) back and neck.

The degree of the burns is difficult to tabulate, as it varied in different cases and at different sites, but it may be stated that most of the men had a considerable area of second-degree burning. A fact that may be of some significance is that all had been immersed in a mixture of salt water and oil for periods varying from a half to one and a half hours. These cases were received in hospital 120 hours later after preliminary treatment in one of H.M. hospital ships. This treatment consisted of tannic acid and flavine dressings without previous cleansing under anaesthesia, which procedure was no doubt contra-indicated by the condition of the men at that time.

On admission the general condition of the patients was fair, considering what they had been through, and the danger of primary shock and toxæmia had passed. Many of them, however, were in a shocked state owing to pain and lack of sleep, and at first frequent injections of morphine had to be given. When the dressings were removed the burnt areas almost without exception were found to be septic, patches of tannic crust and solidified discharge coming off with the gauze and leaving a raw infected surface which was extremely tender. The burnt limbs were now laid on sterile towels and swabbed over with a solution of 5 per cent methylene-blue and 1 per cent brilliant-green. They

were next sprayed with a 20 per cent solution of tannic acid in 1 in 1,000 acriflavine, and the area dried with an electric hair-drier. No dressings of any sort were used. The tannic acid spraying and drying process was repeated three-hourly by day for the next forty-eight hours and the area occasionally dabbed with the dye mixture.

The crust which formed was sticky at first but soon became hard with the constant use of the drier. Great care was necessary at night to keep the burnt surface free from contact with bedclothes and towels, to which it would stick with consequent removal of the crust. The backs of the legs, the front of the wrists, the neck, and the back were troublesome in this respect, and these surfaces usually took longer than the average time to heal. The use of bed cradles and the slinging of limbs with bandages were found very helpful in avoiding this contact. A thick hard crust coloured blue by the dye was successfully formed on most surfaces. In the majority of cases pus collected below the covering and dripped from its edges or from cracks at the flexures. In no case was the crust incised to evacuate pus, but further applications of tannic acid were occasionally employed to harden patches where it had become softened.

Fever was present in all cases, the swinging temperature sometimes reaching a high level at first but always settling in a few days. Most of the severest burns were on the dorsal surface of the hand and fingers. Daily movement of the fingers was found sufficient to prevent them adhering to each other, as the usual practice of separating them with gauze was not adopted.

#### HEALING

From periods of five days onwards the crust begins to peel or break off at the edges. As soon as sufficient crust had come off, active and passive flexion of the finger-joints was started. Special attention should be given to the metacarpo-phalangeal joint, over which the new epithelium is always rather tight.

The edge of the crust as it receded was treated with the dye mixture till only a small central area was left. The patients seemed sorely tempted to pick off the edges of the crust as healing took place, a procedure which sometimes resulted in reinfection and delay in the date of their discharge. The time of healing in infected cases is considerably reduced by this method of treatment. Evidence of pus and raised temperatures disappeared in an average of three days. In most cases only a small scab of crust remained in the centre of the burn after twenty-one days, and the patients were ready for discharge. When the surface is constantly disturbed by the application of dressings the healing time is greatly prolonged. This point is well demonstrated in one case in which in the early stages of treatment additional dressings of flavine were used on the back of one hand. The crust was disturbed by removal of the gauze, and finally a Thiersch graft was necessitated by excessive granulations and delayed epithelization. Healing of this hand was not complete in five weeks from the beginning of treatment. It seems certain this would not have occurred had the surface been left to heal under the crust, as the other hand, which was just as badly burnt and which was not dressed with gauze, was fully healed, with almost full movements, in twenty-three days.

After the crust is off, the new skin, which is delicate and sometimes rather tender, is treated with sterile petroleum jelly daily. Passive stretching of the skin by flexion of the fingers was persisted with by the patients themselves until full movement was obtained. No form of splinting was used in any of these cases.

#### RESULTS

Of the eighteen patients treated one died of bronchopneumonia. It seems surprising that others did not develop chest complications, in view of the period spent in the sea. With the exception of one case, mentioned above, in which a skin graft was necessary, the remaining sixteen cases were ready for discharge within twenty-one days.

All these men were severely burnt and the burnt areas were septic on admission. Full movements at all joints were present on discharge and there were no contractures. Absence of scarring of face and hands was remarkable, and almost the only evidence of their burns was the appearance of the finger-nails.

#### CONCLUSIONS

The treatment by tannic acid and dye therapy of eighteen cases of severe septic burns has been described.

Tannic acid treatment has not failed when sepsis is established. Pus formation is not an indication for removal of the coagulum, and incisions into it are seldom, if ever, necessary.

The speed of healing is greatly impeded if the coagulum softens and comes off and gauze dressings have to be used.

Satisfactory final results were obtained. Absence of scarring and contractures was noteworthy. In burns affecting the hands normal movements and function were obtained in sixteen out of eighteen cases.

### The Prescription of Aspirin

(From the *Lancet*, Vol. I, 10th February, 1940, p. 278)

It is not uncommon for practitioners to prescribe aspirin in a suspension of mucilage and tincture of orange in preference to the more general tablet form. There has always been some little doubt whether patients should leave the bottle on the shelf indefinitely and expect the same results as are obtained from

the freshly-dispensed mixture. Tomski and Waller (*Pharmaceut. J.*, Jan. 27, 1910, p. 53) show that these doubts are not without foundation. They find that if acetylsalicylic acid (3 per cent) is dissolved in 50 per cent alcohol and kept under ordinary laboratory conditions it decomposes at the rate of about 1.5 per cent in a day, 6.0 to 6.5 per cent in a week and 13.5 to 14.5 per cent in a month, liberating salicylic acid which is a gastric irritant. They also find that a suspension of the same strength kept under the same conditions loses 0.3 per cent in a day, 1.6 to 2.0 per cent in a week and 7.0 to 8.0 per cent in a month. Their conclusion is that suspensions should be prescribed in preference to solutions in alcohol. The following prescription is a useful one:—

R. Acid. acetylsalicyl.	..	..	gr. 80
Pulv. trag. co.	..	..	gr. 40
Syr. limonis	..	..	ʒi
Aq. chlorof. ad	..	..	ʒviii
Sig. ʒfs S.O.S.			

This mixture will keep fairly well, but should be made up freshly if it is to give its maximum effect and be as little irritating as possible. Syrup of lemon is suggested because of the temporary scarcity of orange peel for the manufacture of orange preparations which, by the way, the Minister of Supply has included under 'non-essential medicines'. On the question of solutions of aspirin prepared with ammonium acetate or potassium citrate Tomski and Waller point out that the loss due to decomposition has long been established; thus the Natural Formulary recipe for 'mist. acid. acetylsal' is not to be commended.

## Reviews

**A TEXTBOOK OF X-RAY DIAGNOSIS.**—By British authors. (In three volumes.) Edited by S. C. Shanks, M.D., M.R.C.P., F.F.R., P. Kerley, M.D., M.R.C.P., F.F.R., D.M.R.E., and E. W. Twining, M.R.C.S., M.R.C.P., F.F.R., D.M.R.E. Volume III. 1939. H. K. Lewis and Company, Limited, London. Pp. xiv plus 800, with 710 illustrations. Price, £3 3s.

THE circumstance which has led to the appearance of the third editor's name on the dedication page is a sad blow to British radiology, for at the time of his death Edward Wing Twining was in the prime of life and one had a right to expect many more years of useful service from him. He however played an important part in the preparation of this volume which was in its final stages at the time of his death.

This third volume, which is by far the largest of the three, is devoted almost entirely to bones, for, though the first two hundred pages are headed 'the central nervous system', the bony supports of the brain and spinal cord loom so large in the pathology of these structures that the generalization is still more or less true. Additional methods of investigating brain tumours and other pathological processes, such as ventriculography and encephalography, alone or combined with angiography have passed out of the stage of being dangerous procedures only conducted by one or two specialists to become the routine examinations in certain conditions: this whole section is very ably written by Hugh Cairns and M. H. Tupe.

The next part is on the accessory nasal sinuses and mastoid processes. This is a branch in which considerable advances have been made in recent years, aided largely by the great precision of the apparatus available.

Part III is on bones, joints and soft tissues and occupies about two-thirds of the book and there are no less than twelve contributors including the two editors. This part is of course divided into a number of sections; of these the first is a very useful one on

normal structures, which we recommend the practitioner to study very carefully so that he is not misled by the inexperienced radiologist who has a flair for mis-interpretation and who so frequently fails to take a skiagram of the good limb for comparison. The last section, on localizations of foreign bodies, is one that is likely to be referred to very frequently during the next year or so. It is a subject in which considerable advances have been made since the last war.

The last three parts are all short ones, on the teeth and jaws, on the eye, and on cineradiography.

The third volume completes this very important work. It is a book that is not written primarily for the radiologist, though one hopes that every radiologist in the country possesses one, but for the physician and the surgeon. We cannot emphasize too strongly the importance of the physician and surgeon reading his own skiagrams and making his own interpretations, in which one hopes he will be guided by the radiologist. Physical examination has its limitations and these are fully recognized: radiography also has its limitations, but there are many radiologists who are loth to recognize this fact. The physician and surgeon can only hope to avoid becoming radiologist-ridden by learning to interpret their own skiagrams, and we know of no work that will help them to do this better than the three volumes of this excellent textbook.

**HUMAN HELMINTHOLOGY: A MANUAL FOR PHYSICIANS, SANITARIANS AND MEDICAL ZOOLOGISTS.**—By Ernest Carroll Faust, A.B., M.A., Ph.D. Second Edition. 1939. Henry Kimpton, London. Pp. 780. Illustrated with 302 engravings. Price, 40s.

NINE YEARS have elapsed between the appearance of the first and second editions of this book, and during this interval there have been many advances in our knowledge of helminthology as applied to human beings, and most of these have been incorporated in the new edition. This applies, among other conditions,

# Confidence in Antisepsis

THE high germicidal efficiency of 'Dettol' with its safety and convenience, have won for it a leading position in hospitals and private practice, and make it a most useful disinfectant for first aid at home, for personal hygiene, and for gargling and bathing.

'Dettol' maintains its efficiency in the presence of blood and other organic matter, and can be used in high concentration, thus giving a wider margin of safety.

It is absolutely non-poisonous and non-staining, and possesses a distinctly pleasant smell.

# A HANDBOOK ON DIABETES MELLITUS and ITS MODERN TREATMENT

By  
J. P. BOSE, M.B. (Cal.), F.C.S. (Lond.)

Third Edition

Thoroughly Revised, partly re-written and brought up to date with a new chapter.

Price Rs. 7-8.

Contents.—Antiquity of diabetes—Insulin and its later modifications—Incidence of diabetes and mortality and some of the common etiological factors—Carbohydrate metabolism—Pathology of diabetes—Symptoms of diabetes—Diagnosis of diabetes mellitus—Blood sugar and blood lipoids—Principles of dietetics and their application in the treatment of diabetes—Insulin treatment—Some of the dangers and complications of diabetes and their treatment—Diabetes in children—Glycosuria and life insurance—Author's simplified method for estimation of sugar in blood—Examination of urine—Protamine zinc insulin—Tables of food values and average weight, etc.—General index.

## THACKER SPINK, CALCUTTA

especially to strongyloides infection and creeping eruption.

For the most part the figures are the same but about twenty have been added, fifteen altered or modified, and six or seven omitted. Advantage, in substituting newer and more accurate figures, has not always been taken, however.

In nomenclature we are pleased to note that the list headed 'Names of parasitic helminths of man and pathological designations for infections with these parasites' has been to some extent modified and every infection is not now invariably named after the generic name of the worm with the affix 'iasis' followed by the specific name. But we note that this modification has not been carried as far as we consider it might have been, for instance in the first edition 'Heterophyiasis heterophyes' and 'Heterophyiasis katuradi' both appeared and they are replaced in the new edition by 'Heterophyes infection' for both of them, this is all to the good, but then we note 'Hymenolepiasis diminuta' and 'Hymenolepiasis nana' still appear in the new edition. Such inconsistencies can be indefinitely multiplied if the two lists are compared closely. We regret that the author, having withdrawn some of the absurd names he concocted for his first edition, did not complete the purge and slaughter them all in the second edition.

There are a few spot maps showing the world distribution of certain important worm infections. Such maps, unless they are accurate, are better omitted, otherwise they will lead astray the inexperienced, with perhaps serious results. A glaring example is that in the distribution of *Echinococcus granulosus*, India is shown as free from this infection. The map was wrong in the first edition and has been reproduced in the second.

We are glad to see that the names *Fulleborniidae* and *Fullebornius* have been dropped and the old names *Dracunculidae* and *Dracunculus* re-established.

There is a new chapter on anthelmintics in general with a fairly detailed description of all the important drugs in this class. This, like all summaries, contains many dogmatic statements that are open to objection if the full facts are known, and are therefore likely to be somewhat misleading to the inexperienced. Apart from the danger of some of the remarks misleading the tyro it seems redundant because the description of each type of infection contains a paragraph on 'Therapeutics' which gives the best specific treatment available.

The book is a very useful reference book particularly for the specialist in helminthology, but as such its value could be greatly enhanced by correction of errors, some of which have been referred to above. But the cost is high and makes it a luxury for the general practitioner who is only called upon to treat worm diseases as a small part of his work even in countries where this type of infection is prevalent. Such a book as 'Clinical Parasitology' by the author of the volume under review in collaboration with Craig is much better value for the general practitioner because it contains all the essentials in 'Human Helminthology', with protozoology and entomology of medical interest as well.

P. A. M.

**STEDMAN'S PRACTICAL MEDICAL DICTIONARY.**—By Thomas L. Stedman, A.M., M.D., and Stanley Thomas Garber, B.S., M.D. Fourteenth Revised Edition. With Etymologic and Orthographic Rules. 1939. Baillière, Tindall and Cox, London. Pp. xii plus 1303, with 23 plates and numerous illustrations. Price, 37s. 6d.

To the shame of British medical publishing houses, the medical profession in the British Empire has to rely on American medical dictionaries. For the average medical reader, and writer, in Great Britain this is not so serious, as he is usually able to distinguish American spellings and, we hope, to avoid them, for the colonial and 'Empire' reader it is much more serious, as he is often less familiar with the English language and is much more easily led astray, but for

the editor of an English journal published outside Great Britain the circumstance is a tragedy, as he has to spend half his time changing 'hemoglobin' into 'hæmoglobin' and 'sulfate' into 'sulphate', until he finds he has swung the pendulum too far, so that he has to reinstate 'hemiplegia' which his over-enthusiastic staff had changed into 'hæmiplegia'.

In the circumstances, we must be very thankful to American publishers that we have any medical dictionaries at all in the English, or near-English, language, and we certainly owe a special debt of gratitude to Dr. Stedman, who died on 27th May, 1938, at the age of 84; at the time he was actively engaged in preparing the fourteenth edition of this excellent dictionary.

Dr. Stedman wasn't just content to make a comprehensive dictionary; he had a weakness for etymology and one of his avowed objects was the purification of medical etymology. He certainly achieved a degree of 'purification' and apparently this was sufficient to satisfy him for in the eleventh edition of his dictionary he claimed that his purpose had 'been nearly attained'. One of his greatest triumphs was the restoration by the final 'e' to the alkaloids and chemical bases, to distinguish these from glucosides, in the *Journal of the American Medical Association*, and the transformation of the offensive 'k' to the correct 'c' in words derived from the Greek, e.g., *ancylostoma* and *leucæmia*. We cannot help feeling that Dr. Stedman's life must have been a difficult one or his powers of rationalization particularly well developed to be able to strain at such gnats and yet swallow the whole corps of camels that the American language provides.

He explains that the Greek diphthongs *ae* and *oi* become *a* and *o* in Latin and the same, or simply *e*, in English. It is a pity that he hadn't a little more to say on this last point; we should like to have heard how he justified the American practice. Nevertheless, Dr. Stedman with the limitations of his American loyalties was a great scholar, has served medical literature well, and will be missed.

The present volume was largely prepared under his direction. It is well up to the standard of its predecessors. A pleasing innovation is the reproduction in English of the Hippocratic oath as a frontispiece.

**CHRONIC ARTHRITIS.**—By Robert T. Monroe, A.B., M.D. (Reprinted from Oxford Loose-Leaf Medicine). Edited by H. A. Christian, A.M., M.D., LL.D., Sc.D. (Hons.), F.R.C.P. (Hon.). 1939. Oxford University Press, New York and London. Pp. vii plus 84. Price, 8s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

This is a small handbook on the subject of chronic arthritis written by the author primarily for the Oxford Loose-Leaf Medicine from which it has been reprinted. It begins with a foreword written by Dr. Henry A. Christian who considers that as the proportion of older people are increasing the incidence of diseases of the joints is also going up. After describing briefly the anatomy and physiology of joints and their various architectural units, the author has put forward a very simple classification based on structure rather than on etiology. He calls the diseases of the synovia, which are also known as rheumatoid arthritis, atrophic arthritis owing to the prevalence of atrophy and asthenia in such conditions. Diseases of the joint cartilages, which are known as osteoarthritis, have been classed as hypertrophic arthritis and the diseases of the extra-articular supporting tissues as periarticular fibrositis. In dealing with these three types of arthritis the author has traversed a wide field by discussing the relative merits of the different factors in an unbiased manner. For instance, while not overlooking the part played by infective foci in the etiology of atrophic arthritis he has not been a blind faddist but has always kept an open mind. His remark that too many teeth have been sacrificed in the name of infective etiology is very wise. While infection plays an important rôle in the causation of atrophic arthritis the former, according to the author, has no direct bearing on the

hypertrophic type where trauma is the most important etiological factor. The description of the clinical features of the different types of arthritis will be read by everybody with interest and the subject of their management and treatment will be found most comprehensive and of much practical value.

In this connection, the writer has very pertinently commented on the use of some of the drugs and this should be a check to their irrational and indiscriminate use. He goes on to say 'it is fruitless to review the amazingly long list of antirheumatic remedies. Some show ingenuity, as bee venom, histamine and cholin iontophoresis and chaulmoogra oil; others are thoughtlessly conceived as pills of concentrated spinach; many are improper combinations of sedatives, salicylates, laxatives and potentially harmful drugs. They flourish on the gambling spirit of people, who are glad to try their luck on escaping the difficult programme that nature eventually enforces'.

The whole subject has been presented in such a simple and practical manner that this book will be found extremely useful to every practitioner, each and every one of whom has frequently to deal with patients afflicted with this very chronic and painful malady.

M. N. D.

**THE SYNOVIAL MEMBRANE AND THE SYNOVIAL FLUID WITH SPECIAL REFERENCE TO ARTHRITIS AND INJURIES OF THE JOINTS.—By David H. Kling, M.D. Baillière, Tindall and Cox, London. Pp. 283, with 80 illustrations and 34 tables. Price, 25s.**

THIS monograph is based upon the findings of a large amount of original research conducted by the author over a period of fifteen years. His work proves that the old theories regarding the structure and function of the synovial membrane, and the origin and function of the synovial fluid, are inadequate.

A proper study of the synovial membrane reveals that it is not a simple structure throughout; it contains secretory elements in certain areas. These areas produce the normal synovial fluid, which consists chiefly of mucin, by active secretion. This would seem to dispose of the theories which seek to account for the presence of mucin by calling it the interstitial tissue of the synovial cells, produced by their degeneration.

In pathological conditions, effusions consist of the mucin produced by the activity of the secreting cells and also of a transudate or exudate derived, *via* the synovial membrane, from the circulation. There is thus ascribed to the synovial membrane a dual structure and function, and to the fluid a dual origin.

Much of the book is taken up by descriptions of experimental technique and results, and tables of data and other findings. The concluding chapters indicate the clinical applications of all this work, and the reader will find suggestions for routine biochemical and microscopical investigation of joint effusions.

A thoughtful and painstaking book, it is recommended to those interested in the problems of joint conditions, both medical and surgical.

W. McN. N.

**MYTHOLOGY OF THE SOUL: A RESEARCH INTO THE UNCONSCIOUS FROM SCHIZOPHRENIC DREAMS AND DRAWINGS.—By H. G. Baynes, M.B., B.C. (Cantab.). Baillière, Tindall and Cox, London. Pp. xii plus 939. Illustrated. Price, 32s. 6d.**

In his preface the author maintains, and perhaps rightly, that the type of mental disorder now labelled 'Schizophrenia' lies at the very roots of the psyche. Hence, to investigate it, only an introverting psychological method is suitable. The author regards Jung's analytical method as set forth in his 'Psychology of Dementia Præcox' to be the only effective introverting technique in western Europe. To all who have been appalled by the seemingly insoluble riddle of the schizophrenic's mind, the author's view that psychology as a science is deeply bound up with the history of

civilization, of philosophy and of religion and, above all, with primitive mentality, will make a strong appeal. This is also Jung's view. The basic feature of this remarkable book is the study of two patients of the author, one of whom was himself a doctor. The other patient was by profession a draughtsman. Both patients were psychoanalysed but in addition to this, both were encouraged to draw whatever came into their minds. With the exception of the reproduction of three paintings by Paul Klee, a reproduction of the *Lamaist Vajra-Mandala*, and the *Muladhara Chakra* from Avalon's *Serpent Power*, the 53 illustrations are all pictures drawn by the author's two patients. The author is by no means the first individual to trace out the inner experiences of schizophrenics and the same order of experiences in primitive races. Long before the advent of psychoanalysis psychologists were aware of the unexpected light which a study of early psychic stages in evolutionary development threw upon the study of dreams and functional disturbances of thought. The present work goes a long way to confirm the hypothesis that the abnormal process is a primitive process. An ardent disciple of Jung, the author would appear to think that the transformation of the libido as conceived by Jung is sufficient to explain all archaic beliefs, myths, fairy tales and the like. In everyone of the magic archaic experiences are present as the undercurrent of the waking thoughts of the day, but only in specifically schizophrenic types does this undercurrent come to active conflict with the ordinary thoughts of the understanding. In schizophrenia it is more especially the initial states which really bring these archaic magic experiences to flower. The biological revolution of puberty often forces the disease to its first manifestation. In this period of life experiences take place which may plunge the human being into a shoreless maelstrom of uncertainty. Whether to follow his enthusiastic impulses and give himself freely to the world or to withdraw gloomily into the self. This and much more the author describes with meticulous precision. Every student of psychology in any of its branches cannot fail to profit by a study of the fascinating material presented to his inspection.

O. B.-H.

**THE ANATOMY OF THE HUMAN SKELETON.—By J. Ernest Frazer, D.Sc. (Lond.), F.R.C.S. (Eng.). Fourth Edition. 1940. J. and A. Churchill, Limited, London. Pp. viii plus 300, with 219 illustrations, many in colour. Price, 30s.**

THE reason given by the author for the production of the fourth edition of this book is that the modifications in terminology had not been finally decided upon when the third edition was published. In addition, however, certain changes and corrections have been incorporated.

This is not a simple description of the bones such as one is accustomed to find in the typical textbook of anatomy, for although the bones naturally form the basic structure of the book, as they do of the human body, their description is amplified by a full discussion of all the structures with which they come into relation as well as the sites of attachment of muscles, ligaments, etc. The descriptions are clarified by numerous black-and-white drawings and coloured plates in which the various areas on the bones are marked in special colours indicating the attachment of special structures, for example, brown for muscles, blue for synovial membranes, yellow for ligaments and so on. Once this colour scheme has been understood the reader can see at a glance what functions different parts of a bone perform.

It is a book that would be useful for a student, to give him a wider insight into the true function of the skeleton than he is likely to acquire from the ordinary textbook, but we doubt if there are many students who can afford another thirty shillings (twenty rupees) on a book that can never replace but only act as an adjuvant to the standard anatomy he must possess.

## CREMAFFIN

(Cream of Magnesia with Liquid Paraffin)

A pleasantly flavoured emulsion free from any oily taste. Cremaffin is an ideal antacid and gentle laxative.

### CREAM OF MAGNESIA WAFERS

Each wafer contains the equivalent of one teaspoonful of Regesan Cream of Magnesia.

## BURNOL

A creamy emulsion containing 0.1% of the powerful non-toxic antiseptic Neutral Acriflavine presented in handy collapsible tubes ready for immediate application.

BURNOL has given excellent results in the treatment of burns and scalds, tropical sores, tinea infections, Dhobie itch, insect bites, minor injuries, ophthalmia of all types, suppurating wounds, and septic conditions generally.

# From ENGLISH MEADOWS

A WEST OF ENGLAND PASTURE

*Farmer & Stockbreeder*

Cow & Gate Milk Food is made by special processes from the milk of the world-famed pasture lands of the West of England. The most modern and scientific methods are applied to every stage of its preparation, so that the valuable and exceptional nourishment of the purest and richest milk is available in *easily digestible* and *absolutely safe* form.

This English Food from English meadows with its wholesome nutrition has brought a great deal of happiness to mothers in India. Firm flesh without flabbiness, sound well-defined bones, and the smile of Health and Happiness—these are some of its attributes. Richest of all in Vitamin D (250/300 International Units per pint of milk). *It is not repacked in India.*

**"THE BEST MILK FOR BABIES WHEN NATURAL FEEDING FAILS"**

Distributing Agents : Carr & Co., Ltd., Wittet Road, Ballard Estate, Bombay,  
also at Calcutta, Karachi and Madras.

**THE CARE OF YOUNG BABIES.**—By John Gibbons, M.B. (Cambridge), M.R.C.P. (Lond.). 1940. J. and A. Churchill, Limited, London. Pp. ix plus 169, with 8 plates and 5 text-figures. Price, 3s. 6d.

MANY books on the subject of the rearing of infants have been produced in recent years: some good; some indifferent.

This little book is not only in the former category, but is in the highest class, and the author is to be congratulated on the extremely good advice he has laid down for mothers in language which is easily understandable to the lay mind, for the book is in no sense of the word, a medical one per se.

Dr. Gibbons makes reference to many of the 'old wives tales' which were in vogue during the latter part of the last century and the beginning of this one, and disposes of them, in many cases, misleadingly with logical arguments.

He makes reference to the fond grandmamma who so often upsets the careful routine laid down for the infant.

He cites instances where good advice has been flouted, with such firmness, that one may be excused for believing that he would like to have added to the Litany, 'From the stupidity of some mothers, Good Lord deliver us'.

This is a truly excellent booklet which every mother can read with advantage.

**ILLUSTRATIONS OF BANDAGING AND FIRST-AID.**—Compiled by Lois Oakes, S.R.N., D.N. (Leeds and Lond.). 1940. E. and S. Livingstone, Edinburgh. Pp. vii plus 248. Illustrated with 290 photographs. Price, 6s. Postage, 6d.

'It is the aim of this book to enable the student, by means of pictures, to quickly master (Oh, Lois!) the science and art of bandaging and first-aid in fractures and hæmorrhages'. 'For the sake of clarity the operator is not always shown in the position that he would normally occupy in relation to the patient, and, for the same reason, not always holding the bandage exactly as it would be held in the natural circumstances'. We've got you, and the idea is a very sound one, but 'for the sake of clarity' it might have been expressed rather differently.

These two sentences will, we hope, give the reader a line on the scope of the book and on the weakness of the writer's literary style, but we do not honestly think that the latter matters. The photographs are excellent, and, even if a large percentage of the explanatory sentences contain unattached participles, the meanings of such sentences as 'note that the ears are covered up, in applying this bandage' are really quite clear.

There are four sections, triangular bandaging, roller bandaging, first-aid in hæmorrhage, and first-aid in fractures.

It is a book that will be useful to the doctor, the student, the nurse and the 'first-aider', and all those that have to teach them.

**TEXTBOOK OF PUBLIC HEALTH.**—By W. M. Frazer, O.B.E., M.D., Ch.B., M.Sc., D.P.H., and C. O. Stallybrass, M.D. (State Medicine), Ch.B., D.P.H., M.R.C.S., L.R.C.P., Order of St. Sava. Tenth Edition. 1940. E. and S. Livingstone, Edinburgh. Pp. x plus 504. Illustrated. Price, 21s. Postage, 7d.

This tenth edition is practically a new text. It accomplishes fully its stated objective of covering the information required by examining bodies for the English D.P.H. A mine of information has been compressed within the 500 pages. The text possesses the great advantage of having been compiled by authors who are both teachers of a university and at the same time are practitioners of public health administration. It is of interest to note that this textbook began its career in 1874 as 'Medical Police' with subsequent evolution of its title through 'Forensic Medicine and Public Health' to 'Public Health' alone, reflecting the trend of practice. The full accounts provided of the

recently consolidated Public Health (1936), Housing (1936) and Food and Drugs (1938) Acts will be found particularly useful. The chapters on Genetics and Mental Hygiene are somewhat superficial and lack practical indication of their specific utilizability in administration. Also the advice as to site and construction of hospitals, particularly isolation, is not in line with present epidemiological knowledge but conforms to legal requirements that lag very badly in this respect. One trusts that the concluding chapter on Medical Aspects of Civil Air Defence may be required no longer 70 years hence in a textbook of Public Health. Technical description of types of bombs and their action indicates the queer twist given to the trend of public health by world conditions.

The tenth edition can be heartily recommended to anyone desirous of reference to English public health practice. Its value in India lies in furnishing basic information, particularly with respect to the impersonal public health services. In its personal public health, the absence of consideration of particular problems of rural public health would be considered the chief drawback under local conditions.

**BENIGN LYMPHOCYTIC MENINGITIS: (ACUTE ASEPTIC MENINGITIS).**—By Rustom Jal Vakil, M.D. (Lond.), M.R.C.P. (Lond.), D.T.M. & H. (Lond.), F.R.F.P.S.G. 1939. Printed by V. V. Bamardekar at the India Printing Works, Fort, Bombay. Sole Agents:—The Popular Book Depot, Grant Road, Bombay 7. Pp. viii plus 94

This small handbook contains a summary of the work done and clinical features and diagnosis of that little-understood condition acute aseptic meningitis which is also known as benign lymphocytic meningitis. The general medical profession, particularly in India, is not at all familiar with this condition and it is generally labelled as meningism, poliomyelitis, tuberculous meningitis or encephalopathy due to various diseases. A comprehensive description of the disease will therefore be welcome to the profession. The author states that benign lymphocytic meningitis is a definite disease of the central nervous system involving the meninges and is caused by a filter-passing virus which has been identified and isolated. In the blood of infected person and experimentally-inoculated animals, antibodies develop and the demonstration of the latter by protection experiments constitutes an important test for diagnosis of the condition. The writer lays emphasis on the confusion which this condition often causes in the diagnosis, particularly of tuberculous meningitis and he has therefore devoted a special chapter to this subject. He says that while tuberculous meningitis is uniformly fatal, benign lymphocytic meningitis has always a favourable prognosis. At the end of the book, there are records of five English cases and two Indian cases. A very exhaustive bibliography is also appended and this will be of great help to anybody who may be interested in the disease.

The two Indian cases reported by the author are not very convincing and certainly one of them has been diagnosed purely on clinical grounds even without the help of the lumbar puncture. In this respect Dr. Vakil cannot be considered to have escaped the errors of a general practitioner although, of course, he has suggested benign lymphocytic meningitis.

The book is an excellent critical review of benign lymphocytic meningitis and should be read by every practitioner in India.

M. N. D.

**HYGIENE FOR NURSES.**—By John Guy, M.D., D.P.H. (Camb.), F.R.F.P. & S. (Glas.), F.R.C.P. (Edn.), and G. J. I. Linklater, O.B.E., M.D., D.P.H., D.T.M. & H., M.R.C.P. (Edin.). Fifth Edition. 1940. E. and S. Livingstone, Edinburgh. Pp. xlii plus 239. Illustrated. Price, 5s. Postage, 5d.

This subject is too often rendered dull and tedious to nurses by much superfluous subject-matter. The

authors have avoided this pitfall, and the book makes interesting reading, besides supplying all the knowledge that the nurse in training requires for practical purposes and examination, in hygiene and dietetics.

**HEALTH BULLETIN, NO. 14. MALARIA BUREAU, NO. 6. 'HOW TO DO A MALARIA SURVEY.'**—By Colonel Sir S. R. Christophers, F.R.S., I.M.S. (Retd.), Lieut.-Colonel J. A. Sinton, M.D., D.Sc., I.M.S. (Retd.), and Lieut.-Colonel G. Covell, M.D., D.P.H., I.M.S. Fourth Edition revised by Lieut.-Colonel G. Covell, I.M.S., Director, Malaria Institute of India. 1939. Published by Manager of Publications, Delhi. Pp. vi plus 208. Illustrated. Price, Re. 1-12 or 2s. 6d.

THIS was one of the earliest publications of the Malaria Survey of India. It has proved invaluable to malariologists in India and abroad. The present, the fourth edition, has been revised by Colonel Covell.

It is well illustrated by line drawings throughout and there are invaluable tips to help the malarial surveyor not only to carry out the various procedures but to do them rapidly and accurately.

It is a low-priced publication and every malariologist in India should possess a copy.

**HEALTH BULLETIN NO. 6. MALARIA BUREAU NO. 1. 'LECTURES ON MALARIA.'**—By Lieut.-Colonel G. Covell, M.D., D.P.H., I.M.S. 1940. Published by the Manager of Publications, Delhi. Pp. 33. Price, As. 5 or 6d.

THERE appears to be a real need for a bulletin containing rather more detailed information regarding malaria, to meet the requirements of officials and others who are not necessarily medical men, but whose duties constantly bring them into contact with the manifestations of the disease, such as engineers, forest officers, members of the Indian Civil Service, officers of the defence services, railway officers, managers of tea, coffee and rubber estates and of other industrial concerns. Although such individuals may already possess some knowledge of the basic facts concerning malaria, this is often incomplete, and they are usually most anxious to learn more about the subject.

The lectures included in this bulletin are designed to afford the type of information likely to be most generally useful in the above-mentioned circumstances, and to supply answers to the questions which experience has shown are most frequently asked.

Though not primarily written for the medical man, there are few doctors who will not learn a great deal from these lectures. They are both encouraging and inspiring. We recommend them very strongly to the general medical reader as well as to the malariologist.

**MEDICAL RESEARCH COUNCIL. SPECIAL REPORT SERIES, NO. 235. 'THE CHEMICAL COMPOSITION OF FOODS.'**—By R. A. McCance and E. M. Widdowson. 1940. Published by His Majesty's Stationery Office, London. Pp. 150. Price, 4s.

THE nutritional and dietetic treatment of disease, as well as research into problems of human nutrition, demand an exact knowledge of the chemical composition of food. The pioneering investigations into food chemistry were made in Germany and the United States of America, and until after the war of 1914-18 this country lagged far behind. The researches on vitamins which began to make rapid progress soon after the war, and in which this country played a leading part, stimulated a demand for a wider knowledge about human foods. Accordingly, when Dr. McCance approached the Council for support in order that he might determine, in the first instance, the amount of carbohydrate in foods used in the treatment of diabetes, it was recognized that the project was likely to have practical importance, and a grant was made for work along these lines at King's College Hospital, London. For twelve years the Council have continued to support similar and related studies by Dr. McCance and his colleagues, first at King's College Hospital and latterly

at the Department of Medicine, University of Cambridge; and during that time the investigators have gradually extended the scope of their inquiries. A system of analysis has been evolved by which they have determined all the important organic and mineral constituents of foods, with the exception of the vitamins, which have formed the subjects of extensive research by other workers and by different methods. Some idea of the amount of detailed analytical work involved in these chemical studies may be gathered from the statement that as many as twenty different constituents may require to be determined in a single foodstuff.

This systematized analytical procedure has now been applied by Dr. McCance and his colleagues to almost all the foods commonly eaten in Great Britain. The method of approach has been somewhat different from that of previous workers in the same field; for the foods have been analysed, not only in the raw state, but also as prepared for the table, and studies have been made of the losses introduced by cooking. The investigators have also examined the question whether all the constituents of a food are really available for the body's use; whether they are decomposed in the alimentary canal, or fail to be absorbed. Some of the analytical data have already appeared in earlier reports in this series, and the present volume includes previously published figures—which have been carefully checked and corrected where necessary—as well as many others which are new. It should thus contain all the quantitative data likely to be required for practical work involving detailed knowledge of the chemical composition of British foods. It cannot, however, be regarded as completely superseding the three previous reports, for the latter contained much information which has not been reprinted.

An unusual feature in this report is the inclusion of about one hundred recipes of common English dishes, including both the ingredients and a short description of how they are prepared. This will serve the double purpose of helping the physician to calculate the value of a diet of which these mixed dishes form a part, or conversely of helping the nurse or patient to work out an appetizing diet along the lines prescribed by the physician. These recipes are cleverly selected from standard cookery books by Miss C. M. Verdon-Roe.

It is a book which will be of very great value to the Indian worker, particularly if he uses it in conjunction with his *Health Bulletin No. 23* which supplies the analyses of foods that are peculiarly Indian in origin.

## Abstracts from Reports

### ANNUAL REPORT OF THE MYSORE STATE DEPARTMENT OF PUBLIC HEALTH FOR 1938.

EXCEPT for a rise in the incidence of plague, public health was generally satisfactory. Five thousand, one hundred and ninety-six deaths from plague were reported during the year against 4,812 in the previous year. In connection with the control of plague, in addition to the anti-plague inoculation and disinfection of houses, cyano-gas fumigation was recommended for adoption in various places. Six thousand, two hundred and eighty-four houses were cyano-gassed, 2,874 in the Kolar Gold Field Sanitary Board area, 100 in the Bangalore City and 3,310 in other places. Eight hundred and eighty deaths from cholera occurred during the year against 4,239 in the previous year. During the year, 789 deaths from smallpox were reported against 1,095 in the previous year. The number of vaccinations was 250,780.

The revised system of registration and compilation of the statistics of births, deaths and marriages introduced in Bangalore and Mysore cities and on the Kolar gold fields and the districts of Bangalore and Shimoga have given good results.

# WHY AGAROL FOR CONSTIPATION ?

Among the therapeutic measures advocated for overcoming constipation, none has proved more consistently successful than AGAROL—the original emulsion of mineral oil and agar-agar with phenolphthalein.

Agarol renders the faecal mass plastic and pliable with unabsorbable moisture. It lubricates the intestinal

tract and gently stimulates peristalsis, ensuring an easy and complete evacuation.

Used over a reasonable period, Agarol gradually restores muscular tone and functional activity of the bowel, with the gratifying assurance that natural evacuation will follow without the need for further medication.

No. 2.	The Relationship of Rice to Beri-Beri in India, by LT.-COL. ROBERT McCARRISON, C.I.E., I.M.S., and ROLAND V. NORRIS, D.Sc., F.I.C.	Re.	1-12-0
No. 3.	Provisional List and Reference Catalogue of the Anophelini, by LT.-COL. S. R. CHRISTOPHERS, C.I.E., I.M.S.	Re.	1-12-0
No. 4.	Reports of the Kala-Azar Commission, India. Report No. I (1924-25), by LT.-COL. S. R. CHRISTOPHERS, F.R.S., I.M.S.	Rs.	8-8-0
No. 5.	The Distribution of Anopheline Mosquitoes in India and Ceylon, by MAJOR G. COVELL, M.D., I.M.S.	Rs.	3-8-0
No. 6.	A Study of Indian Medicinal Plants. <i>Holarthra anti-dysenterica</i> , Wall. by REV. FATHER J. F. CAIUS, S.J., F.L.S., M.S.C.I. (Paris), and DR. K. S. MHASKAR, M.D., M.A., D.Sc., D.P.H., D.T.M. & H.	Rs.	3-8-0
No. 7.	A Critical Review of the Data Recorded regarding the Transmission of Malaria by the different Species of Anopheles; with Notes on Distribution, Habits and Breeding-places, by MAJOR G. COVELL, M.D., I.M.S.	Rs.	3-4-0
No. 8.	Preliminary Enquiry into Beri-Beri in Burma, by LT.-COL. J. TAYLOR, D.S.O., M.D., D.P.H., I.M.S., MAJOR C. DE C. MARTIN, M.B., I.M.S., and SUB-ASST. SURGEON U. THANT	Rs.	2-12-0
No. 9.	The Incidence and Spread of Cholera in India; Forecasting and Control of Epidemics, by SIR LEONARD ROGERS, M.D., F.R.C.P., F.R.C.S., F.R.S., I.M.S. (Retd.)	Rs.	5-0-0
No. 10.	Beri-Beri Columbarum, by LT.-COL. R. McCARRISON, C.I.E., M.D., D.Sc., F.R.C.P., I.M.S.	Rs.	5-12-0
No. 11.	Yeasts and Sprue, by LT.-COL. F. P. MACKIE, I.M.S., and G. D. CHITRE, B.M.S.	Rs.	3-12-0
No. 12.	The Epidemiology of Cholera in India, by LT.-COL. A. J. H. RUSSELL, C.B.E., M.A., M.D., D.P.H., I.M.S., and E. R. SUNDARARAJAN, M.A.	Rs.	9-4-0
No. 13.	Puzzles and Fallacies in the Examination of Stained Films in the Tropics, by LT.-COL. R. KNOWLES, I.M.S., LT.-COL. H. W. ACTON, I.M.S., and ASST. SURGEON B. M. DAS GUPTA	Rs.	4-12-0
No. 14.	Studies on Asiatic Cholera, by F. D'HERELLE, M.D., MAJOR R. H. MALONE, M.D., I.M.S., and M. N. LAHIRI, M.B.	Rs.	5-0-0
No. 15.	An Investigation into the Value of an Etherized Vaccine in the Prophylactic Treatment of Rabies, Part VII, by LT.-COL. J. CUNNINGHAM, C.I.E., D.A., M.D., I.M.S., and MAJOR R. H. MALONE, M.D., D.P.H., I.M.S.	Rs.	7-12-0
No. 16.	A Study of Indian Medicinal Plants, II. <i>Gymnema Sylvestre</i> , Br., by DR. K. S. MHASKAR, M.D., M.A., D.Sc., D.P.H., D.T.M. & H., and REV. FATHER J. F. CAIUS, S.J., F.L.S., M.S.C.I. (Paris)	Rs.	4-4-0
No. 17.	Studies in <i>Schistosoma Spindale</i> , Parts I—VI, by N. HAMILTON FAIRLEY, O.B.E., M.D., D.Sc., F.R.C.P., LT.-COL. F. P. MACKIE, K.H.S., O.B.E., M.D., M.Sc., D.P.H., F.R.C.S., F.R.C.P., I.M.S., and F. JASUDASAN, L.M. & S.	Rs.	8-12-0
No. 18.	Studies in the Parasitology of Malaria, by LT.-COL. R. KNOWLES, I.M.S., and R. SENIOR WHITE, F.R.S.E., assisted by ASST. SURGEON B. M. DAS GUPTA	Rs.	14-12-0
No. 19.	Indian Plant Remedies used in Snake-Bite, by DR. K. S. MHASKAR, M.D., M.A., D.Sc., D.P.H., D.T.M. & H., and REV. FATHER J. F. CAIUS, S.J., F.L.S., M.S.C.I. (Paris)	Rs.	2-12-0
No. 20.	Leptospirosis in the Andamans, by LT.-COL. J. TAYLOR, D.S.O., I.M.S., and DR. A. N. GOYLE, M.B., Ph.D.	Rs.	6-0-0
No. 21.	Larvæ of Anopheline Mosquitoes, with full Description of those of the Indian Species, by DR. I. M. PURI, M.Sc., Ph.D., F.E.S.	Rs.	11-8-0
No. 22.	Studies in Avian Spirochaetosis, Parts I & II by LT.-COL. R. KNOWLES, I.M.S., B. M. DAS GUPTA, and B. C. BASU, M.Sc.	Rs.	5-8-0
No. 23.	The Life Line of the Thyroid Gland, by COL. R. McCARRISON, C.I.E., K.H.P., I.M.S., and K. B. MADHAVA, M.A., A.I.A.	Rs.	12-12-0
No. 24.	Notes on Indian Scorpions, by REV. FATHER J. F. CAIUS, S.J., F.L.S., M.S.C.I. (Paris), and DR. K. S. MHASKAR, M.D., D.P.H.	Rs.	6-8-0
No. 25.	Reports of the Kala-Azar Commission, India. Report No. II (1926—1930), by LT.-COL. H. E. SHORTT, F.Z.S., I.M.S.	Rs.	5-8-0
No. 26.	An Investigation into the Value of an Etherized Vaccine in the Prophylactic Treatment of Rabies, Part VIII, by LT.-COL. J. CUNNINGHAM, C.I.E., M.D., I.M.S., MAJOR R. H. MALONE, M.D., I.M.S., and MAJOR A. C. CRAIGHEAD, I.M.S.	Rs.	5-8-0
No. 27.	Haffkine's Plague Vaccine, by LT.-COL. J. TAYLOR, D.S.O., M.D., D.P.H., I.M.S.	Rs.	5-12-0
No. 28.	An Investigation into the Relative Immunizing Value of the Kasauli and Paris Strains of Rabies Virus, by LT.-COL. H. E. SHORTT, F.Z.S., I.M.S., Director, Pasteur Institute of India, Kasauli, MAJOR R. H. MALONE, M.D., L.R.C.P.S., D.P.H., I.M.S., MAJOR A. C. CRAIGHEAD, M.B., D.P.H., I.M.S., and ASST. SURGEON J. P. McGUIRE, D.C.M., I.M.D.	Rs.	3-0-0
No. 29.	The Histopathology of Malaria with Special Reference to the Function and Origin of the Macrophages in Defence, by WILLIAM H. TALIAFERRO and H. W. MULLIGAN	Rs.	3-8-0
No. 30.	Studies on the Epidemiology of Filariasis in Travancore, by M. O. T. IYENGAR	Rs.	4-8-0
No. 31.	The Present Position of Hemp-Drug Addiction in India, by BR.-COL. R. N. CHOPRA, C.I.E., M.D., S.C.D., K.H.P., I.M.S., and CAPT. GURBAKSH SINGH CHOPRA, M.B., B.S., A.I.R.O.	Rs.	4-0-0
No. 32.	The Rice Problem in India, by DR. W. R. AYKROYD, S.C.D., M.D., DR. B. G. KRISHNAN, CAPT. R. PASSMORE, B.M., I.M.S., and A. R. SUNDARARAJAN, M.Sc.	Rs.	3-8-0

**THACKER, SPINK & CO. (1933), LTD., P. O. Box 54, CALCUTTA**

The total number of births during the year was 150,410 (146,737), the computed birth rate being 22.0 per mille of population as compared with 21.6 in the preceding year. The total number of deaths was 102,228 (102,118) giving a death rate of 14.9 per 1,000 of population as against 15.1 in the previous year. The total number of deaths among children under one year of age was 16,082 (15,567) giving an infant mortality rate of 106.9 against 106.1 in the previous year.

Experimental work was continued in order to determine the standards of purity of most of the common articles of food with reference to their nutritional value. As a result thereof, action was taken to discourage the use of polished rice and to encourage the use of hand-pounded rice. Experiments on other articles of food are being conducted.

During the year, 190 cinema shows were arranged in different places in the districts. Two health exhibitions were held, one at the Annual Dasara Exhibition at Mysore, where a large section on nutrition and its importance was newly added and the other at Hassan in connection with the State Women's Conference.

The health centre at Closepet continued to do good work. Village improvement work was started by the health league in 18 new villages. Improvements were effected to several houses by providing latrines, soak pits, manure pits, and windows and by plastering and white-washing them.

**Malaria control.**—Control of malaria is a very important public health problem in the State as malaria accounts for over 30 per cent of the total mortality. Control work was continued in the cities of Bangalore and Mysore and in Hiriyur, Mudgere, Nagenahalli, Mandya and ten selected villages in the Irwin Canal area. It was started in Chikmagalur and Sakrepatna also. Malaria survey was completed in Shimshapura, Belur, Jog and Devarayasamudram and in ten villages in the Marconahalli area, 17 villages in the Closepet area and two villages close to Bangalore as well as in the Alageshwar tea estates, the area around the Princess Krishnammanni Sanatorium, Mysore and Balehalli village near Chikmagalur. The annual spleen and parasite survey of the Bangalore and Mysore was done, as usual. The spleen rate for Bangalore was found to be 0.13 as against 0.31 in the previous year and the parasite rate 0.91 against 0.5. The spleen and parasite rates for Mysore city were 1.3 and 2.2 per cent against 2.6 and 7.2 in the previous year. Both malarial and Paris green were used as larvicides. The effects of malaria engineering measures were observed during the year in the three villages.

The guinea-worm staff visited 960 villages during the year, 524 step wells were examined and 66 wells were newly stocked with fish. The larvicidal fish was renewed in 111 wells, and 19 wells were treated with perchloron.

The staff on hook-worm control carried on the work of propaganda and the construction of bore-hole latrines, in the villages where infection was found to be heavy. They visited 1,539 houses in 38 villages. One hundred and thirty bore-hole latrines were constructed during the year.

In addition to the work on water-supply scheme at Mysore, Bethamangala, Kolar, Hiriyur, Harihar, Shimoga, Sagar, Saklespur, Shikarpur and Hassan, 14 towns and villages were provided with protected water-supply.

Plans for the improved lay out of five places and type designs of slaughter-houses, mutton stalls and rat-proof dwelling houses were prepared during the year.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1938. BY LIEUT.-COLONEL A. M. V. HESTERLOW, M.B., Ch.B. (EDIN.), B.Sc., P.H. (EDIN.), D.T.M. & H. (EDIN.), I.M.S., DIRECTOR

THE death rate for the year 1938 was higher than the decennial average by 2.77. A noticeable increase was recorded in the number of deaths from cholera (6,465).

The increase in the number of deaths from cholera was the principal factor in raising the death rate in 1938.

Diseases	1938	1928-37
Cholera .. ..	1.50	0.70
Smallpox .. ..	0.21	0.21
Plague .. ..	.. ..	.. ..
Fevers .. ..	13.33	12.27
Dysentery and diarrhoea .. ..	1.50	1.23
Respiratory diseases .. ..	0.87	0.76
Injuries .. ..	0.25	0.25
All other causes .. ..	4.75	4.22
<b>TOTAL .. ..</b>	<b>22.44</b>	<b>19.65</b>

Nine hundred and seventy-two thousand, six hundred and ninety-six persons were inoculated with cholera vaccine excluding those inoculated in tea estates. Four hundred and ninety-five thousand, eight hundred and seventy-two doses of bacteriophage were issued during the year under report. As in past year, seven mobile epidemic units, each consisting of three sub-assistant surgeons and six disinfectant carriers, were employed; this staff was found inadequate. When there is a severe epidemic which breaks out in several districts simultaneously, affecting extensive areas where communication is not good, it becomes impossible for the staff to cover the whole area. It was for this reason and to make the unit more useful that it is now customary to designate as the epidemic unit—a unit consisting of one sub-assistant surgeon and two disinfectant carriers and to post these in suitable centres in the district from which infected areas would be more readily accessible, instead of locating them all at district headquarters. In such circumstances, the only alternative is to close the Public Health dispensaries and to utilize the staff for epidemic duty, dislocating the system of kala-azar treatment work, which is very undesirable. Additional units are therefore imperative.

One hundred and fifty deaths from cholera were reported from tea estates during the year compared with 220 deaths in 1937. The corresponding ratio per mille being 0.12 and 0.22 respectively.

A total of 618 villages was infected with smallpox. Mortality from smallpox was reported from 67 out of 148 registration circles. The highest number of deaths (280) was recorded in May and the lowest (46) in September.

No case of plague was reported.

Fevers were responsible for 59.46 per cent of the total provincial mortality as compared with 62.13 per cent in the previous year. These figures include deaths from malaria, kala-azar and also from various other diseases, which have fever as their predominant symptom.

Two hundred and thirty-five deaths from cerebro-spinal fever were reported from three districts.

Three thousand, two hundred and thirty-four cases of yaws were treated against 2,607 in 1937. In each of the districts of Goalpara and Nowgong, three more centres undertook the treatment of yaws. Two sub-assistant surgeons received training in the diagnosis and treatment of yaws in each of the districts of Kamrup and Nowgong. The treatment with neosalvarsan has proved very successful.

Twenty-five cases of naga-sore were treated in the Kamrup district during the year under report against 73 in 1937.

The number of deaths from kala-azar was greater in 1938 by 281 than that of the preceding year. The number of patients treated was larger by 5,217. The increase in deaths is shared by the districts of Sylhet, Kamrup and Sibsagar and the increase of cases treated

is shared by all districts. The method of diagnosis and treatment of kala-azar was the same as in previous years. Neo-stibosan is again being used in urban areas only at the discretion of the medical officers. The price of this drug has now been reduced.

In Cachar district 422 villages were surveyed and 331 suspected cases were discovered of which 104 were found to be positive. All these cases were brought under treatment.

Two kala-azar treatment centres, one at Ratanpur and the other at Matijuri in the Hailakandi subdivision, were opened during the year under review.

Four thousand, three hundred and seventy-five lepers received treatment in the leper asylums and other centres of treatment under the Medical and Public Health Departments during the year under review. Of these 910 lepers were treated in the leper asylums, wards and colonies.

#### SEVENTY-SEVENTH ANNUAL REPORT OF THE GOVERNMENT CINCHONA PLANTATIONS AND FACTORY IN BENGAL FOR THE YEAR 1938-39

TOWARDS the middle of the year under review the convention price of quinine sulphate rose by 1d. per ounce due chiefly to a continued fall in the value of sterling. Government prices, however, remained steady throughout the year. An examination of recent import figures reveals an interesting feature, namely, that the Indian quinine trade has been gradually passing from the Dutch and the British into the hands of the Germans. This is undoubtedly due to the system of subsidized exports that has prevailed in Germany. The bark, of course, still comes mainly from Dutch sources in Java.

Mr. Wilson's enquiry into the prospects of cinchona cultivation in India, referred to in our last report, was completed during the year. His report gives a brief account of the recent trend of development of cinchona cultivation in India, both through Government and private enterprise, and shows that, taking India as a whole, there has been little progress towards reducing the margin between the country's total consumption of quinine and its production. On the findings of the report the scope for future development in cinchona lies mainly in the south of India. This may be explained by the fact that the whole table-land of the Deccan offers suitable ranges of elevation, while in the north, the elevations are to be found only along a narrow belt at the foothills of the Himalayas and its offshoots.

The report brings out in striking manner the paucity of quantitative data on cinchona cultivation in India. Neither the yield tables nor the cost figures given by Mr. Wilson can be taken as authentic. They have not been derived from statistical averages, but are based on general experience. They give, nevertheless, useful indications which should be of help towards formulating schemes of extension in new areas, where no experimental work has yet been done. The need for well organized quantitative data is being increasingly felt in the Bengal Cinchona Department in connection with the planning of production and distribution. The present system of plantation mensuration which was devised nearly thirty years ago has completely broken down under the altered methods of cultivation and harvesting.

The soil studies in connection with the Wilson enquiry give interesting generalizations in the field of which little is yet known to us. The results must, however, be accepted only on a tentative basis and before a proper correlation can be established between soil factors and the growth of cinchona, more comprehensive schemes of sampling must be devised to eliminate the climatic and inheritance factors. Further soil studies on an extensive scale are desirable not only to find the characteristics best suited to cinchona, but also with

a view to devising methods of maintaining these characteristics over a series of planting cycles. This is one of the really pressing problems of cinchona cultivation in India, because of the rigorous climatic and topographic conditions in which cinchona has generally to be grown in this country.

Mr. Wilson stands on undisputed ground when he stresses the need for research. This need has been previously mentioned in our own reports. There is on the one hand room for improvement in our present methods of selection, propagation, cultivation and harvesting. On the other hand it is necessary to place even the existing methods on a scientific basis, so that they may depend for successful exploitation not so much on that empirical experience, which is known as the personal touch, as on the observance of principles established by experiment which take into account the varying conditions of locality and time. The successful cultivation of cinchona is no doubt an art, but it is an art that, to obtain perfection, must take the fullest advantage of existing knowledge.

#### REPORT OF THE MEDICAL RESEARCH COUNCIL, LONDON, FOR THE YEAR 1938-39

##### MEDICAL RESEARCH AND THE WAR

DURING the past year the work of the Medical Research Council has gone steadily forward and, except in the case of their administrative staff, the continuous state of war expectancy affected it but little until the late summer. The policy of the council has been to encourage their research staff and grantees to continue their investigations as under normal conditions. On the outbreak of war this policy has been maintained, although some research workers have had to respond to special calls—to join the defence services, to take part in emergency schemes, or to undertake special investigations suggested by war conditions.

It cannot be denied that the disturbed political atmosphere of the past year has brought increased difficulties to those whose work depends so greatly upon concentration of thought and action, and upon freedom from worry. At the same time, perusal of this Annual Report, and especially the account of the work done at the National Institute for Medical Research and at other special centres throughout the country, will show that a harvest of discovery has been procured in spite of the unrestful situation.

The council foresaw that the work at the National Institute would be at least as important in time of war as in time of peace, and took action to provide protection for the staff at Hampstead. Since the outbreak of hostilities, therefore, the staff of the National Institute have been able to proceed with their work. It cannot be expected, however, that medical research either there or elsewhere can remain unaffected by war. Apart from changes and possibly some reduction in personnel, the natural desire of many investigators is to leave their peace-time problems and direct their attention to subjects of immediate war interest. The presentation of new war problems requiring investigation is therefore usually received with enthusiasm by the research worker. The danger, in fact, is not that of failure to investigate such problems but rather that, by switching over to other objectives of immediate practical interest, the fruits of promising research unrelated to war should be lost. It is the intention of the council, so far as they are able, to prevent such losses to important knowledge.

At the same time, it is recognized that war conditions in themselves offer special opportunities for the acquisition of knowledge which is by no means of emergency interest only. It will be remembered, for instance, that the Medical Research Council (then Committee) came into being immediately before the last war, and during their early years directed most of their attention and energy to the solution of problems presented and made urgent by the emergency. In the words of the Annual Report for 1917-18, 'the needs of war have given stimulus to enquiries upon many

# THE CALL OF PAIN

The call of pain is seldom stilled, and relief is of primary importance to the suffering patient. The paroxysmal pain of dysmenorrhœa, the persistent and intense throbbing of migraine, the shooting pains of neuralgia, the pain in affections of the bones and joints, the pain resulting from accidents — all these, and many other conditions, yield with impressive readiness to the sedative and analgesic efficacy of Veganin. With Veganin there is no systemic disturbance, no habituation. It may therefore be safely entrusted to the patient as a dependable means of relieving and preventing pain.

## VEGANIN TABLETS

Prepared by WILLIAM R. WARNER & CO. LTD., LONDON, ENGLAND.

### A Call for Help

*Veganin Tablets present acetylsalicylic acid, phenacetin and codeine in synergistic combination, whereby the individual action of each constituent is greatly enhanced.*

*Veganin Tablets are not advertised to the public.*

*Supplied in tubes of 10 and 20.*

*A trial supply to Physicians on request.*

MARTIN & HARRIS Ltd.,  
Mercantile Buildings, Lall Bazar,  
CALCUTTA.

Also at Bombay, Madras, Karachi  
and Rangoon.

## *The Weaning Period*

From six months of age onwards, the mineral constituents of the infant's dietary assume increasing importance.

Allenburys Malted Food No. 3 is specially adapted for use after six months of age. It contains the necessary amounts of iron, calcium, phosphorus, and of vitamin D.

Allenburys Malted Food has a basis of specially cooked and dextrinised ten flour; this is aided by the diastase present in a complex grains and sugars to form the baby's introductory solid foods.

*Descriptive literature will  
be sent on request.*

sides, and out of the circumstances of the time some unusual opportunities and facilities have come to scientific workers'. The history of work done during the years 1914-18 is a remarkable one, and a perusal of the records of the Medical Research Committee of those years cannot but excite admiration both for the success with which the opportunities offered were seized by workers in this field and for the inspiring energy with which the Secretary, Sir Walter Fletcher, carried out the general policy. It was the first time in the history of this country that organized scientific endeavour in medical research ever had a chance of justifying itself, and right well did it respond.

It will be asked what contribution medical investigation can make in the present war. It is at least certain that the more recent developments of blood transfusion, together with a well-organized service for allowing this to be carried out on a large scale, will lead to results far better than those obtained by the transfusion of gum acacia solution introduced in the later part of the war of 1914-18 through the work of the Committee on Shock.

In the case of wound infection, probably the largest single cause of death among wounded men reaching hospital in the last war, it can be safely predicted that modern discovery in the chemotherapeutic treatment of bacterial infection will be one of the outstanding beneficial factors. Where the infection is due to hæmolytic streptococci, it may be hoped that the established curative effect of the sulphanilamide group of compounds will be as successful in wounded men as it has proved in puerperal sepsis and septicæmia. The evidence of the curative effect of these compounds in gas-gangrene infection is not so certain, but what evidence there is suggests that in this case also they will be life saving. It will be necessary as soon as possible to get evidence on this point, and especially to evaluate the relative curative effects of the sulphanilamide compounds and gas-gangrene antitoxin. Although the use of gas-gangrene antitoxin still receives wide support, its beneficial effects have never been established with certainty. Needless to say, however useful the new chemotherapeutic compounds will prove, it is not likely that the need for proper surgery in the treatment of wounds will diminish.

Another matter which presses for early solution is the possible prophylactic effects of the sulphanilamide derivatives, apart from their curative action. Arrangements have already been made by the Army Medical Service to determine whether the administration of these compounds immediately following injury will prevent subsequent infection by the more common pathogenic micro-organisms.

#### WAR EMERGENCY SERVICES

During the two years preceding the war the Medical Research Council were entrusted with a number of responsibilities, on behalf of H. M. Government, for the preparation of various emergency medical services.

#### Medical supplies

One of the first things of the kind which the council were asked to undertake was the organization and supply of certain antitoxins to be held in readiness for war purposes.

#### Specialist personnel

The ordinary work of the council places them in a unique position as regards contact with those who have special knowledge of different branches of medical science and allied subjects. They have thus, both before and since the outbreak of war, been able to assist in finding men possessing the highly specialized qualifications required for various items of emergency work which have arisen.

#### Blood transfusion depôts

The council also undertook the organization of four depôts for the collection, storage and supply of blood for transfusion purposes. These are situated in the home counties and are intended—in addition to serving their own immediate neighbourhoods—to augment the arrangements made by the hospitals in London itself.

#### Nutrition in time of war

During the last war knowledge of human nutrition which was then new proved to be of great value in dealing with questions of the nation's food supply under conditions of restriction. It is no less vital that this knowledge should be applied now, if similar conditions recur.

#### Research on war problems

Some of the medical problems presented by the war are old ones for which no complete solution had been found. Among these is the question of shock occurring after serious wounds or severe operations. The council have appointed a special committee to review this problem in the light of present-day knowledge, and to organize both laboratory and clinical studies in the subject. Related to this is the question of blood transfusion, with regard to which various investigations are in progress.

Other subjects have taken on fresh aspects under changed conditions. For example, the physiological problems of aviation present themselves in new forms in relation to the flying of modern war machines. In this field the council have been assisting the Royal Air Force, and their secretary is chairman of the special committee set up by the Air Ministry.

#### Virus diseases

*Influenza: epidemic studies.*—Dr. Stuart-Harris, working in association with the institute, studied the clinical conditions in a number of successive outbreaks, and collected material from representative cases for laboratory investigation. Even with material from typical cases, all attempts to transmit a virus infection to ferrets and mice were unsuccessful in the early stages, and it was not until the middle of February that evidence of a connection of influenza virus with the outbreak was obtained. From that time onwards the virus was recovered from a proportion of the cases in each outbreak visited; and additional cases gave evidence of its presence in the increase of neutralizing antibodies observed in samples of blood serum taken during and after the attack.

Altogether, of the throat-washings obtained from different outbreaks only 7, out of 59 tested, yielded virus infecting ferrets. Some of these strains appeared to be of low virulence for the test animals, though all showed antigenic relationship with some of the strains obtained in the more typical epidemics of earlier years.

*Dimensions and properties of viruses.*—In collaboration with Dr. T. F. McNair Scott at the Wellcome Research Institution, Dr. Elford has applied his methods of ultrafiltration and differential centrifugation to determining the dimensions of the infective units of lymphocytic chorio-meningitis; this is a virus disease affecting the brain membranes of mice, and has in more than one laboratory been accidentally found to be transmissible to man. The diameters of the units, as determined by these independent methods, showed excellent agreement, the calculated average values being 50 and 46 millimicrons respectively (a millimicron being a millionth of a millimetre).

#### Immunology

*Reversed anaphylaxis.*—Dr. van den Ende has completed an investigation, which he had undertaken at Cambridge, on the phenomenon termed 'reversed anaphylaxis'. It was known that if an antiserum to guinea-pig serum was prepared by a course of injections into a rabbit, the serum of the immunized rabbit evoked in a normal guinea-pig a train of symptoms closely resembling that observed in the ordinary anaphylactic shock. The completion of the experiments has been deferred by the incidental discovery that the antibody globulin, from the serum of a rabbit immunized against pneumococcus (type I), is a distinct antigen from the corresponding globulin of normal rabbit's serum—a point of interest at least as great as that which led to the experiment.

*Tissue fixation of antibodies.*—A further technical advance has been made in the method, by the discovery

that the sensitizing fixation of antibodies—producing a condition of passive anaphylaxis—does not require the maintenance of the organ in a state of physiological activity at body temperature.

**Bacterial antigens.**—Dr. Elford has initiated a physico-chemical study of the molecular dimensions of these antigens, and of the polysaccharide haptens which can be dissociated from them.

#### Leprosy

Sir Patrick Laidlaw has made experiments which have an interesting bearing on the relation between human leprosy and that occurring in the rat. The rat disease, which is caused by an organism very similar to that found in the leprosy lesions of man, is relatively rapid in development and is transmitted without difficulty from rat to rat; but there was only one previous record of a successful attempt to transmit leprosy to the rat by material from a case of leprosy in man. During the past year material from cases of human leprosy in the Belgian Congo had been sent by air mail to Dr. A. Dubois of Antwerp, and this had been used to inoculate Syrian hamsters.

With this material Sir Patrick Laidlaw found it remarkably easy to transfer a rapidly spreading infection not only to hamsters but the readiness with which the infection was transmitted to rats as well as hamsters, and the observations made on the tissues of these animals after death, suggested to Sir Patrick Laidlaw that the human lesions from which the material was originally obtained were due to infection with the organism of rat leprosy, and not with the organism of the usual human type. This opinion has been confirmed by Dr. Dubois and also by Professor Adler, to whom microscopic preparations and descriptions of the findings were submitted.

With regard to the infection of hamsters with the bacillus of typical human leprosy, it is important to distinguish mere survival of organisms at the site of inoculation from active multiplication and infective

spread to other tissues. Sir Patrick Laidlaw has accordingly studied the behaviour of a number of other mycobacteria. Such organisms differ from true leprosy bacilli in being capable of growth on artificial media. In most cases they could be recovered from the sites of inoculation in hamsters as long as six months after injection; but the survival was strictly local, no organisms being found in the lymph glands, spleen, liver, or other organs. A mycobacterium obtained from butter survived for months in this restricted manner, as well as those which had originally been found in association with leprosy lesions.

#### Protistology

By the methods which had already proved so fruitful in the study of the life-cycles of *Entamoeba histolytica* and *Entamoeba coli*, Mr. Dobell has now worked out a large part of the life-cycle of *Endolimax nana*. He has made further progress with the study of the intestinal flagellates of these hosts, and the knowledge of them required for practical purposes is now nearly complete. Attention has also been given to the flagellate commonly found in the human mouth, with a view to deciding the proper nomenclature of this organism.

[These are a few abstracts from this interesting and valuable report which is all we are unfortunately able to find space for. Important work has also been done on chemotherapy and endocrinology and many other subjects. Apart from the amount of information obtained in this report the list of 37 special committees at the end indicates the wide scope the activities of the Medical Research Council covers. All research workers should have a copy as from it they may gain ideas for lines of their own researches or, on the other hand, be prevented from overlapping in work that is being efficiently pursued elsewhere. It is published by His Majesty's Stationery office and the price is three shillings.—EDITOR, I. M. G.]

## Correspondence

### ROUTINE TREATMENT OF EPILEPSY, WITH SNAKE VENOM

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Cobra and Russell viper venoms are used together in the treatment of epilepsy. The former acts as an anticonvulsant drug, and also probably reduces sensitivity of the higher centres to extraordinary incoming impulses. Russell viper venom appears to alter the mineral and water metabolism and thus influences the epileptic convulsions. In addition to this, extract of *Rauwolfia serpentina* is added to the venom therapy since it is a good nerve sedative, hypnotic and lowers blood pressure, and thus lowers cerebral excitability. The treatment may be detailed briefly as follows:—

#### ROUTINE TREATMENT OF EPILEPSY WITH VENOMS

##### Drugs to be used:—

- (1) Cobra venom 1 to 10 mouse units (m. u.).
- (2) Russell viper venom 2 to 20 mouse units.
- (3) Extract *Rauwolfia serpentina* 10 to 30 drops in water, twice daily.

##### Treatment:—

Intramuscular bi-weekly injections of cobra and Russell viper venom, mixed together in the following doses:—

- Dose no. 1. Cobra venom 1 m. u. and Russell venom 2 m. u.
- Dose no. 2. Cobra venom 2 m. u. and Russell venom 4 m. u.
- Dose no. 3. Cobra venom 3 m. u. and Russell venom 6 m. u.

So on till 10 doses are administered. Rest for one month and repeat the above course again.

Three to four such courses to be completed, later on one course every six months.

Record of the fits, the dates of occurrence and duration of fits to be recorded, regularly, throughout the treatment.

#### Extract *Rauwolfia serpentina*:—

Ten to thirty drops to be given in an ounce of water at bedtime and early morning or when the fits are anticipated. Doses of rauwolfia and venom may be regulated according to the local and general reaction and according to the response of the patient.

#### *Bromides and luminal*:—

These may be given in the beginning to control the fits, and the latter drug if fits are very frequent and severe in type. Dilantin Sodium Kapsels (Parke, Davis & Co.) is another good drug worth trying. It has been reported to have given encouraging results and is preferable to luminal.

A paper on the above treatment as employed at the School of Tropical Medicine, Calcutta, was read in the Physiological Society in January 1940.

Yours, etc.,

J. S. CHOWHAN,

M.B., B.S., CAPTAIN, A.I.R.O.

Biochemical Standardization Laboratory,  
All-India Institute of Hygiene and Public Health.

CALCUTTA,  
23rd March, 1940.

# The Influence of Virol on the Growth of Children

*A Summary of Investigations\* published in the  
"Medical Officer," March 30 and April 6, 1935*

A NUMBER of children, all receiving their customary home diet, were given either No Supplement, Cod Liver Oil, Halibut Liver Oil (with milk to provide equal calories) or Virol. The experimental scheme provided that each child should have a period on each treatment in turn, in such a way that every possible sequence was included. Rigid statistical control was thus possible.

## Gain or Loss in Weight on Various Supplements :—

Supplement	Total gain in ozs. over all periods	Average gain per child per week in ozs. over all periods	Total loss in ozs. during summer period only	Average loss per child per week in ozs. during summer period only
No Supplement - -	88	0.3	— 103	— 1.4
Cod Liver Oil - -	287	1.0	— 77	— 1.1
Halibut Liver Oil with milk - - - -	333	1.2	— 184	— 2.6
VIROL - - - -	762	2.6	— 7	— 0.1

Whereas earlier investigations had shown that the mere addition of vitamins had no effect on growth, these investigations have conclusively proved that Virol—a balanced food containing all the necessary vitamins—has a definite and remarkable effect in bringing the rate of growth up to the recommended standard. Virol was the only one of the supplements used that promoted this ideal rate of growth.

Virol was the one and only preparation that maintained the children's weight in the hot weather.

\* The full report will be sent on application to Messrs. A. H. Wheeler & Co.,  
Sudama House, Wittet Road, Ballard Estate, Bombay.

# ST. BARTHOLOMEW'S HOSPITAL OPERATION TABLE

with the  
Latest Improvements

including

Easy to operate Release Lever for lowering the table; Trendelenburg position increased to 55° tilt; Foot operated rubber-covered Floor Brake.

The St. Bartholomew's Hospital Operation Table is now manufactured in five different models and thus supplies a range of modern operation tables embodying the latest ideas of well-known surgeons for carrying out surgical operations.

All models can be supplied with either tripod or platform base.

Model A

In Trendelenburg position, 55° tilt, showing shoulder rests and instrument tray in position.

Model B  
in chair position,  
with heel supports  
and bladder irriga-  
tion tray.

Model AC

in lateral position, with back elevator and lateral supports.

Over 1075 of these tables are in use at home and abroad.

*A descriptive booklet, fully illustrated, will be sent on request.*

**ALLEN & HANBURY LTD.**

(Incorporated in England)

**CLIVE BUILDINGS, CALCUTTA**

and at 37 Lombard Street, London, E.C.3

## Service Notes

### APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL E. COTTER is confirmed in the appointment of Public Health Commissioner with the Government of India, with effect from the 30th August, 1939.

Lieutenant-Colonel W. J. Webster, M.C., Assistant Director, Central Research Institute, Kasauli, is appointed to officiate as Director of that Institute, *vice* Colonel J. Taylor, granted leave.

On transfer from Ferozepur, Lieutenant-Colonel K. R. Batra assumed charge of the Office of Civil Surgeon, Jullundur, on the forenoon of the 6th April, 1940.

On transfer from Jullundur, Lieutenant-Colonel Jamal-ud-Din assumed charge of the Office of Civil Surgeon, Rawalpindi, on the afternoon of the 12th April, 1940.

On transfer from Montgomery, Major P. C. Dutta assumed charge of the Office of Civil Surgeon, Ferozepur, on the forenoon of the 22nd April, 1940.

On transfer from Campbellpur, Major B. Temple-Raston assumed charge of the Office of Civil Surgeon, Dalhousie, on the 30th April, 1940.

Captain R. I. Reid is confirmed as Deputy Assistant Director-General (Medical Stores), with effect from the 28th February, 1940.

Captain C. L. Greening, an officer of the Medical Research Department, is appointed to officiate as Assistant Director, Central Research Institute, Kasauli, *vice* Lieutenant-Colonel W. J. Webster.

Captain H. A. Ledgard is appointed to officiate as an Agency Surgeon, with effect from the forenoon of the 1st April, 1940, and is posted as Residency Surgeon, Kashmir, with effect from the same date.

Captain F. W. Allinson, Civil Surgeon, Bakargani, on relief, is appointed to act as First Resident Medical Officer, Presidency General Hospital, Calcutta, *vice* Captain W. McN. Niblock.

Captain F. W. Allinson made over charge of the Barisal Jail to Dr. N. Das, on the afternoon of the 9th April, 1940.

Captain J. White, Civil Surgeon, Midnapore, is appointed to act as Superintendent of the Midnapore Central Jail, in addition to his own duties, *vice* Major B. Chaudhuri, with effect from the date on which the latter relinquishes charge of that jail to join the military.

Captain D. W. Taylor, Civil Surgeon, Dalhousie, has been recalled for military duty and made over charge of his duties at Dalhousie, on the 30th April, 1940.

Captain F. V. Stonham, Civil Surgeon, Sargodha, has been recalled for military duty.

### LEAVE

Colonel J. Taylor, C.I.E., D.S.O., K.H.S., Director, Central Research Institute, Kasauli, is granted leave on average pay for 1 month and 26 days combined with leave on half-average pay for 5 days, with effect from the 15th April, 1940.

Major W. Aitchison, Civil Surgeon, on 6 months' leave *ex-India* on Medical Certificate from 12th April, 1940, in continuation of 17 days' leave in India from 26th March, 1940, with permission to prefix the Easter and the Holi holidays from 22nd to 25th March, 1940.

Major M. K. Afridi, Assistant Director, Malaria Institute of India, is granted leave on average pay for 1 month, with effect from the 22nd April, 1940.

Major G. F. Taylor, Professor of Clinical Medicine, K. E. Medical College, Lahore, made over charge of his duties on the 21st April, 1940, and proceeded to England as medical attendant to Mr. D. Gainsford, I.R. He will be treated on 3 months' leave from the date he reaches England.

Captain W. McN. Niblock, First Resident Medical Officer, Presidency General Hospital, Calcutta, is granted leave, with effect from the date on which he is relieved.

### PROMOTION

Lieutenant-Colonel N. S. Jatar, C.I.E., D.S.O., Inspector-General of Civil Hospitals and Inspector-General of Prisons, C. P. and Berar, has been advanced to the higher position of his rank, *i.e.*, to the rank of Lieutenant-Colonel, selected for increased pay for ability and merit, with effect from 22nd October, 1939.

### RETIREMENTS

Lieutenant-Colonel J. P. Canteenwalla. Dated 28th February, 1940.

Lieutenant-Colonel M. L. Puri. Dated 13th April, 1940.

Lieutenant-Colonel T. H. Thomas retires on account of ill health. Dated 3rd March, 1940.

Major G. Dockery retires on account of ill health. Dated 12th February, 1940.

## Notes

### QUINACRINE

#### Composition and properties

QUINACRINE is the dihydrochloride of a synthetic acridine derivative with the following formula:—

2-chloro-7-methoxy-5-diethylamino isopentylamino acridine.

The solubility of Quinacrine in water is about 1 in 100, and the solution gives a neutral reaction. Being a dye substance, its administration may be followed

by a harmless yellow pigmentation of the skin. Where it is desired to administer the drug by injection in cases of coma, in very young children and in cases of gastric upset, Quinacrine Soluble (the dimethane sulphonate of the base) is employed.

Quinacrine acts on the asexual forms of all three malarial parasites, as well as on the gametocytes in benign tertian and quartan malaria, but its action on the schizonts of *Pl. falciparum* is perhaps its outstanding property. Its schizonticidal action seems to be the most powerful of any known anti-malarial remedy.

Quinacrine does not cause vertigo, tinnitus or anorexia. Its use is not contra-indicated in pregnancy, in cardiac disease or in blackwater fever. There appears to be some tendency to cumulative effect, and care should therefore be taken to ensure proper spacing of doses and courses of treatment. Quinacrine is of low toxicity, but in susceptible individuals, particularly towards the end of a course of treatment, the drug may give rise to gastric discomfort and occasionally to headaches. These forms of intolerance can be largely prevented by administration of copious fluids and by taking the drug during meals.

Quinacrine Soluble should be given by intramuscular or subcutaneous injection in a daily dosage the same as that of Quinacrine, injections being given once or twice in the course of 24 hours. The contents of the ampoule are dissolved in from 1.5 to 5 c.cm. of sterile distilled water.

### PRAEQUINE

#### *Composition and properties*

PRAEQUINE is a salt of a synthetic quinoline derivative, having the following structural formula:—

8-diethylamino isopentylamino-6-methoxy quinoline.

It is a tasteless pale yellow granular powder relatively insoluble in water but readily soluble in alcohol. It has the power, not possessed by other anti-malarial drugs, of destroying the gametocytes of all types of malarial parasites, and it is therefore of particular value as a prophylactic of the disease. It is usually administered following treatment with Quinacrine in order to diminish the likelihood of relapse.

Praequine is a highly active substance and the prescribed dosage must not be exceeded, otherwise toxic symptoms may appear, e.g., severe epigastric pains, nausea, vomiting, headache cyanosis and methæmoglobinuria. The drug should be used with caution in cases of hepatic dysfunction and of severe anæmia.

A variety of techniques of treatment are in common use. In cases of benign tertian and quartan malaria some authorities are content to give Quinacrine by itself in a course of treatment lasting from six to eight days. The temperature usually returns to normal by the second or third day, and the parasites can no longer be found in the blood stream after the third or fourth day.

Others give 30 grains of quinine in the first two days of treatment and then change over to Quinacrine for the remainder of the eight days' course of treatment.

It is the practice in some localities to follow a six days' course of quinine, after an interval of two days, by the administration of Praequine for a further five days.

In malignant tertian malaria it is common practice to give a six days' course of Quinacrine followed, after a rest period of two days, by a five days' course of Praequine. Praequine is of particular value in this form of malaria on account of its action upon the crescents.

Treatment with Quinacrine given orally may be replaced by twice daily injections of Quinacrine Soluble, in urgent cases, for two or three days after which the drug can be given by mouth.

We understand that a copy of the Quinacrine/Praequine booklet will be forwarded to any member of the medical profession on request to Messrs. May and Baker (India), Limited, 11, Clive Street, Calcutta, India.

### BOVRIL, LIMITED

#### (FORTY-THIRD ANNUAL GENERAL MEETING)

IN 1939 the Bovril sales showed a considerable increase over these of 1938. This improvement was to be expected in our home sales, but considering the many abnormal trade conditions throughout the world the increase in our export trade was a very satisfactory feature of our business.

Since the beginning of the war much of our production has been for the Services, and although demands were often made at very short notice we were able in every case to satisfy them. In this connection it should be noted that our Government contracts are now accepted on a cost basis, and the allowed margin of profit is very small. The Ministry of Supply are to be complimented on this policy, as it enables them to purchase at the lowest possible prices. The manufacturer, however, who is working for the Government on a cost basis may in certain circumstances be involved in losses; this is particularly liable to happen in a business such as ours, where large stocks of raw materials must be held for normal trading. It may be necessary to draw upon these stocks for special contracts; in this case the stocks must be replaced, but often at greatly increased prices. It is, therefore, clear that in these cases the cost should in a measure be based upon replacement prices, otherwise serious losses may be incurred.

In these days of food rationing and long hours of overtime on the part of industrial workers, the need for Bovril and the goodwill towards it is greater than ever. Needless to say, this ever-increasing goodwill is something we intend to foster and maintain.

Like most firms we already find ourselves working short-handed; of the office staff alone 46 members have joined up.

## Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

*Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.*

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

## Original Articles

### OBSERVATIONS ON SOME UNUSUAL TOXIC EFFECTS OF SULPHANILAMIDE THERAPY

By M. N. DE, M.B. (Cal.), M.R.C.P. (Lond.)

*Professor of Medicine, Medical College, Calcutta*  
and

N. R. KONAR, M.B.

*House Physician, Medical College Hospitals, Calcutta*  
(From the Department of Medicine, Medical College, Calcutta)

SINCE the discovery of prontosil rubrum by Domagk, a large volume of literature has been published recording the results obtained both in the laboratory, as well as clinically, with drugs belonging or related to sulphanilamides. As the latter are being used more extensively and in bigger doses the dangers which may be associated with their administration are more and more appreciated and any further observation on the subject should be welcome.

Amongst the toxic symptoms observed since the early days of prontosil therapy cyanosis is by far the commonest. It is not associated with any respiratory distress and investigations have shown that it is not necessarily accompanied in all cases by a change in the blood pigment. It seems more likely that it is due to the formation of a pigment in the body from the condensation products of the drug itself (Marshall and Walzl, 1937). Posner and his colleagues (1938) described a highly unstable form of methæmoglobin which they thought, might account for cyanosis in some of these cases. In many instances, however, the cyanosis is associated with sulph- or methæmoglobinæmia (both intracorpuseular). Sulphæmoglobinæmia is due to the union of the intestinal sulphuretted hydrogen with hæmoglobin, a reaction which is catalysed by sulphanilamides. This untoward effect may be avoided by withholding purgatives, except very mild ones like liquid paraffin, by giving a low residue diet and excluding articles containing sulphur, eggs, onions, garlic, etc. [Archer and Discombe (1937), Paton and Eaton (1937)]. Methæmoglobin however causes no trouble as it is rapidly reconverted into hæmoglobin when treatment with sulphanilamide drugs is stopped and glucose and oxygen administered.

Nausea with epigastric pain and occasionally vomiting may be produced by this group of drugs. These symptoms are more common with the newer remedy, M. & B. 693. It usually stops after the drug is withdrawn. Drug fever may occur seven to twelve days after the treatment has been started but is not common. A rash occurs in about six per cent of cases [Hageman and Blake (1938)]. Hallam (1939)

reported severe skin rash and general reaction following the administration of M. & B. 693 in a patient who also had exposure to ultra-violet light. He thinks that when the skin is photosensitized by some chemical reaction, following the administration of M. & B. 693, an exposure to moderate doses of ultra-violet light precipitates the onset of intense reaction. Bettley and Simon (1939) reported a bullous eruption due to the use of sulphanilamide. They discussed the various causes of the rash and according to Tedder (1939) put them in three groups: (1) Eruptions due to sensitization. These are somewhat like allergic reactions and can be reproduced even by the administration of a single dose of the drug. (2) Eruptions due to toxic effect of the drugs. These disappear if the dosage of the drug is reduced. (3) Eruptions due to the combined effects of sulphanilamide and light. In the first two groups the rash is more or less generalized but in the third it occurs mainly or wholly on the surfaces exposed to light. Thompson (1939) reports cases of rash resembling measles, rubella and scarlet fever after the administration of M. & B. 693. Agranulocytosis is by far the most dangerous condition produced by these drugs. Fatal granulocytopenia following administration of the sulphanilamide group of drugs has been reported by Sheket and Price (1939), with post-mortem studies. The fundamental picture is that of toxic granulocytopenia with arrest of the development and maturation of the myeloid cells. The authors consider that in these cases quantity and prolonged use of the drugs are more important factors than idiosyncrasy. Although this effect of the sulphanilamide group of drugs on the leucopoietic function of the bone marrow is a serious one and is often discussed, it is not so frequent as may be thought. The writers have not yet seen an instance of this complication during their routine use of M. & B. 693 in the wards of the Medical College Hospital.

Amongst the nervous symptoms which may arise, depression, headache and dizziness are common. Palpitation, paræsthesia, tinnitus and peripheral neuritis have also been noted very rarely.

During the routine use of M. & B. 693 especially in the treatment of pneumonia we often see a condition which may very well be considered as a toxic manifestation and which sometimes gives rise to a good deal of alarm. We have not so far been able to find any reference to this subject. In a case of acute lobar pneumonia, no sooner is M. & B. 693 exhibited in adequate doses, than the patient begins to perspire profusely and the temperature drops down to normal or even subnormal. This condition usually develops 24 to 48 hours after the treatment has been started. In some cases, the sweating is so severe that the patient's clothes have to be changed several times in the

day and night. In such a condition, the skin feels cold and clammy, urine diminishes considerably, the patient looks weak and exhausted and the whole picture resembles that of collapse. This upsets not only the patient's relatives but also the practitioner who is treating the case. Such a dangerous depression of the vasomotor system not only leads to a marked concentration of the circulating toxins but also lowers the temperature of the body and maintains it at a low level. This prevents the development of a healthy reaction of the tissues to the invading micro-organisms and their toxin, and delays the mobilization of an adequate amount of antibodies. Thus actual resolution is often hampered and convalescence chequered by complications with irregular pyrexia.

Hæmolytic anæmia is another rare complication of sulphanilamide therapy. Unlike agranulocytosis it occurs in the first few days of the treatment (usually 2 to 4 days). There is a sudden fall in the number of red cells with varying amount of jaundice and hæmaturia. According to Buttle (1939), no fatal case has yet been recorded.

Though cyanosis alone is the commonest feature of the toxic effect of the drug, profound blood destruction, producing hæmolytic anæmia and death, has seldom been found associated with the cyanosis. In view of the extreme rarity of such a complication compared with the widespread use of the drug, we consider it imperative to report two fatal cases in which cyanosis associated with marked blood destruction developed after the administration of sulphanilamide preparations.

It may be mentioned that one of our patients developed a generalized erythematous rash after taking a drug of the sulphanilamide group for high continued fever after childbirth. But as such eruptions are somewhat common and have already been reported by others, we do not propose to discuss the subject in our present paper.

### Clinical notes

*Case 1.*—R. J. P., aged 43, Parsi male, was admitted under one of the writers (M. N. D.) on 3rd February, 1939, for continuous fever for 12 days. The patient had been a chronic sufferer from antrum disease. The latter was painful recently when he felt feverish (21st January, 1939). The patient had an exposure to short-wave diathermy over the painful area on 27th January after which he had a high rise of temperature with rigor. The fever used to vary between 102° and 105°F. Pulse rate was between 110 and 120 and respiration 32 and 40 per minute. No abnormality was detected in the heart or lungs. Abdomen was distended and tympanitic. Liver and spleen were not palpable. As the temperature was persisting at a high level, the attending physician administered drugs of the sulphanilamide group. The patient had one tablet of prontosil album three times a day for five days from 28th January to 1st February. He had also intramuscular injections of 10 c.cm. of 2.5 per cent solution of prontosil rubrum daily for three consecutive days from 30th January to 1st February. The prontosil was then discontinued as it had no effect on the temperature. He had a plain diuretic and diaphoretic mixture. The patient was kept on liquid diet and his bowels were

moved by soap and water enema. There was no sign of improvement; on the contrary the patient became more and more toxic and developed hiccough on 2nd February. He looked distinctly cyanosed on 3rd February when he was removed to the hospital. On admission the patient was found to be toxic, comatose and markedly cyanosed. The temperature was 105°F. and pulse, which was 126 per minute, was soft and feeble. Blood pressure 110/70 mm. of mercury. Respiratory rate was 36 per minute. Tongue coated, dry and deeply cyanosed. Abdomen distended and tympanitic. Liver and spleen were not enlarged. Heart sounds were feeble and lungs were clear. The tongue, tip of the nose, the lobules of the ear, and the finger nails were bluish in colour. Fifteen ounces of red coloured urine were drawn out with a catheter. He was having frequent, loose, foul-smelling stools.

*Laboratory reports.*—Hæmoglobin—46 per cent, red cells—2,400,000 per c.mm., leucocytes—62,000 per c.mm., polymorphonuclear cells—61 per cent, lymphocytes—26 per cent, monocytes—5 per cent, eosinophiles—8 per cent, malarial parasites—nil, poikilocytosis, anisocytosis, many nucleated red cells and myelocytes present. Examination of the blood 24 hours later showed hæmoglobin—40 per cent, red cells—2,400,000 per c.mm., leucocytes—15,912 per c.mm., polymorphonuclear cells—88 per cent, lymphocytes—5 per cent, monocytes—7 per cent, eosinophiles—nil, malarial parasites—nil, normoblasts, poikilocytosis and anisocytosis present. Halometric index—4.8, size of red cells—7.17 $\mu$ , blood culture—positive to *B. typhosus*, Widal reaction—T, 'H' positive up to 1/125, blood hæmolyzed easily. Spectroscopically it showed bands, characteristic of oxyhæmoglobin. Blood taken for van den Bergh test and bilirubin content hæmolyzed on two occasions.

*Urine.*—Colour—brownish-red, reaction—acid, albumin—present, sugar, acetone, bile salts and bile pigments—nil. Occult blood test—positive. Microscopical examination—a few hyaline casts.

The patient gradually became more comatose and the cyanosis deepened. The respiratory rate went up to 44 per minute and pulse rate to 130 per minute. The temperature was maintained at 105°F. The patient died on 5th February, two days after admission into the hospital.

*Case 2.*—B. C. K., aged 22 years, male, was admitted on the 21st July, 1939, with complaints of swelling of the left inguinal glands for six days and high fever for three days. The patient, who came recently from Assam, had a rise of temperature up to 105°F. associated with swelling of the left inguinal glands and accompanied by headache, vomiting and rigor on the 19th July, 1939, at 5 p.m. An examination of the blood showed a leucocytosis of 10,750 per c.mm. with 78 per cent polymorphonuclear cells. No malarial parasites could be found. The patient took a tablet of prontosil rubrum at 6 p.m. and another at 10 p.m. on 20th July. Throughout the whole day and night, the temperature varied between 103° and 105°F. He was brought to the hospital next morning (21st July). His bowels were constipated. The patient had no quinine, atabrin nor purgatives.

*Condition on admission.*—Patient was semi-conscious and at times delirious. He was jaundiced and markedly cyanosed. Neck was slightly stiff. Kernig's sign positive. Pupils equal and reacted well to light. Eyes congested. There was a generalized flush all over the body. Deep reflexes sluggish. Tongue coated and dry. Abdomen soft. Liver and spleen not palpable. Heart sounds weak; pulse rate 120 per minute. Blood pressure 120 mm. of mercury. Temperature 104°F. Respiration 28 per minute. Lungs clear. Left inguinal glands swollen and tender. Penis, scrotum and testis healthy. On lumbar puncture 25 c.cm. of clear cerebrospinal fluid was drawn under moderately increased pressure. As there was retention of urine, the patient was relieved by catheterization and red coloured urine was drawn out.

*Laboratory reports.*—Hæmoglobin—80 per cent, red cells—4,200,000 per c.mm., leucocytes—15,600 per c.mm., polymorphonuclear cells—78 per cent, lymphocytes—20 per cent, monocytes—2 per cent, eosinophiles—nil,

malarial parasites—none seen, microfilaria—none found, coagulation time—6 minutes, bleeding time—4 minutes, halometric index—1.7, size of red cells—7.32  $\mu$ , platelet count—100,000 per c.mm., reticulocyte—2.2 per cent, partial hæmolytic commencing from 0.5 per cent saline and complete at 0.36 per cent. Blood urea—80 mgm. per 100 c.cm., non-protein nitrogen—64 mgm., cholesterol—130 mgm. per 100 c.cm., van den Bergh reaction and bilirubin content could not be done as the blood hæmolyzed. Spectroscopic examination—presence of methæmoglobin, agglutination reaction—negative to T. A. B. and leptospira, blood culture—no growth. The hæmoglobin per cent came down to 60 within the course of the next 24 hours.

Urine.—Colour—deep red, reaction—acid, specific gravity—1015, sediment—present, albumin—copious. Sugar, acetone, diacetic acid—nil, bile salts and pigments present, indican—nil, occult blood test—positive. Microscopical examination—a few pus cells, red blood corpuscles and epithelial cells. No casts seen. Spectroscopic examination of urine—presence of methæmoglobin.

Cerebrospinal fluid—clear, no white blood corpuscles seen in the centrifugalized deposits. Red blood corpuscles—a few seen in the centrifugalized deposit. Culture—no growth.

Progress of the case.—Patient gradually became more unconscious. His temperature remained high. Bladder had to be relieved by catheter and the bowels by enema. Later on he developed œdema of the lungs and died on the 26th July, the fourth day after admission into the hospital.

### Comments

It will be seen that in the first case, which was a severe attack of typhoid fever, prontosil was administered in moderate doses under a mistaken diagnosis of antrum trouble. The patient had taken altogether 7.5 gm. of prontosil album tablets and 30 c.cm. of 2.5 per cent solution of prontosil. The cyanosis first appeared on the seventh day after the administration of prontosil album was started, and two days after the drug was discontinued. The patient had not taken any purgative or articles of diet containing sulphur. It is true the patient had an exposure to short-wave diathermy one day prior to the commencement of prontosil therapy but it is very difficult to say if this exposure to diathermy had any relationship with the development of cyanosis. It is quite reasonable to believe that the cyanosis was due to the formation of a dark-coloured oxidation product of the drug itself, the patient being unusually susceptible to sulphanilamide and this susceptibility having been further intensified by a severe infection with *Bacterium typhosum*. Whatever might be the underlying factor responsible for the development of cyanosis, the most interesting point is the rapid hæmolytic of red cells resulting in hæmoglobinuria. In many infective diseases, specially when severe, hæmolytic of red cells may sometimes take place in susceptible individuals, giving rise to hæmoglobinuria and methæmoglobinuria. In the case under discussion the patient did not reveal any evidence of hæmolytic although his red cells had been sensitized by the powerful bacterial toxin till a certain concentration of sulphanilamide or its oxidation product in the blood had initiated the explosion, when rapid hæmolytic took place.

Moreover the hæmolytic of red cells might also help in the production of cyanosis, thus starting a vicious circle. Another interesting point in the case was high leucocytosis with increase in the polymorphonuclear neutrophils, a fact which is an unusual effect of the drug on the function of the bone marrow. One useful lesson which one may profitably learn from the study of the above case is not to indulge in indiscriminate use of sulphanilamide drugs in every case of severe infection, as the latter might serve as the 'last straw' and precipitate catastrophe.

The second case, in which the attending physician suspected streptococcal septicæmia superimposed on filariasis, is an example of extreme drug allergy resulting in the formation of methæmoglobin, rapid blood destruction, methæmoglobinuria and hæmaturia. There was a leucocytosis and the hæmoglobin came down quickly from 80 per cent to 60 per cent within 24 hours. Blood hæmolyzed easily and a spectroscopic examination showed bands characteristic of methæmoglobin. There was also considerable damage to the kidneys as the blood urea was raised to 80 mgm. per cent. Both hæmaturia and methæmoglobinuria were noticed. There must have been a great susceptibility on the part of the patient to sulphanilamide drugs as he developed cyanosis with hæmaturia and methæmoglobinuria after taking only two tablets of prontosil rubrum. These symptoms were noticed within 12 hours of the administration of the drug. Apart from the usual toxic effect of prontosil, viz. cyanosis, blood destruction with hæmoglobinuria is the unusual feature. Here also the severe degree of toxæmia, whatever might have been its origin, must have been the primary factor in producing a suitable soil for the subsequent damaging effect of the specific remedy. The destruction of red cells, however, was not so severe as in the first case.

### Summary

1. A brief résumé of the toxic symptoms after administration of sulphanilamide drugs has been presented.

2. Two fatal cases associated with cyanosis and a hæmolytic condition, hitherto unreported, have been described and the possible causes have been discussed. Hæmaturia and methæmoglobinuria were also noticed in the last case.

3. A note of warning has been sounded against indiscriminate use of the sulphanilamide group of drugs in every pyrexial condition.

It is a pleasure to acknowledge our thanks to Lieut.-Colonel J. C. De, M.R.C.P. (London), I.M.S., Superintendent, Medical College Hospitals, Calcutta, for his permission to publish the case notes. We are also indebted to Professor B. P. Tribedi, Professor of Pathology, Medical College, Calcutta, and Bacteriologist to the Government of Bengal, and Professor P. De, Professor of Physiology, for the various pathological and biochemical reports. Thanks are also due

# TREATMENT OF OPIUM ADDICTION WITH LECITHIN AND GLUCOSE AND ITS EFFECTS ON ABSTINENCE SYMPTOMS

By R. N. CHOPRA, C.I.E., M.A., M.D., Sc.D. (Cantab.),  
F.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S. (Retd.)

and

G. S. CHOPRA, M.B., B.S.

CAPTAIN, A.I.R.O.

(From the Department of Pharmacology, School of Tropical Medicine, Calcutta)

THE problem of addiction to opium in India has been the subject of considerable attention. This is due to the fact, that this habit is prevalent in certain parts of the country and is responsible for producing considerable impairment of the health and general prosperity of the people. It is for this reason that both preventive and curative measures have been the subject of consideration in various provinces with a view to eradicating the evil.

The authors for many years past have been interested in this problem and have evolved a method of treatment of opium addiction which has given satisfactory results in their hands as well as in those of others. A careful study of the withdrawal symptoms and the biochemical and biophysical changes in the blood was made in a large series of cases of opium addiction in the Carmichael Hospital for Tropical Diseases. All these individuals were males and a careful examination showed that they were not suffering from any other ailment of a serious nature before admission. In all cases the usual dose of opium was continued until the patients had become accustomed to their new surroundings and the hospital discipline. During this period the mentality of the patient with regard to the drug habit was carefully studied. It was made clear to him that in spite of all the treatment that he would receive, he may have to undergo considerable inconvenience and trouble from the symptoms which would follow the withdrawal of

the drug, and that his active co-operation was absolutely essential at every stage of the treatment. This took from two to five days. After the patient had got quite used to the new surroundings, the supply of opium was suddenly and completely discontinued with the full knowledge and consent of the patient. The ensuing abstinence symptoms were carefully and systematically observed and noted in each case, and efforts were made to combat them by different means. The blood of each addict was examined three times, firstly on admission, secondly during withdrawal and thirdly after the cure, for N.P.N., blood sugar, water content, lecithin and cholesterol content and blood urea.

## Biochemical and biophysical studies

Observations made by such workers as Sollier (1910), Maguin (1909), Pierce and Plant (1928) have shown that in addiction of long duration, general dehydration of the body takes place owing to excessive perspiration, abnormal salivation and obstinate diarrhoea. These facts strongly suggested to us that such a process of dehydration may have an ultimate effect on the fluid content of the blood. We, therefore, undertook to determine the changes in the physico-chemical properties or in the protein fraction of the blood in the addicts treated by us in the hospital. The present authors (1935, 1937) found that, in most of the cases, the state of addiction was invariably accompanied by an increase in the fluid content of the blood, and were inclined to believe that an excessive secretion on withdrawal will have a reverse effect, leading to an increase in the percentage of serum proteins.

The recent work of Chopra and Roy (1937) on the blood-lipoid changes in opium addicts before, during and after withdrawal, pointed to the probability of a diminution in the water content of the blood on withdrawal, which led Chopra and Ganguly (1939) actually to determine the effect of withdrawal on the blood fluid and also to explain, if possible, the rationale of the treatment of opium addiction with lecithin and glucose. Blood sera from the addicts under treatment were examined for total proteins before, during and after the withdrawal of the drug. In most of the cases it was found that concentration of proteins present in the serum before treatment underwent a definite increase during the withdrawal period and returned gradually almost to the pre-withdrawal value after the addict had undergone the prescribed treatment. The increase in the total protein content during the period of withdrawal, as a general rule, runs parallel to the appearance of withdrawal symptoms. Excessive outflow of water from the body causes one of the most marked withdrawal symptoms that have been observed in almost all the cases studied by us. This apparently points to a disturbance in the fluid equilibrium in general. The effect of treatment may, therefore, be taken to have

restored the fluid equilibrium of the system to its previous level.

Chopra, Mukherjee and Chopra (1935) observed that increase of the euglobulin fraction in the serum of addicts probably meant an ultimate drainage of phosphate from the nerve cells. Lecithin treatment was, therefore, suggested on that basis. In the majority of cases lecithin decreased the intensity of withdrawal symptoms and shortened their duration. But in spite of its administration, the abstinence symptoms were very severe in some of the subjects and in these cases intravenous injections of 25 c.cm. of 25 per cent glucose helped to ameliorate the condition. Although lecithin by itself was unable to cope with the severity of the withdrawal symptoms it doubtless removed the craving for the drug in the majority of cases.

The rôle of glucose, in coping with the abstinence symptoms, can thus be understood. By treatment the ultimate effect seems to be the restoration of the water balance. Therefore, any drug that confers a fluid-retaining power to the blood would be expected to have good effect. Carbohydrates in general and glucose in particular are known to possess this water-retention capacity. Glucose, therefore, in addition to stocking the liver with glycogen, to enable it to cope with the unusual strain on this organ during the process of elimination of morphine, helps the retention of water in the blood and keeps up the blood hydration level to its normal value. From the above considerations we may conclude that lecithin tones up the nerves of addicts by supplying the lipo-phosphates, and glucose helps to restore the disturbed water balance. It is therefore not difficult to see how these two together produce the desired effect in removing the drug craving and alleviating abstinence symptoms in opium addicts.

#### *Treatment of opium addicts with lecithin and glucose*

In view of the above biochemical and biophysical findings it was possible to evolve a method of treatment of opium addiction with lecithin and glucose. Briefly the method is as follows :—

On the evening before the treatment is started, the patient is given a dose of calomel (2 to 3 grains), followed by a saline purgative the next morning. The drug is then suddenly and completely withdrawn and the patient is watched for the development of withdrawal symptoms, which in the majority of cases start on the same day and attain their maximum within 24 hours. The actual treatment was formerly started when the withdrawal symptoms became intense and unbearable, in order to study the biophysical and biochemical changes which are produced in the individual during this period. Lately it has been found distinctly advantageous to start lecithin and glucose the day before opium is withdrawn so that the inconvenience to the patient is reduced to a minimum.

Lecithin (Ovo lecithin, Merck) is given by the mouth in form of pills containing 5 to 20 grains three times a day, and continued usually for five consecutive days. In a number of patients lecithin by mouth causes nausea, and in such cases, the drug may be given in the form of a colloidal solution by injection, the usual dose being 2 c.cm. of 1 per cent solution, twice daily. Experience has shown that lecithin, when given by injection, acts better than when it is given by the mouth. Besides this, the amount required to produce the desired effect is comparatively small and consequently the cost of treatment is considerably reduced. During the period of abstinence the patient is encouraged to take plenty of fluids and glucose by the mouth, as these greatly ameliorate the symptoms of withdrawal.

There is no doubt that in the majority of cases lecithin decreases the intensity of the withdrawal symptoms and shortens their duration. In spite of its administration in some of the patients the abstinence symptoms were severe and in these cases intravenous injections of 20 c.cm. of 25 per cent glucose as well as glucose by the mouth greatly helped to ameliorate the condition. These are given with a view to stocking the liver with glycogen, and in order to enable it to cope with the strain, which no doubt falls on this organ, during the process of elimination of morphine and other alkaloids of opium from the system. We usually give an intravenous injection of glucose every morning for the first three or four days, and if necessary repeat it in the evening when the symptoms are severe. The injections are then stopped and glucose, if still required, is given by the mouth. In severe cases attended with cramps it was found that addition of 10 c.cm. of a 10 per cent solution of calcium gluconate to the glucose solution given intravenously helped greatly in ameliorating this symptom. No other drug is necessary during this period except a brisk saline purgative every morning to help in the elimination of the alkaloid through the gastro-intestinal tract. No further treatment as a rule is required after the first week.

The diet during this period is light because patients, as a rule, cannot take much on account of the gastro-intestinal disturbances produced by the withdrawal. Glucose, milk, and fruit juices are given freely by the mouth for the first two or three days during the withdrawal period. On the fourth day, when the abstinence symptoms begin to disappear and the appetite returns, a diet rich in proteins and lecithin in the form of eggs, milk, beans, fish, chicken, fruits, bread and butter is given.

After the completion of the actual treatment, that is after the complete withdrawal of the drug has been effected, the patients are kept under observation in the hospital for a fortnight or more. A twenty-four hours' specimen of urine is examined for the presence of morphine, in order to see if any of the patients are taking

the drug secretly. In the ordinary course of events the alkaloid can be detected in the urine for four to five days after the withdrawal of opium; after that it cannot be detected except in rare cases where excretion is prolonged. If, therefore, after this period the alkaloid was still found, the presumption was that the patient was taking the drug. If repeated examinations of the urine show the absence of alkaloids it was concluded that the drug was no longer being taken and the habit is cured\*.

On the second day of the actual treatment, most of the patients report that the discomfort had decreased by half. When seen a few weeks after the treatment, many report that the drug had lost its taste and charm and in some cases very small quantities of it produced the sensation of nausea. The treatment undoubtedly

\*For the detection of morphine in the urine the method of Deckert (*Klin. Woch.*, 15, 697, 1937) was followed:

Ten c.cm. of the urine is heated with 0.3 gm. of  $\text{Na}_2\text{CO}_3$  until the first bubbles rise and is then quickly cooled. It is then transferred to a separating funnel and thoroughly shaken with 10 c.cm. of acetic ether. After the layers have separated, the acetic-ether layer is transferred to a small porcelain dish through a filter-paper and evaporated to dryness on a water-bath. The residue is diluted in 0.25 c.cm. of water with one drop of nitric acid (sp. gr. 1.15) and a drop of 10 per cent ammonium molybdate solution added. After careful whirling of the porcelain dish, the contents are filtered through a compressed cotton plug placed in the upper part of the neck of a funnel. The dish is rinsed with two successive quantities of water (0.25 c.cm. and 0.15 c.cm.) which are passed through the filter. The cotton plug is then pressed down to the lower opening of the funnel, so that no filtrate remains in the funnel. A drop of 2 per cent solution of ammonium vanadate is then added and well mixed. A turbidity develops, depending on the morphine content.

gave rise in a number of cases to a definite feeling of aversion for the drug, whether by smoking or by the mouth, and the craving for the drug was stopped and cure was effected.

In order to effect a permanent cure a complete overhaul of every patient was carried out with a view to determining if any septic or toxic foci were present in the body, as morbid conditions of this kind are a common cause of opium addiction in this country. If routine laboratory examinations revealed such conditions as dysentery, sprue, helminthiasis, sinusitis, conjunctivitis, etc., these were treated during the period of observation after treatment.

The mental outlook of the addict also showed a remarkable change. After the treatment the persons who were sad, morose, apathetic and who had pale and sallow complexion, became cheerful, ate well, improved in general health and put on weight. They became more sociable, docile and respectful and showed inclination to do their ordinary work. They now felt interested in their surroundings and were observed to be more active than other patients in the hospital. After discharge from the hospital, it was ascertained that most of them had become useful members of society and followed their vocations with interest.

#### *Abstinence symptoms*

We will now briefly describe some of the chief abstinence symptoms met with in the patients treated in this series and how these were controlled.

#### *Nervous and psychical disturbances*

A perusal of table I will show the nature, frequency and course of the common nervous disturbances, which were encountered in this

TABLE I

*The nervous and psychical disturbances in a series of 200 opium addicts on sudden withdrawal of the drug*

Symptoms	Frequency, per cent	Time of onset	Time of maximum intensity	Time when they disappeared	Remarks and symptomatic treatment if necessary
1. Yawning, lassitude, general depression and restlessness.	95	1st day	3rd and 4th day.	4th day	Mixture containing iron and strychnine is helpful if they persist after 4th day.
2. Cramps and pains in limbs.	80	2nd "	3rd day	5th "	Calcium gluconate intravenously, massage, glucose by mouth, aspirin, barbiturates.
3. Headache ..	50	3rd "	4th "	7th "	Aspirin and barbiturates are helpful.
4. Paræsthesias ..	15	3rd "	5th "	7th "	Bromides, valerian and calcium are helpful.
5. Tremors of hands ..	6	3rd "	5th "	7th "	No special treatment required.
6. Emotional disturbances, feeling of impending death, melancholia.	15	3rd "	5th "	10th "	Occupational therapy.
7. Insomnia and nervous excitability.	80	1st "	3rd to 5th day.	10th day after.	A very troublesome symptom, yields to hot foot bath before retiring, massage, barbiturates, liquid extract of <i>Rauwolfia serpentina</i> in 10 to 15 minim doses every night.

series after complete and sudden withdrawal of the drug.

#### *Digestive disturbances*

The effects on the alimentary system are severe when the patient is taking the drug in large doses. The results of analysis of various symptoms pointing to the derangement of the digestive organs have been summarized in table II.

showed any remarkable abnormality except in one case in which signs and symptoms of serious heart block were observed on withdrawal of the drug. This gradually disappeared after a week and no special treatment was necessary except the usual administration of glucose intravenously.

The total course of treatment varied from 7 to 12 days and during this period the change in the condition of the addicts was remarkable.

TABLE II

*The digestive disturbances produced in a series of 200 opium addicts on sudden withdrawal of the drug*

Symptoms	Frequency, per cent	Time of onset	Time of maximum intensity	Time when they disappeared	Remarks and symptomatic treatment if necessary
1. Anorexia and distaste for food.	80	2nd day	4th to 5th day.	8th to 10th day.	No special treatment necessary.
2. Epigastric pain and abdominal disturbances.	28	3rd "	4th to 6th day.	8th day	No special treatment necessary and if they persist after 8th day may be due to intercurrent diseases such as hookworm, or chronic bowel infection, etc., which should be properly diagnosed and treated.
3. Diarrhoea ..	45	2nd "	3rd day	5th "	No special treatment necessary.
4. Nausea and vomiting	38	2nd "	3rd "	6th "	Ice to suck and 10 drops of adrenaline hydrochloride (1 in 1,000) sublingually.
5. General abdominal discomfort and pain.	18	4th "	6th "	14th "	Keep bowels open with purgatives. Lavage of the stomach.

#### *Disturbances of body secretions*

General imbalance of secretions of the body is a very common phenomenon after withdrawal of opium. The symptoms observed under this heading have been tabulated in table III.

The patients treated in the hospital were kept under further observation for a period varying from 4 to 12 weeks in order to rehabilitate and train them to the new environment, and to watch for any relapse occurring. The

TABLE III

*The imbalance of general secretions of the body as seen after withdrawal of the drug in 200 opium addicts*

Symptoms	Frequency, per cent	Time of onset	Time of maximum intensity	Time when they disappeared	Remarks and symptomatic treatment if necessary
1. Running of the nose and sneezing.	70	1st day	3rd day	5th day	If these persist after the 5th day, an examination of the nasal cavities and accessory sinuses may reveal some pathological condition, which may be radically treated by operation or by general treatment.
2. Lacrymation ..	55	Few hours	2nd "	4th "	If these persist then treat the cause, <i>i.e.</i> , blepharitis, trachoma, opacities, etc.
3. Salivation ..	20	1st day	3rd "	6th "	No treatment necessary.
4. Sweating ..	10	2nd "	3rd "	7th "	Do.
5. Spermatorrhœa ..	5	4th "	6th "	7th "	Bromides.

#### *Cardio-vascular system*

Electrocardiographic examinations of patients were made before withdrawal, during withdrawal and after treatment. None of them

period of rehabilitation and rebuilding of the personality of an addict may sometimes extend to a few months, according to the personality of the addict.

### Results of the treatment

The results obtained in the special hospital series are given in table IV.

Table IV shows that complete cure was effected in 70 per cent of this series. The dose was reduced by 80 per cent in 10 per cent, and by 50 per cent in 15 per cent of cases. The treatment failed completely in 5 per cent of the series, and there was a relapse to the habit in the remaining 5 per cent. Thus it appears that the results are more encouraging (i.e., 70 per cent cure) than with any other forms of treatment which have so far been tried in this country.

It may be of interest to state that in April last the senior author was requested by the Government of Assam to help and advise them in connection with the opium prohibition campaign which was being started there and he deputed the junior author to go and work in the field. Before actually starting the campaign a large number of medical men were trained in the method of treatment with lecithin and glucose and over one hundred treatment centres were established in the Upper Assam Valley, where prohibition was to be started. During this campaign nearly 12,568 addicts were successfully treated.

### Summary and conclusion

On the basis of the biochemical and biophysical investigation into the blood of opium addicts it has been possible to evolve a new method of

### RADIOLOGICAL APPEARANCES OF THE HEART AND LUNGS IN CASES OF HYPERTENSIVE HEART FAILURE\*

By RUSTOM J. VAKIL, M.D. (Lond.), M.R.C.P. (Lond.),  
D.T.M. & H. (Lond.), F.R.F.P.S.G.

*Honorary Assistant Physician, J. J. Hospital, and Tutor,  
Grant Medical College, Bombay; sometime First  
Assistant, Heart Hospital, Liverpool*

A FLUOROSCOPIC examination of the chest is frequently rewarded by valuable information, in cases of high blood pressure. It was with a view to gaining further insight into the radiological problems associated with hypertensive heart failure that the present investigation was undertaken.

A large number of cases of high blood pressure with signs of cardiac failure have been examined fluoroscopically, in order to determine radiological appearances, characteristic of this type of case. In order to determine the exact shape of the heart and the cardiac measurements, thirty-five cases of hypertensive heart failure were subjected to orthodiagraphy; in some of these cases, teloradiograms were also taken. Investigations were limited to subjects

\* Working with the aid of a medical research grant from the trustees of the late Sir Ratan Tata.

12,000 addicts, with very good results. The cost of the treatment is reasonable.

TABLE IV

Results of treatment in a series of 200 opium addicts

treatment of opium addiction. Its effects upon different withdrawal symptoms have been discussed. It would appear that the central nervous system and the digestive system bear the brunt of this addiction and the symptoms produced during the abstinence period are greatly modified and ameliorated by this treatment. The course of treatment varies from 7 to 12 days. The results of the treatment are very encouraging and better than other forms of treatment tried by us. This treatment is suited for mass treatment and has been successfully used in a campaign in Assam in a series of over

ranging in age from forty to seventy; the systolic pressure in no case was under 160 mm. of mercury, while one or more signs of cardiac failure, either 'left-sided' or 'right-sided' or both, were present in all cases selected for detailed investigation.

The impressions gained from this clinical material have been incorporated in the present paper; a much larger series of cases must be investigated before assuming the following deductions as representative of hypertensive heart disease, in general.

#### *Radiological appearances*

For the sake of simplicity, the radiological appearances of the heart, aorta and lungs in hypertensive heart failure are considered separately.

*Cardiac silhouette.*—At first sight, there appears to be no constancy about the size or shape of the cardiac silhouette in such cases. Closer inspection, however, permits classification of the silhouettes into certain distinct types. I have come to recognize five main types of cardiac silhouette in these cases:—

(1) In a few of the cases, there is no apparent abnormality of the cardiac silhouette, either in shape or size; the cardiac contours appear normal on inspection; measurement of the various diameters of the heart reveals no abnormality. Such a perfectly normal silhouette is compatible with hypertension of even moderate severity and long standing. One of my male patients, aged 60, has had a systolic blood pressure over 200 mm. of mercury for more than five years, and yet his heart is normal, both clinically and radiologically. A woman of about 50 was observed over a period of six months, at the Liverpool Heart Hospital, with a pressure persistently fixed at 300 mm. of mercury and yet at no time was there any indication of cardiac enlargement, clinically or radiologically.

The degree of enlargement of a heart is no guide to the height of the blood pressure in a given case; for instance, severe grades of cardiac enlargement are not infrequently seen with pressures of 160 or 180 mm.; conversely, cases with pressures well over 200 mm. have shown little or no enlargement of the heart.

A heart that is normal radiologically is not necessarily normal pathologically, for minor degrees of hypertrophy are not detectable even by expert radiologists. According to White (1931) an increase of as much as fifty grammes in the weight of the heart may pass undetected radiologically.

The presence of a normal cardiac silhouette in cases of severe or long-standing hypertension may be explained along the following lines:—

(a) The high blood pressure may be of too short a duration; one should realize that hypertrophy of heart muscle is a slow process taking weeks or months to develop; also, that hypertrophy in the early stages causes no change in the contour of the heart, and hence escapes

detection. This line of reasoning, however, fails to explain the great majority of cases, where the high pressure has existed for more than a few weeks.

(b) If the heart be small to begin with, of the type known as the 'hypoplastic', 'vertical' or 'drop' heart (frequently observed in individuals prone to tuberculosis), then increase in size will not be apparent for some considerable time after the onset of hypertrophy. It may be months or even years before the hypertrophy becomes detectable, radiologically, in such cases.

(c) If the hypertrophy of cardiac musculature, in cases of hypertension, be limited to certain sections of the heart only, then it may remain undetected for some time after its onset. The investigations of Kireh (1930) show that in the early phases of hypertension, hypertrophy of the left ventricle is not diffusely distributed but remains confined for some time to the 'outflow tract' of that chamber (i.e., that region of the left ventricle which extends from the apex to the aortic orifice). Even within the confines of the 'outflow tract' itself, hypertrophy starts first in the terminal portion, that is at the aortic end of the tract rather than at the apex.

Since the region of the 'outflow tract' adjacent to the aortic orifice (i.e., the site of early hypertrophy) does not form part of any border of the cardiac silhouette, lack of demonstrable enlargement of the heart in the early phases of hypertension becomes understandable. The only alteration in the silhouette, in such cases, is in the nature of 'elongation' of the heart, with the apex over-riding the diaphragmatic contour.

Out of a total of thirty-five cases, investigated from the point of view of heart size, five showed perfectly normal cardiac silhouettes.

(2) The 'duck-shaped' or 'boot-shaped' heart (figure 1). This was observed in just over

Fig. 1.—'Duck-shaped' or 'boot-shaped' heart.

a third of the cases studied. It represents a local or preponderant hypertrophy of the left ventricle. The main features of such a cardiac silhouette are: (a) A 'rounding of the cardiac apex'; this has been attributed to hypertrophy of the apical portion of the 'outflow tract'. (b) The lower portion of the left border of the heart becomes more rounded or outwardly convex than normal. (c) The most lateral point of the left border of the heart is situated on a much higher plane than normally. (d) The

In nearly-all fever cases, on admission to hospital, blood culture was taken as a routine. Media used were glucose broth and bile salt media. From  $1\frac{1}{2}$  to 2 c.cm. of blood from the patient was added to each of the above media at the bedside and incubated for at least 5 days (in some cases up to 10 days) before declaring them 'negative'.

#### Blood smear examination

(a) Out of 56 cases, a blood smear was examined in 55 for malaria parasites and differential leucocyte count. Only one case showed mixed infection of benign tertian malaria and typhus fever.

(b) Differential leucocyte count:—Polymorphonuclear cells ranged from 60 to 82 per cent. Lymphocytes counted from 16 to 32 per cent. Large mononuclear cells ranged from 1 to 8 per cent (excepting the case with infection of malaria which gave 9 per cent). Eosinophiles counted from 0 to 5 per cent.

#### Weil-Felix reaction and Widal test

Sera of patients were put up for these tests according to history and provisional diagnosis, and repeated if necessary.

#### Technique in brief

Concentrated alcoholized suspensions of OX19, OX2, and OXK for Weil-Felix reaction and dead emulsions of T. 'H', Para A 'H' and Para B 'H' and concentrated alcoholized suspension of T 'O' for Widal tests were used. These suspensions and emulsions were obtained from Kasauli. All sera were tested against OX19 and OX2 as a routine and if both gave negative results combined with negative results in Widal test, the sera were put up against OXK.

Routine dilutions of sera put up in both tests were in 1 in 25, 1 in 50, 1 in 125 and 1 in 250 with controls. In some cases further tests with higher dilutions were also put up.

Dreyer's tubes were kept in a water-bath at 52°C. for 4 hours and then in an incubator at 37°C. for 15 to 20 hours. Readings were then taken by the aid of Dreyer's comparator with lamp. Before decisive readings were taken, sediment at the bottom of each tube was disturbed from the higher to the lower dilutions to distinguish true agglutination from mere sedimentation. To express the results in standard agglutination, Dreyer's reduction tables were used.

A patient whose serum gave standard agglutination of any of the three proteus strains at least in 1 in 125 dilution combined with other findings, clinical and laboratory, has been included in this series of typhus fever, while cases giving positive standard agglutination in lower dilution than 1 in 125 are not included.

The commonest local strain in Bangalore is proteus X19 but a few cases of OX2 are also met with.

#### Result of Weil-Felix reactions

Proteus strain	Number of cases	Percentage positive
OX19 ..	50	89.3
OX2 ..	5	8.9
OXK ..	1	1.8 (imported case)
<b>TOTAL ..</b>	<b>56</b>	<b>100.0</b>

#### Results of Widal tests

Total number of cases tested ..	56
Number of cases negative ..	42

The remaining 14 cases showed agglutination of one or two enteric organisms either in 1 in 50 or lower dilutions.

#### Urine and stool culture

In 17 cases cultures of urine and stools were done and, in each of these, 3 specimens of urine and stools were cultured on 3 consecutive days after the temperature returned to normal. So, 51 urine and 51 stool cultures were done, and all were negative as regards enteric and proteus group of organisms.

#### Wassermann reaction in typhus cases

Stott (1935) cited a case showing a strongly positive Wassermann reaction during the febrile stage, and negative during convalescence and later without any antisyphilitic treatment. The question arises whether a certain percentage of typhus cases like those of malaria do show positive W. R. or not? Sera of 25 definite cases of typhus during the febrile stage were tested for W. R. In 24 cases the reaction was negative but in one case it was positive (W. R. +), becoming negative during convalescence, showing that there is a possibility of a typhus case giving positive W. R., though only during the febrile stage.

#### Symptoms

1. *Temperature*.—Onset is nearly always sudden with headache and rigor. In most cases it is continuous and remittent, but in a few even intermittent.

The following table gives the duration of all the cases:—

Duration in days	Number of cases	Duration in days	Number of cases
8	1	16	6
11	5	17	5
12	5	18	1
13	12	19	1
14	7	27	1*
15	12	* Complicated by pneumonia and recovered.	

In 93 per cent of cases the duration of fever is 11 to 17 days and the extremes are 8 to 19 days.

The fall is usually by lysis and in some cases the temperature takes a week or so to settle down to normal.

#### Other symptoms

**Rash.**—Roseolar rashes appear almost all over the body, mostly over the chest, back, palms, forcarms, and soles. Twelve out of this series (all of whom had fair skin) showed typical rash, but it is always difficult to decide about the rash in dark-skinned persons.

**Bronchial symptoms.**—The respiratory tract is not found to be involved as a rule, as some authorities believe, but bronchial symptoms are fairly common. Twenty-four, i.e., about 43 per cent of the cases, suffered from cough and other bronchial symptoms and signs, and 1 case developed pneumonia but recovered.

#### Diagnosis

All cases were diagnosed on the clinical symptoms and signs along with Weil-Felix reaction. Cases whose sera agglutinated any of the three strains either in a dilution of 1 in 125 or over were diagnosed as typhus fever.

#### Prognosis

It is good; and no death was recorded in this series of cases. Hyperpyrexia, toxæmia, and complications such as broncho-pneumonia were noticed.

#### Treatment

There is no specific treatment for the disease. Symptomatic treatment with good nursing always proved enough to bring about cure.

#### Discussion

It was suggested by Lieut.-Colonel Hance, I.M.S., the residency surgeon, that fever cases, whose sera do not agglutinate *B. typhosus* and *B. paratyphosus* A, and agglutinate *B. paratyphosus* B only, though in a low dilution, along with negative blood cultures, but otherwise running a course like those of enteric fever may be typhus cases. This view was confirmed by subsequent laboratory tests and about 2 cases a month were diagnosed in these two hospitals as 'typhus fever'. Apart from this there are likely to be more victims who did not come to these hospitals and were treated by local medical practitioners.

From the fact that only one case was notified before this work was taken up, and from talks the writer has had with private practitioners in Bangalore during these years, it was stated that the existence of the disease with which most of them are now familiar was not known to them before. It is recommended, therefore, that blood of continuous fever cases should not only be tested for Widal reaction but also simultaneously for Weil-Felix reaction against proteus X19 and X2 as a routine.

The most important factor in the diagnosis of typhus fever is the Weil-Felix reaction. It is found that some sera from non-typhus fever

## COMMON COLD RESPONSIBLE FOR GRAVE SUSPICION OF RABIES IN THE DOG AND A DISCUSSION ON ASSOCIATED CONSIDERATIONS INCLUDING RABIES IN MONGOOSES AND BATS

By S. D. S. GREVAL

LIEUTENANT-COLONEL, I.M.S.

The School of Tropical Medicine, Calcutta  
and

M. J. NICHOLAS, I.M.D.

The Pastur Institute, Calcutta

THE intention is (I) to describe observed cases and give crucial points in the differential

(Continued from previous column)

cases do agglutinate proteus strains in low dilutions, but never higher than 1 in 100. So, it is safe to diagnose a continuous fever case as typhus whose serum has agglutinated any of the strains in 1 in 125 dilution or higher. In doubtful cases Weil-Felix reaction should be repeated after a few days to find any rise in titre.

#### Summary

1. Fifty-six cases of typhus fever were diagnosed and treated in the Bowring and Lady Curzon Hospitals, Bangalore, during 1936, 1937 and 1938.

2. Incidence.

(i) All ages above 8 years, mostly adults, have suffered.

(ii) Both sexes, mostly males, were the victims.

(iii) The disease prevails in all communities, but mostly among the poor.

3. In Bangalore typhus is more prevalent (i) during spring and autumn and (ii) in the thickly populated areas.

4. The nature of vector of disease in Bangalore is still to be investigated.

#### Acknowledgments

My thanks are due to Lieut.-Colonel J. B. Hance, I.M.S., for valuable suggestions and permission to publish this article. It is my pleasant duty to acknowledge the help and co-operation rendered by the staffs of the pathology department and the Bowring and Lady Curzon hospitals, particularly to Dr. A. St. C. Bartley, Dr. M. R. Sirsi and Dr. Ramchandra Rao.

diagnosis of rabies, (II) to recommend a line of prophylaxis for humans who have been bitten or have come into contact with the saliva of a suspicious dog of the kind described, (III) to comment on isolation *versus* destruction of the dog and (IV) to add a note on mongooses and bats as carriers of rabies.

### I. Observed cases

(i) *A case recently observed.*—A male dachshund, aged 4 years, belonging to one of the writers (S. D. S. G.) was observed on 19th March, 1940, to have congested eyes. The right eye was kept partly closed. Minor injury was suspected and eye drops (zinc sulphate 0.25 per cent) instilled. In holding the dog for the drops it was observed that the nose was full of mucus which was discharged by sneezing immediately after the drops. This occurred in the evening and the dog retired as usual to his basket on the verandah on the ground floor. He was quieter than usual during the night.

Next morning, he showed signs of malaise and weakness. Nose was hot and dry. Stairs were negotiated deliberately instead of with a bounding rush and a position in the sun on the top verandah (usual in winter) sought. Warm milk with sugar was given. Condition appeared to improve. The usual daily food (bones with meat and *chapati*) was refused. Evening stroll was not allowed.

On 21st no change for the worse was observed. The weakness had disappeared.

On 22nd milk and sugar diet was given during the day and fried liver (a weekly ration) at night. No stroll was allowed. The dog was observed to pass large quantities of water standing on all fours like a puppy, in the compound.

On 23rd at midday it was observed that the dog could not close its mouth and that after drinking water the last lap of water flowed out of the mouth together with frothy saliva. He was isolated on the top verandah and on being left alone showed unusual restlessness. By 4-30 the mouth was open, copious froth appeared with attempt at drinking water and ropy saliva was hanging from the angles of the mouth at rest. The second writer saw the dog at this stage. Provisional diagnosis of rabies was made and the dog secured, by a strong double rope tied to the verandah railing, for further observation.

Points for the diagnosis were: (i) dropping of the jaw, (ii) foaming at the mouth and thick ropy saliva, and (iii) a slight restlessness.

Points vitiating the value of the above points were: (i) although the jaw was dropped, the tongue was normal in colour and action, (ii) foaming at the mouth occurred only with drinking water, (iii) the restlessness was not marked and was due to confinement, (iv) sleep was normal, and (v) bark and growl were normal.

Points definitely against the diagnosis of rabies were: (i) no alteration in the familiar gaze, (ii) no movements indicative of muscular inco-ordination, (iii) no ferocity, and (iv) no weakness anywhere excepting the lower jaw. Importance of individual peculiarities of movements must here be mentioned. The dog always lifted a leg when moving fast and dragged his hind quarters when moving a few inches (suggestive of dumb rabies in a sick dog seen for the first time).

History of a dog bite was negative; of a probable mongoose bite, diagnosed from the shape of the bite and the presence of a wild mongoose in the locality over a year ago, positive; and of a bat bite a few days previously possible on account of an angular bleeding scratch (likely explanation, however, being ends of wires in the garden). Both wild mongooses and bats are seen very close to the house.

The second writer at this stage remarked that his dog had shown the same symptoms last year, about the same time, for two days.

No stool or urine was passed this day. Lightly fried liver cut into small pieces was greedily devoured. Two

pieces bigger than the rest were ejected with a short cough but ultimately chewed with great exertion and swallowed. On the ejected pieces curdled milk was seen. Evidently there was a stasis of food in the pharynx.

A short stroll was arranged, and the dog passed urine. On 24th morning the condition was unaltered. The question of commencing prophylactic treatment for the family and the servants was considered.

By evening the condition was improving. Although foaming at the mouth appeared with drinking, there was no flow of saliva otherwise. The mouth was not open to the same extent. The idea of commencing the prophylactic treatment was shelved. The dog was taken out for a stroll. Stools and urine were passed. Diet of milk and liver was continued.

On 25th morning the condition was found to have improved further. There was no foaming when the dog drank water. The process, however, was very slow and the water was made opalescent and tinged salmon-pink. Even big pieces of fried liver were greedily devoured.

During the day a tailor remarked that he had recently seen at Shamnagar near Barrackpore, dogs which were foaming at the mouth like mad dogs but not biting anyone. It was now decided to call in a veterinary surgeon to obtain information on the prevailing diseases.

In the evening a veterinary practitioner of experience was called. He stated that the condition was due to a chill. He had treated a few days previously two newly-imported dogs suffering from the same condition. The pathology of the condition was inflammation of the sub-maxillary glands which interfered with the elevation of the jaw. When asked to confirm by palpation he did so. No external swelling, however, was visible and the dog did not give any indication of pain when the palpation was done. Salicylates or tincture of iodine internally was recommended. In the opinion of the veterinary practitioner the evidence was 99 per cent against rabies.

On 26th the condition was found to have improved still further. Difficulty in drinking water still persisted. The water was still rendered opalescent and tinged pink. The deposit from the water gave the chemical test for blood and consisted of granular debris, epithelial cells, and an abundance of mixed flora.

Tincture of iodine (B. P.) 2 minims inside a butter bolus was given.

All semi-solid and even solid food was readily swallowed. Milk was refused and water preferred.

On 27th improvement continued. The dog in spite of at least 8 days' illness appeared neither weak nor thin. The diagnosis of rabies was given up.

On 28th the dog was discharged from isolation.

All usual habits were quickly resumed.

### (ii) Previously observed cases recalled.—

Three other cases have been included in the foregoing description. They are one Calcutta-bred wire-haired terrier belonging to the second writer and two imported great danes seen and treated by the veterinary practitioner. Then there were the dogs observed by the tailor at Shamnagar near Barrackpore Bazaar and village information in rabies is not unreliable. The ownerless dogs are not without keepers altogether. They are many peoples' common pets and a marked change in them is bound to be noticed by someone. This is especially true of the village dogs.

### II. A line of prophylaxis for humans who have come into contact with suspicious dogs of the kind described

The prophylaxis planned in the present case represents the writers' recommendation. Three

subjects were considered for antirabies treatment: (i) the first writer who had a ruptured blister on the sole of one foot and might have trodden bare-footed on a spot of saliva on the floor of his bedroom on 23rd March before the dog was isolated; (ii) his son under 3 years of age who in the garden threw a handkerchief into a collection of water from which the dog had drunk, picked it up and then dropping it under harshly given instructions put his fingers in his mouth in embarrassment (entry of dog's saliva into the mouth); and (iii) a servant who was particularly friendly with the dog. None of these subjects were bitten. The third subject had neither blisters nor swallowed the dog's saliva yet his close association with the dog made it possible for the saliva to come into contact with a not readily visible breach in his skin. The first writer has reported a death from rabies in a victim to whom prophylactic treatment was not given because no visible breaches in his skin had been found, and cited other instances (Greval, 1936). A death is occasionally reported even in treated cases of class I (licks only). Two such deaths appear in the Annual Reports of the Pasteur Institute of India, Kasauli, for the last two years (Smith, 1938; Webster, 1939). A statistically-inclined reviewer, opposed to giving treatment when the skin is unbroken (no obvious bite or wound, S. D. S. G.), called the writer's case 'unfortunate' (McKendrick, 1936). The League of Nations Report on Rabies (Marie *et al.*, 1927) leaves open the question of treating licks. A textbook on medicine with a section on rabies written by a medical man with Indian experience definitely discredits treatment as superfluous for licks without obvious bites or wounds. With such views and advice the writers' opinion is definitely at variance. They hold that the infection depends more upon the infectivity of the rabid animal than upon the severity of the bite or the susceptibility of the bitten animal. That is why the infection rate in different batches of bitten humans and animals varies from *nil* to 80 or 90 per cent (Harvey and McKendrick, 1923). A capricious variation in the infectivity alone is much more likely than in both the severity and the susceptibility. The well-known fact that every strain of street virus, proved to be so clinically and microscopically, does not succeed in passage, strengthens this hypothesis. This statement has been repeated from a previous publication (Greval, 1936) in view of the difference in opinion and of the risk run by those who are refused treatment. Cases of licks by definitely rabid animals *must* be treated as cases of medium severity at least.

Had the dog got progressively worse, weakened and died of the disease he was suffering from in a few days, and the brain been examined for Negri bodies and found negative, should the three subjects at risk have been given treatment? In the writers' opinion, yes. A negative microscopical finding should not interfere

with clinical finding or presumption, when the result would be fatal. Development of the Negri body is a gradual process and the dog may die before it is developed.

Could the dog have had an abortive attack of rabies from which he has recovered but which made him infective? Such a possibility cannot be ignored. It has been known since Pasteur's time (Marie *et al.*, 1927). The points against the diagnosis of abortive rabies are: (i) there was no mental change or neuro-muscular weakness, apart from the one suggested by the open mouth, and (ii) three other dogs suffered from similar symptoms and recovered (recovery from rabies is an extremely rare event).

The possibility of recovery from rabies and the consequent latency of infectivity was perhaps given more importance than it deserves by the International Rabies Conference of 1927 when it recorded 'Hitherto doctors, veterinary surgeons and laymen have been unanimous in asserting that there is no danger of rabies if the biting animal is still alive. This view is entirely erroneous . . .' (Marie *et al.*, 1927). In Indian experience the well-known rule that there is no risk to the contacts if the dog is alive and well for 10 days after the contact, followed at all the Pasteur institutes and antirabies centres in India, has worked very well (Shortt, 1933). The first writer remembers a dog which died on the 11th day of observation and was proved to be rabid microscopically. It was not, however, well on the 10th day (*alive and well* should go together).

Reports have been received of deaths from hydrophobia in subjects bitten by dogs which were healthy when the subjects died. The culpability of such dogs, however, has remained not proven. The following account is quoted from the last Annual Report of the Pasteur Institute of India, Kasauli (Webster, 1939).

'An interesting case of hydrophobia was reported from Faridkot centre. A man developed hydrophobia two months after being bitten by a dog which was quite healthy when the patient developed the disease and died. On an enquiry being made from the Chief Medical Officer, Faridkot State, as to whether there was another possible source of infection he writes:—

"Although there is no definite history of his having been bitten by any other dog but this cannot be excluded."

### III. Isolation versus Destruction

Authorities frequently issue orders which make it appear that securing and destroying a dog supposed to be rabid are of the same value. This definitely is not the case. By destroying a suspected animal, *before* the Negri body has developed, the suspicion may never lead to a positive microscopical finding of rabies. The negative microscopical finding will lead to (i) many medical advisers not recommending treatment, (ii) many cases at risk not taking

treatment, and (iii) many cases taking treatment half-heartedly. The opposite danger also exists. A dog like the ones described and cited may be regarded as rabid and killed, and quite a large number of people given treatment needlessly. Apart from inconvenience, expense and waste of time, the treatment is not altogether devoid of sequelæ.

Securing a dog, particularly a pet dog which is not already suffering from furious rabies, is not difficult. Observing it in the home, in a veterinary hospital or in an antirabies clinic is not difficult either. In the home a deep verandah, a long strong rope which can be doubled (a clothes-line will do) and plenty of phenyle are all that is necessary. If the dog turns out to be definitely rabid it can be held in the middle of the long rope made taut and tied to two posts or pegs. It can even be taken out for a limited stroll between two men.

#### IV. Mongooses and bats as carriers of rabies

When attention was drawn to rabies in the mongoose in India (Greval, 1932, 1933) it was stated that, according to Blanford (1891), *Herpestes* Illiger was the only generic type known within the Indian area; he recognized eight species. For a time the generic name *Herpestes* Illig. was replaced by *Mongos*, Geof. and Cuv. and all Indian mongooses were referred to it (Wroughton, 1918), but later *Herpestes* was again revived for the Indian forms (Thomas, 1921). At present, ten species and ten varieties of Indian mongooses are recognized (Wroughton, 1918, 1921; Thomas, 1921). In South Africa at that time the yellow mongoose, *Cynictus penicellata*, was taken to be the sole transmitter of rabies (McKendrick, 1931).

Attention was drawn to bats as carriers of rabies in Trinidad in the same year (McKendrick, 1932) and more detailed information made available four years later (McKendrick, 1936). The vampire bats *Desmodus rufus* and *D. rotundus* are the species so far incriminated. 'The possible relation of fruit-eating and other bats in the spread of the disease appears to require further investigation'.

A disconcerting observation made on the bats is that 'four *Desmodus* bats after inoculation with bovine rabies virus, though showing no symptoms of rabies themselves, were capable of transmitting the infection to twenty-four healthy cattle within one to four months after experimental inoculation. One such bat, killed after five months, was proved to have its salivary glands infected'.

A still more disconcerting observation (McKendrick, 1937) is that the bats may recover from furious rabies (not dumb rabies or after paralysis has set in) and become carriers.

Bats of the genus *Desmodus* Wied. are confined to tropical America and South Mexico (Weber, 1928). Bats or Chiroptera of the Indian area have been revised in the *Journal of*

(Continued at foot of next column)

## HORMONES IN MENSTRUATION AND PREGNANCY

PHYSIOLOGY, PATHOLOGY AND TREATMENT—A

RÉSUMÉ

By A. P. PILLAY, O.B.E., M.B., B.S.

Bombay

THE theories regarding the rôle of hormones in menstruation and pregnancy current in former

(Continued from previous column)

the Bombay Natural History Society (Wroughton, 1918). Forty genera and 123 species, excluding subspecies and varieties, of bats are known from the Indian limits.

#### An acknowledgment

For up-to-date information on mongooses and bats the writers are indebted to Dr. Bains Prashad, D.Sc., F.R.S.E., Director, Zoological Survey of India, Calcutta.

#### Summary

1. A dog suffering from chill presented for a whole day the picture of a dog suffering from rabies. Three other dogs presenting the same symptoms are cited. All recovered.

2. Close contact with a suspicious dog like the ones described should be followed by prophylactic antirabies treatment if nothing further were known about the dog.

3. Isolation with a view to observation of the suspected dog, for making sure of the diagnosis of rabies, is much to be preferred to destruction of the dog.

4. Mongooses and bats can carry rabies.

years were found to be untenable in the light of extensive and more elaborate researches which became possible after synthetization of these hormones. The controversies as to the methods of action of hormones are still raging and often the conclusions of one group of research workers clash with those of others. The result is that a close student of the science of endocrinology is bewildered by the mass of data thrown at him. With all this, certain salient points stand out of these discussions as established facts and suggest new or modified lines of treatment in disorders of menstruation and pregnancy. It is thought that a résumé of these facts will be of practical help to practitioners who have neither time nor facilities to wade through voluminous medical literature.

#### *The sex hormones*

The hormones that are believed to be concerned with the physiological sex functions of women are those of the ovary, anterior pituitary, adrenal and thyroid. There was a time when thyroid products were used extensively in functional sex disorders of the female but their use was empirical and is now almost given up.

Our knowledge regarding the adrenal cortex hormone is still meagre. It is known, however, that hypersecretion of this hormone gives rise to virilism and the hypomenorrhœa, amenorrhœa, and sterility associated with it, while its deficiency causes Addison's disease. Chemically this hormone closely resembles progesterone and biologically, it is believed, to have actions more or less similar to progesterone and the male sex hormone.

#### *The anterior pituitary hormones*

The anterior pituitary gland is known to secrete at least a dozen hormones which control in some way or other all endocrine and non-endocrine organs of the body. The hormone that is concerned with menstruation and pregnancy is prolactin and this is believed to be two, or to have two functions, follicle-stimulating and luteinizing. There is another hormone, prolactin, the lactogenic hormone, which is concerned with the secretion of milk in the breasts during the later stages of pregnancy and the post-partum period.

While prolactin is the anterior pituitary hormone proper, anterior-pituitary-like hormones, or gonadotropic hormones as they are called, have been isolated from the urine and blood serum of pregnant women and mares. No synthetic products of these hormones are available.

Attempts to reproduce artificial menstrual cycles with prolactin and gonadotropic hormones have been successful in laboratory animals but not in human females. The present belief is that the anterior pituitary is not directly or actively responsible for causing menstruation (Engle, 1939). Clinical administration of gonadotropic substances has also met with very little therapeutic success (Davis and Koff, 1938).

It is not denied that prolactin and the gonadotropic hormones, especially those prepared from the serum of pregnant mares and believed to be very potent, may have their place in the treatment of developmental defects, but even here their practical applicability has not yet been clearly defined. The concepts regarding the anterior pituitary hormones are changing daily. On the other hand, our knowledge of ovarian hormones is now so definite that, as Corner (1939) says, the menstrual cycle can be successfully initiated whenever we desire, with no other armament than a syringe and a few ampoules of ovarian hormones.

#### *Ovarian hormones*

The two ovarian hormones known, and synthesized so far, are the follicular hormone, œstrin, and the luteal hormone, progesterone. Œstrin is present in the blood of young girls as early as the age of eight (Fluhmann and Murphy, 1939) and is therefore believed to be secreted even by immature ovaries.

Progesterone, on the other hand, is secreted by the corpus luteum and the formation of this begins only at puberty.

At the time of puberty the ovaries begin to secrete increasingly large quantities of œstrin, and this under the stimulus of the anterior pituitary hormone causes ripening of a Graafian follicle, its rupture and liberation of an ovum. This process, known as ovulation, occurs at about the middle of the inter-menstrual period. The empty follicle now becomes a corpus luteum. Ovulation and corpus luteum formation occur cyclically every month. The corpus luteum begins to secrete progesterone from about twenty-four to thirty-six hours after its formation and continues to do so for the next ten or twelve days, when it retrogresses. About forty-eight hours after the retrogression of the corpus luteum, menstrual bleeding begins.

While the secretion of progesterone is cyclic or periodic, the secretion of œstrin is continuous, first by the follicle and later by the corpus luteum. Recent researches have shown that the corpus luteum secretes a larger quantity of œstrin than even the Graafian follicle. In other words, the aggregate amount of œstrin present in the system is greater during the second half of the menstrual cycle than in the first half (Neustaedter, 1939).

#### *The physiology of menstruation*

It was once believed that menstruation was induced by the corpus luteum 'by some positive effect on the uterus, its presence and activity building up the endometrium to a hæmorrhagic phase'. It is now known that the corpus luteum acts in quite a different way. The menstrual cycle has two phases, the follicular phase and the luteal phase, so called because the follicular hormone and luteal hormone respectively are in control during these phases. The follicular phase starts from the beginning of the menstrual

flow till ovulation occurs and the luteal phase from the time the corpus luteum begins to secrete progesterone to the onset of the menstrual bleeding.

The function of œstrin is not only to ripen the Graafian follicle and cause ovulation but also to inhibit or hold in check menstruation, which does not occur as long as this hormone circulates in the system in sufficiently high amounts. Progesterone checks this menstruation-inhibiting property of œstrin and itself inhibits menstruation. When the corpus luteum, which has been secreting progesterone and œstrin, undergoes retrogression, the woman is suddenly deprived of the inhibiting actions of both œstrin and progesterone and the endometrium breaks down and menstruation ensues.

The uterus will not bleed during the first half of the cycle because the follicle is furnishing the menstruation-inhibiting œstrin and it will not bleed during the second half because the corpus luteum is furnishing progesterone, another menstruation-inhibiting hormone. It has also been proved that total deprivation of œstrin is not necessary to produce menstruation, but merely lowering its level is enough for the purpose.

#### *Non-pathological varieties of menstruation*

*Anovulatory menstruation.*—It is now well recognized that anovulatory types of menstruation are fairly frequent at puberty, at the menopause and in the post-partum period. In women of the child-bearing period, this type of menstruation is seen associated with sterility and amenorrhœa. According to Rock, Bartlett and Matson (1939), 'Sterility patients with a history of menstrual irregularities, even though flowing normally at the time of examination, should arouse suspicion of anovulatory menstruation, since such a failure of ovulation is three to nine times more frequent among these patients than among those whose menstrual history is normal'.

Anovulatory menstruations cannot be explained by the usual œstrin-progesterone-deprivation theory, since there is no formation of corpus luteum in their cycles. Some gynaecologists do not consider anovulatory menstruation as normal menstruation, but this attitude is wrong, as the one resembles the other in every way except in the absence of corpus luteum, and in bleeding taking place in one from a proliferative mucosa, and in the other from a progestationally transformed mucous membrane. The women are in good general health, only they will not conceive.

This type of menstruation proves that corpus luteum is not essential for producing menstruation. Fluctuations in œstrin level in these cases are caused cyclically, it is believed, as a result of the give and take of the pituitary-ovarian or pituitary-ovarian-adrenal relationship; or by the action of some, as yet unrecognized, progesterone or androgen-like hormones produced in the ovary (Corner, *loc. cit.*). Or it may be caused by the action of prolactin. These are all mere

speculation. No statistics as to the relative frequency of anovulatory and ovulatory menstruations are available, but during the course of my investigations on vitamin C and ovulation, I found seven cases of anovulation in twenty-six cycles tested. The ages of the women ranged from fifteen to thirty-six.

Anovulatory types of menstruation are important only as a cause of sterility. The treatment for the condition is by injections of œstrin, as it is deficiency of follicular hormone that causes anovulation. Some gynaecologists advocate gonadotropic hormones. My experience of three cases is that a single injection of 10,000 to 20,000 units of œstrin on the eleventh day of a cycle usually brings on ovulation. The difficulty in checking the efficacy of any treatment is because anovulatory menstruation often alternates with ovulatory menstruation in the same woman, and so whether ovulation in any cycle is natural or produced by the treatment cannot be determined.

*Multiple ovulations.*—By the term multiple ovulations is meant not the simultaneous development and liberation of more than one ovum during a menstrual cycle, but two or more ovulations occurring on different days in a cycle. They are caused by an excess of follicular hormone production but it is not known as to whether these have any adverse effects on the health of the woman or on her fecundity. Hartman (1939) and his colleagues believe that multiple ovulations are not unusual in women during the child-bearing period. During my vitamin-C tests, I came across two cases of multiple ovulations, one alternating with anovulation and another with the usual uniovulation (Pillay, 1940).

#### *Physiology of pregnancy*

The ovum is liberated every month at about the mid-menstrual period and the present belief is that it is capable of fertilization only for twenty-four or forty-eight hours after its liberation. If within this time it meets a spermatozoon it is fertilized, otherwise it is discharged with the menstrual flow. Embryologists are now definite that the time the ovum, when fertilized, takes to migrate from the fallopian tube to the uterus and get implanted is about ten days, *i.e.*, within the period during which progesterone is secreted by the corpus luteum. For the implantation of the ovum, progesterone is known to be essential. If for any reason the corpus luteum does not secrete a sufficient quantity of progesterone or secretes it only for less than the usual ten or twelve days, implantation of the ovum will not take place. This means degeneration of the endometrium, and the discharge of the fertilized ovum in the resulting menstruation.

It was once thought that progesterone was necessary only in the early stages of pregnancy. This was based on the observations that the corpus luteum degenerated at about the third

month of conception and that pregnancy continued even if the ovaries were removed by operation after the third month.

It has now been definitely established that progesterone is necessary right through pregnancy. For about the first three months the ovaries supply progesterone and then they retrogress. The function of producing progesterone is now taken up by the placenta. The exact time when the transference of this function from the ovaries to the placenta takes place varies in different women and in the same woman in different pregnancies. It is believed to be somewhere between the seventieth and ninetieth days, counting from the first day of the last actual menstruation.

If the corpus luteum fails to secrete a sufficiency of progesterone for any length of time before the placenta begins to secrete it, abortion will result. This is most likely to occur near the time of the transference of the function of progesterone secretion from the ovaries to the placenta and this period is therefore the most critical in pregnancy. It has been recognized for a long time that abortion tends to occur most commonly about the third month, i.e., by our assumption just before the placenta takes over progesterone production. Henry, Venning and Browne (1938) studied the distribution of time of onset of symptoms in five hundred cases of abortion (threatened, complete and incomplete) and found the average day to be the eighty-first from the beginning of the last menstrual period.

In normal pregnancy, the level of progesterone rises from the time the placenta begins secreting it and continues rising up to term. When the placenta separates during labour, progesterone disappears from the system.

Œstrin and prolactin are also present during the whole term of pregnancy. Œstrin, like progesterone, is secreted in the ovary in the first three months, and later by the placenta in increasing quantities. Prolactin is secreted by the chorion from the time of implantation of the ovum up to term in varying quantities. At the time of parturition, all the three hormones disappear from the system. The rôle of anterior pituitary hormones in the physiology of normal gestation has not been definitely ascertained, but it is believed that they play an important part in keeping up the functional integrity of the corpus luteum of pregnancy and later in the placenta's elaboration of progesterone and Œstrin.

'All the factors involved in the initiation of labour have not been ascertained but quantitative studies in women have revealed a marked drop in Œstrin just before delivery and a decrease in progesterone has also been indicated. It is also seen that there is an increase of prolactin before labour begins. The drop and increase appear to take place suddenly' (Smith and Smith, 1939).

The presence of the various hormones in the system and the quantities present are ascertained by testing the blood or urine for their

excretion products, pregnandiol for progesterone and œstrogens for œstrin. Prolactin appears as prolactin. According to Wilson, Randall and Osterberg (1939), 'the excretion of pregnandiol in normal or maximal amounts in the urine of a woman who has missed her period and who has had a normal menstrual history is apparently indicative of early gestation'. The excretion of prolactin from the very early stages of conception is made use of in the well-known Zondek-Ashheim test of pregnancy.

*Puberty.*—There is one factor common in both puberty and menopause and that is a deficient secretion of œstrin. Anovulation is also common during these periods. While a great amount of scientific work has been done on the menopause, puberty seems to have been neglected, since it seldom gives rise to serious symptoms. The conditions that need medical attention during puberty, as far as the sex functions are concerned, are genital infantilism and hypomenorrhœa. The rational treatment in both cases is by œstrin. Hypomenorrhœa gives rise to much anxiety in parents but usually it needs no treatment as menstruation will get regularized when the girl grows older. Œstrin orally, about 3,000 to 10,000 units daily for the first ten days in the follicular phase for two or three cycles, would be all the treatment that would be usually required.

Genital infantilism may need injections of œstrin and, according to some, of prolactin and gonadotropic hormones. In this and other cases of genital dysfunction, it is better to try œstrin first and if this does not give relief, anterior pituitary hormones.

### Menopause

The theories regarding the causation of menopause are varied and conflicting, but two facts stand out clearly from them. These are that there is an excess of production of gonadotropic hormones and that there is some dysfunction of the ovaries causing deficiency of œstrin and absence of ovulation. According to Fluhmann and Murphy (*loc. cit.*), the deficiency in œstrin is not the primary factor concerned in the production of climacteric symptoms, but it is the presence of excessive amounts of gonadotropic substances that cause them.

Whatever the causation of the symptoms may be, all clinicians are agreed that œstrin administration is the correct treatment in menopause. The dosage of œstrin is important. Schneider (1939) gives the following method for deciding accurate dosage. The correct dose is that amount that would give relief, even though only transitory, within an hour after giving the injection. He begins with an initial injection of 500 international units and the strength of the daily injection is increased until the minimal amount which gives relief within an hour is ascertained. This dosage, in his experience, rarely exceeds 10,000 units a day and upon its determination, the patient is put on oral therapy. The dosage

orally will be three times the ascertained minimal injection dose, given in divided doses.

Recently, testosterone propionate has been used to relieve menopausal symptoms. The male hormone is believed to act by depressing pituitary gonadotropic secretion. Treatment is commenced with an initial injection of 10 mg. of testosterone propionate, the subsequent doses and their frequency being decided by the reaction on the symptoms. It has to be borne in mind that we can expect relief of the physical and mental symptoms in menopausal women, only if these are caused by the menopausal condition itself.

#### *Abnormalities of menstruation*

*Diagnosis.*—Before going into the abnormalities of menstruation and pregnancy, a word might be said about the question of diagnosis. Functional menstrual and pregnancy disorders are due to deficiency or absence of particular hormones or upsets in the relative levels of the various hormones. Accurate diagnosis is essential not only to ascertain which particular hormone is deficient or absent, but also to decide on the optimum dose in treatment. For this, hormone assays of urine or blood are necessary.

As Campbell and Sevringhaus (1939) say :— 'We are still of the opinion that diagnoses as to the cause of amenorrhœa, irregular menses, menorrhagia, and sterility cannot be made by any combination of history taking, physical examination and pelvic examination, or with ordinary laboratory tests. The use of the microscopic study of endometrium, or at times of the vaginal epithelium and the pregnandiol excretion give information of prime importance. Without such data diagnoses are inaccurate, and therapy is empirical. Such examinations are to precede the use of expensive and potent endocrine materials. To determine progress, the history of menstrual flowing is likewise inadequate, unless fortified with similar examinations'. In many cases, œstrogen and prolan assays will also be necessary.

*Amenorrhœa.*—Amenorrhœa is a very wide term and under it are included conditions ranging from the complete absence of menstruation to the prolonging of the menstrual cycle and even a scanty flow. *Ætiologically* it is classified as primary or secondary, the difference being that in primary amenorrhœa, the woman has never menstruated, while in the secondary variety, amenorrhœa sets in after she has menstruated for a certain number of years. It may also be complete or relative. Both types of amenorrhœa are caused by deficiency or defective functioning of either of the ovarian hormones. Relative amenorrhœa is not unusual at puberty, during menopause and in virilism. In the latter condition, it is caused, as was mentioned, by an excess of adrenal cortex hormone which appears to have an antagonistic action on œstrin. The treatment of virilism, so far unsatisfactory, has been

with injections of œstrin. In one case of secondary virilism, I administered by injection and orally 100 mg. of œstrin, i.e., 1,000,000 units in two menstrual cycles. This appeared to regularize her 'returns'. Another 150 mg. were given in the next menstrual cycle and this delayed her 'returns' for fifty-three days. Even these massive doses made no impression on the patient's hirsuties.

*Primary amenorrhœa.*—Primary amenorrhœa is usually associated with genital infantilism or hypoplasia, though cases in which the genital organs are apparently normal are also seen. The aim of treatment is to bring on full physical and functional development of the ovaries and uterus. This is believed to be a good field for prolan, if genital hypoplasia is associated with general infantilism, otherwise œstrin is the hormone to be exhibited. Even in the former case, after the course of prolan, œstrin alone or with progesterone in sequence may have to be given.

From the year 1933, when Kaufmann succeeded for the first time in inducing menstruation in a human female castrate by the administration in sequence of œstrin in the follicular phase and progesterone in the luteal phase, this procedure has been adopted as the routine treatment in all cases of amenorrhœa whether primary or secondary. *œstrin* was not administered in the luteal phase under the mistaken belief that there was no production of this hormone by the corpus luteum. To imitate what is occurring in the system, œstrin has to be administered continuously and, during the later stages of this treatment, progesterone is given for about ten days.

The conclusions summarized by Engle (*loc. cit.*) from researches of various workers to date will be most helpful to understand this and other recent therapeutic approaches in menstrual disorders.

1. Withdrawal or reduction of œstrin level results in typical uterine bleeding.

2. Bleeding of œstrin deprivation will not occur if, after œstrin, progesterone is given.

3. After a course of progesterone, however, bleeding *always* occurs after its withdrawal, even if the progesterone injections are followed by injections of œstrin in heavy doses.

4. *œstrin* and progesterone are not antagonistic in their action but are essentially synergistic.

5. The time interval between hormone withdrawal and bleeding is characteristic for each hormone. The onset of bleeding after œstrin withdrawal is 9.2 days, with a range of five to sixteen days. After cessation of progesterone therapy, bleeding occurs on the average of 2.9 days, with a range of two to four days. This is shorter and more constant than after œstrin withdrawal.

6. The real third or pre-menstrual phase is only forty-eight hours or less, when both the

ovarian hormones are not acting on the endometrium.

The rational treatment for primary amenorrhœa is therefore as follows : As the patient has never menstruated, an arbitrary period is fixed as the menstrual cycle. Daily injections of œstrin, 10,000 units, are given from the first day right through the cycle. From the thirteenth day progesterone, 10 mg. doses, is given daily for ten days and stopped. Menstruation may reasonably be expected two to four days after the stoppage of progesterone injections. In long standing and severe cases the treatment is kept up for another two or three cycles.

*Secondary amenorrhœa.*—Secondary amenorrhœa is believed to be caused by the absence of, or a defective corpus luteum, in other words, by having no progesterone to act on œstrin which is continuously produced in the follicle. Two lines of treatment are possible. One is by administering œstrin and producing corpus luteum and the other is by supplying progesterone by injections. As was mentioned, the line of treatment that was being adopted till recently was giving œstrin and progesterone in sequence or œstrin alone in the follicular phase.

Zondek and Rozin (1939) utilized the progesterone-withdrawal principle to initiate uterine hæmorrhage in secondary amenorrhœa, treatment being this hormone alone without preliminary treatment with œstrin. They gave daily injections of progesterone, 10 mg. for five days, and found that bleeding set in sixty hours after the last injection, and the blood discharged resembled menstrual blood in that it did not coagulate. Similar results were obtained by them also by the oral administration of pregneninol, a derivative of progesterone. The oral dose found effective is 300 mg. in five days, i.e., six times the dose of progesterone when given by injection. I have been practising this line of treatment with excellent results. I give 60 mg. by injection in four daily doses of 15 mg. and the bleeding comes on from forty to seventy-five hours after the last injection. The conclusion of Zondek and Rozin that uterine bleeding started in all cases exactly after sixty hours does not appear to be correct in my experience. Doses below 10 mg. of progesterone appear to be ineffective.

One case is worth reporting in detail as it shows the comparative merits of œstrin-progesterone therapy and progesterone therapy alone.

A Hindu woman, age 35, married. Very irregular for the last four years, menses every four or five months and recently none at all. From 6th to 16th June, 1939, she had 20 mg. of œstrin in four doses and from 21st to 26th, 6 mg. of progesterone in three doses. On 28th she had a slight flow for a few hours. On 4th July treatment was resumed and till 15th, she had 25 mg. of œstrin in five doses and from 24th to 26th July, she had daily injections of 5 mg. of progesterone. On 31st July, she got her returns and this lasted for two days.

She had no other menstruation after that. From 8th March, 1940, she was given daily 15 mg. of progesterone by injection for four days and on the fifth day she

was given only 10 mg. The last injection was given at 9 a.m. on 12th, and she got her returns, not very satisfactory, according to her, at 5 a.m. on 16th March, i.e., ninety-two hours later. The œstrin-progesterone treatment took fifty-six days to show results while progesterone therapy took only nine days.

Absence or even delayed menstruation causes great mental depression in women. With progesterone therapy the doctor can guarantee the menstrual flow within two to four days after the cessation of the treatment, while with œstrin therapy, the result takes about three weeks to appear and no definite date can be guaranteed. Then again progesterone therapy is cheaper and more scientific than Kaufmann's method which is being followed at present. In the old œstrin-progesterone treatment, œstrin was a waste as the uterine bleeding would have been initiated by the progesterone alone. According to Zondek and Rozin (*loc. cit.*) the progesterone treatment is not effective in primary amenorrhœa and 'this reveals a characteristic difference between primary and secondary amenorrhœa'.

*Oligomenorrhœa and hypomenorrhœa.*—Oligomenorrhœa and hypomenorrhœa should be included under amenorrhœa. These conditions are generally associated with hypoplasia genitalis and so œstrin treatment is indicated. Hypomenorrhœa has already been described. I have seen excellent results in oligomenorrhœa by a single injection of œstrin, 5 mg., on the eleventh day of the cycle, repeated in two or three subsequent cycles. Ogino has laid down that the one constant feature in all menstrual cycles is that menstrual bleeding takes place on the fifteenth day after ovulation. This seems to be well established, as hypomenorrhœa and other conditions where the menstrual cycle is unduly prolonged, can be brought to the normal type only by shortening the pre-ovulation period. Medication by œstrin to shorten the cycle should therefore be undertaken in the pre-ovulatory period. Œstrin administered in the luteal phase has no effect on the cycle. Progesterone on the other hand can bring on menstruation as and when required.

*Post-coital amenorrhœa.*—There is another form of amenorrhœa which may be called, for want of a better name, post-coital amenorrhœa. It is seen in married women and unmarried girls who have been menstruating regularly but who though they dread pregnancy had exposed themselves to it. This amenorrhœa is not caused by pregnancy, nor can it be considered as pseudo-pregnancy, as there are no other subjective symptoms associated with it. This form of amenorrhœa is due probably to some psychic inhibition of the ovarian function. That coitus plays a part in ovarian functioning is seen from the fact that it initiates ovulation in rabbits probably by some psychic reaction on the pituitary-ovary relationship. Though ovulation in the human female is not influenced by coitus, it apparently suppresses menstruation at least temporarily, by the psychic factors, fear and anxiety.

I selected for progesterone treatment five such cases, one unmarried and four married, who had exposed themselves to becoming pregnant. The menstruation was overdue by six, nine, fourteen, fifteen and twenty-eight days respectively. The first four cases had 60 mg. in four days, and the fifth 75 mg. in five days. The first four women had their menstrual flow, ninety-six, sixty-nine, forty and seventy hours after the last injection, while in the fifth case the treatment was a failure. This case turned out to be a case of pregnancy.

The first case is interesting :—

Married woman with seven children and a fear of pregnancy. She had daily injections of progesterone 15 mg. for four days and the fourth injection was given on 30th January at 12 noon. As she had no flow till 10 a.m. on the 3rd February, she induced me to start œstrin treatment the same morning and was given 14 mg. of œstrin, i.e., 140,000 units. An hour later, she got her returns but this she hid from me as she wanted a good 'flush out'. Twenty-three mg. or 230,000 units were given in the next two days. The flow, which usually lasted only three days, went on this time for twelve days. This case goes to prove the conclusion that œstrin administered after progesterone does not inhibit menstruation even in high doses.

Progesterone is thus seen to initiate menstrual bleeding in post-coital amenorrhœa if it is not due to pregnancy. The treatment may be used therefore as a diagnostic test for early pregnancy when other tests are not feasible. It was mentioned before that presence of pregnandiol in the urine of a woman who missed a period but who was menstruating regularly previously is also a test for pregnancy. All the cases in my series required only one course of treatment and they had so far two and three returns after the cessation of the treatment. I have treated successfully similar cases formerly with daily injections of 50,000 to 100,000 units of œstrin for three to five days. Menstruation came on all right but not before eight to twelve days after the last injection.

*Menorrhagia and metrorrhagia.*—The theory of the causation of menstruation described in this paper makes it possible to believe that pathological uterine bleeding is also caused by fluctuations in levels of ovarian hormones and that no sharp distinction exists between them and menstruation proper (Corner, *loc. cit.*).

Excessive bleeding indicates either low levels of œstrin and/or deficient functioning of the corpus luteum. By the theory we enunciated, viz, that as long as œstrin circulated in the system in sufficiently high levels uterine bleeding was inhibited and that progesterone also suppressed menstruation, treatment of menorrhagia and metrorrhagia can be by the administration of œstrin or by progesterone. Œstrin would appear to be the scientific way of treatment as it raises the œstrin level in the body and also induces corpus luteum formation. If the bleeding is excessive when the patient comes for treatment, progesterone in high doses is to be administered. After bleeding stops, œstrin

and progesterone together or in sequence should be given just as in amenorrhœa. In these cases, urine assays will be helpful in deciding which hormone to exhibit.

It is assumed that cancer, tumours and similar other causes of uterine bleeding have been excluded before hormone treatment is begun. Some gynaecologists advocate anterior pituitary hormones for uterine hæmorrhages, some recommending prolactin and others gonadotropic hormones, most preferring preparations from the serum of pregnant mares as these are believed to be more potent than the others.

The recent organotherapeutic development in the treatment of functional uterine bleeding has been the administration of the male hormone, testosterone propionate. As was mentioned, this product is believed to act through its inhibiting effect on the pituitary. Biologically, while testosterone is antagonistic to œstrin, it has the same action as progesterone in preventing œstrin-withdrawal bleeding even in doses of 5 mg. (Engle, *loc. cit.*). I have noticed immediate and spectacular results in functional bleeding by the combined use of testosterone propionate, 25 mg. and progesterone, 10 mg. It was mentioned that adrenal cortex hormone has similar actions as progesterone and testosterone and therefore it should prove useful in excessive uterine bleeding. There are however no recorded studies on the subject.

*Dysmenorrhœa.*—Dysmenorrhœa is the commonest menstrual disorder and yet very little is known about its causation and its treatment is still unsatisfactory. There are three current theories as regards its ætiology and these are :— (1) deficiency in progesterone, permitting the unopposed action of œstrin upon the uterine muscle; (2) excessive œstrin production causing violent contractions of the uterine muscle; (3) excessive progesterone activity. It is very probable that there is also some nervous element in the causation of dysmenorrhœa.

Till recently, the treatment consisted of injections of œstrin in the first half of the menstrual cycle and of progesterone in the premenstrual week. These were given more or less empirically and so some cases were benefited, while others were not.

Recently other methods of treatment have come into vogue. The most important of these is by testosterone propionate. It was mentioned that this substance inhibits the gonadotropic factors of the pituitary. It causes suppression of œstrin, ovulation and progesterone formation. Large doses of testosterone propionate suppress the subsequent menstruation if given in the follicular phase, but not when given in the luteal phase. Injections of 25 mg., three times a week, in the luteal phase of the menstrual cycle, give excellent results in dysmenorrhœa. One or two courses will be found ample. Testosterone propionate relieves also the discomfort, pain and swelling in the breasts seen in the luteal phase of

the menstrual cycle of some women. The male hormone should, however, be used with caution in women as doses over 500 mg. in one cycle may give rise to signs of masculinization, such as hoarseness of voice, facial hirsuties, suppression of menstruation and so on (Salmon, Geist and Walter, 1939).

Alitchul found small doses of insulin effective in dysmenorrhœa. Schrick (1939) suggests two alternative ways of administering insulin, five units daily before lunch for three to five days before the menstrual period, or a single injection of five to seven units given during the attack. I have seen in two cases relief of pain within fifteen minutes by a single injection of fifteen units given during the attack.

I had also good results, though not so spectacular as with insulin or so lasting as with testosterone propionate, with Benerva (vitamin B<sub>1</sub>) injections, and with vitamin D by injection and orally. Whether these products are really effective is difficult to say, as it is almost impossible to eliminate the psychic element from the therapeutic results obtained in the treatment of dysmenorrhœa.

#### *Abnormal conditions seen during pregnancy*

Very little is known about the endocrine or other causation of abnormal conditions occurring during pregnancy, except that in pre-eclampsia and other late toxæmias, a rise in prolactin level and a drop in œstrin level are noticed. What usually happens in normal pregnancy is, that from the time of implantation of the ovum, the chorion secretes large quantities of prolactin. A rapid decline in its level takes place during the third and fourth months. This decline coincides with the taking over by the placenta of the functions of the regressing corpus luteum. The low level of prolactin is maintained during the fifth, sixth and seventh months during which time the production of œstrin and progesterone steadily increases. Any upset in the normal levels of prolactin and œstrin in these months would give rise to toxæmias of pregnancy. It is also believed that there is some involvement of the adrenal cortex in these toxæmias. In all cases of abnormalities of pregnancy, a test for prolactin estimation should be done. Excellent results have been reported by treatment of such conditions by œstrin and by progesterone.

*Abortion.*—The causes of spontaneous abortion are many but here we are concerned only with its endocrine aspects. From the previous pages it will be clear that deficiency of progesterone and a short phase of corpus luteum are the usual endocrine causes of abortion. Abortion is therefore most likely to occur in the periods between fertilization of the ovum and its implantation in the uterus and just before the placenta takes over the progesterone-producing function from the regressing corpus luteum. That is to say, the danger periods in pregnancy

are the first ten days and the third month after fertilization of the ovum.

Progesterone therapy is the only possible method of treatment in abortion, though, from my limited series of cases, I am of opinion that better results are obtained in threatened abortion by combining testosterone with progesterone. The dosage of progesterone necessary to maintain pregnancy intact in the human being is difficult to determine. According to Browne, Henry and Venning (1939): 'From the pregnandiol assay, it seems obvious that the amount of progesterone produced by the corpus luteum up to the seventieth or eightieth day is 5 to 10 mg. per day, and that the placenta produces a gradually increasing amount as pregnancy advances. How much is the minimum requirement is unknown. It is also unknown, unless determinations are made, how much the patient's own endocrine organs are producing, so that one may be giving 1 mg. of progesterone to a patient in the fourth or fifth month, when she is producing 25 to 50 mg. herself. In any case, it would seem, in view of the above findings, that doses of less than 5 mg. are unlikely to have much effect. This dose should be given daily or every other day, and may be increased in the presence of persisting symptoms. In most cases, either of the threatened or habitual type, therapy should be concentrated during the period of transfer of the function of formation of progesterone from ovary to placenta, since it is at this time that abortion is most likely to occur. If pregnandiol assays are available a definite rise in pregnandiol excretion may be taken as an index that further therapy is probably unnecessary. The danger of wasting treatment on an already dead fetus, and the uselessness of treating a patient after her own placenta has begun to form normal amounts of progesterone, should always be borne in mind'.

The vexed question as to whether hormones can produce abortion has been answered differently by different observers. Some say that it is possible, while others say that it is not. From the theories so far discussed it is clear that theoretically it should be possible to produce abortion in the early stages of pregnancy by the use of œstrin. To me it appears that it would be also practicable during the danger periods of pregnancy, provided it can be decided how much œstrin is required to 'neutralize' the amount of progesterone that is being secreted by the patient's endocrines. Water-soluble products of the follicular hormone act better because of their quicker absorption. It may be mentioned that œstrin has the property of sensitizing the uterus to the action of oxytocic drugs and to local interference. Progesterone has just the opposite action.

*Sterility.*—It is not proposed to go into the causes or treatment of female sterility in detail except to mention one or two endocrine aspects of the subject. A short phase of corpus luteum

activity, as was mentioned, does not permit the implantation of the ovum in the uterus and is one of the usual but neglected causes of sterility. In these cases it is necessary to give as a precautionary measure 5 mg. doses of progesterone by injection daily, from the seventh to the tenth day after a mid-cycle coitus. In habitual abortion, 5 mg. doses of progesterone should be given at least every other day for the first three months.

Another common cause of sterility, and one to which also very little attention is paid, is anovulation. To detect this, an accurate test for ovulation is required. The vitamin-C test I formulated, if found reliable, is simple and can be carried out even by the general practitioner. There is increasing evidence that anovulation, like aspermia, is more common than is usually believed to be possible. The treatment for anovulation has already been described as injections of œstrin.

#### *Mode of administration of hormones*

The synthetic preparations of hormones now available can be administered, unlike the previous natural products, in various ways, such as by injection, orally, percutaneously, through the vagina and by subcutaneous implantation. Injections give the most rapid results and subcutaneous implantation the most sustained. Percutaneous application is claimed to be nearly as effective as injection. Orally five or six times the injection dose are required. I found application of greasy ointments to the skin far too messy and, so in males, I have been prescribing them with good results rectally. This method of administration is not mentioned in any literature and I feel that there will be better absorption if the base used in the preparation of the applications is glycerine-starch instead of vaseline. For subcutaneous implantation, a compressed tablet of the crystalline hormone of the required weight is sterilized in an autoclave and inserted under the skin through a small incision which is then sutured.

In this paper, I did not think it necessary to confuse issues by entering into a discussion of the different chemical products of the various hormones available. There may be slight variations in the degree of efficacy and in the rapidity of action, but these are of minor importance in hormone therapy. The propionates are believed to be more lasting in their effects than the other products. Opinions are divided as to the permanency of the results of hormone treatment. Unless the cause is definitely ascertained and the dose accurately decided, results are bound to be temporary. This is probably why many cases of primary amenorrhœa relapse when treatment is discontinued. The only bad results I have noticed in women, even after giving enormous doses of hormones, were masculinization when the male hormone was administered and the delayed menstruation in the virilism case reported above. The fear that

prolonged use of hormones may cause cancer seems to be unfounded.

#### *Summary*

The œstrin-deprivation, the progesterone-deprivation and the œstrin-progesterone-deprivation theories of menstruation are explained. These make it necessary to rearrange many of our views regarding the rôle of hormones in the physiology and pathology of menstruation. They also make it possible for us to believe that there is very little difference between normal menstruation and pathological functional uterine bleedings and that the treatment of the latter is merely by bringing the œstrin-progesterone level to normal.

It is shown how in amenorrhœa, unassociated with genital hypoplasia, treatment by progesterone is simpler, more rational, and more rapid in effect than œstrin or œstrin-progesterone therapy. The belief that œstrin and progesterone could be given only in sequence and not simultaneously is shown to be groundless. In certain functional disorders their combined use is recommended. The possible causation and treatment of post-coital amenorrhœa is explained.

The recent developments in the use of male sex hormones in functional female disorders are described.

It is shown that to maintain pregnancy intact high and constant levels of progesterone are essential and to prevent abnormal conditions during this period, the normal balance between the ovarian and anterior pituitary hormones has to be maintained.

Abortion and sterility are shown to be similar in the sense that the ætiological endocrine factor behind both is defective progesterone production. Anovulation is considered as common and important a cause of sterility as aspermia.

The effective dosage of hormones and the various methods of administering them are described.

It is emphasized that accurate diagnosis and correct dosage cannot be arrived at without assays of urine or blood for pregnandiol, œstrogen and prolan excretions.

#### *Acknowledgment*

I am indebted to Messrs. Ciba Ltd. and their scientific representative in this country, for placing at my disposal liberal supplies of their hormone products, without which this study would not have been possible.

The products used in this study were :—Follicular Hormone—*Ovocyclin* (ampoules, tablets and ointment); Luteal Hormone—*Lutocyclin* (ampoules and tablets); Male Hormone—*Perandren* (ampoules and ointment); Adrenal Cortex Hormone—*Percorten* (ampoules).

## A Mirror of Hospital Practice

### A CASE OF BANTI'S DISEASE

By J. W. D. GOODALL, M.D., M.R.C.P. (Edin.)  
CAPTAIN, I.M.S.

Second Resident Medical Officer, Presidency General Hospital, Calcutta

IN the British Isles where the discovery of a large spleen causes a mild sensation, Banti's disease is comparatively rare and is included in the syndrome of splenic anæmia. The diagnosis is largely a matter of eliminating other causes of enlarged spleen and is not very difficult.

In India the position is very different, firstly because enlarged spleens are common, and secondly because the cause of some of these enlarged spleens is unknown.

De (1932) examined several hundred enlarged spleens pathologically and found that in an appreciable number of them there was no evidence of any known disease but that clinically these cases had certain features in common. They were commonest in certain districts of Bengal, and always suffered from an irregular type of fever. Therapeutic measures were futile and a secondary type of anæmia with reduction of leucocytes was constantly present. These cases tended to develop fibrosis of the liver with ultimate cirrhosis and ascites. Death from intercurrent infection such as pneumonia or ulcerative colitis was usual.

The above description bears a close resemblance to Banti's disease as was pointed out in an editorial of the *Indian Medical Gazette* (1935). As a result of further research, De (1938) amplified his previous description and gave details of laboratory tests which included the information that the sedimentation rate was

much increased and the fragility of the red blood corpuscles diminished.

Photograph of the patient soon after admission, showing the outline of the spleen.

The question which confronts the clinician is, are these cases which present the above picture to be diagnosed as belonging to the splenic anæmia syndrome, or are they examples of another disease?

Palit (1935, 1937) described two series of cases on which he performed splenectomy for splenomegaly. Seven of these cases were diagnosed as splenic anæmia or Banti's disease. The term Bengal splenomegaly has been applied by others (Connor, 1933; De and Tribedi, 1939) to this type of case.

If a comparison is made clinically between Bengal splenomegaly and Banti's disease certain differences become apparent

(1) Fever is always present in the former and absent in the latter.

(2) Hæmatemesis occurs in 50 per cent of cases of Banti's disease (Whitby and Britton, 1939) but is rare in Bengal splenomegaly.

(3) The administration of iron produces improvement in Banti's disease (Dunlop *et al.*, 1939) but does not do so in splenomegaly.

(4) The leucopenia described in Banti's disease is marked and constant. In Bengal splenomegaly the leucocyte count is reduced, but moderately so. Some of the cases described (Palit, 1937) exhibited a slight leucocytosis.

(5) Death is commonly due to hæmorrhage in Banti's disease and due to intercurrent infection in Bengal splenomegaly.

We may conclude that Banti's disease in India is comparatively rare, whereas Bengal splenomegaly, which closely resembles it, is common. Failure to differentiate between the two conditions is of little importance as treatment is largely the same for both. Better results appear to follow splenectomy for splenomegaly than for Banti's disease.

A case of Banti's disease was recently admitted to the Presidency General Hospital, some details of which may be of interest.

An Anglo-Indian male aged 48 years complained of breathlessness and swelling of the abdomen. He said that he had not been in good health for the past 24 years. He had managed to keep a boarding house until poor health and finances had made it necessary for him to enter a home.

In the last two years he had become breathless on exertion and felt a dragging pain in the abdomen. The exertion of chopping wood in the home proved too much for him and he reported sick to the home doctor. On questioning he admitted having attacks of hæmatemesis, and on these occasions he used to vomit up a 'chamber pot full of blood'. His weight in 1916 was 12 stone but he had gradually lost weight till he became very thin. Recently his abdomen had swollen up. He had not bled from his nose or gums but his stools had been black sometimes. He did not remember being jaundiced.

On being asked about previous illnesses he recited the following list of hæmorrhages which seemed to have left a very vivid impression on him.

October 1916 hæmatemesis. He vomited a chamber pot full of blood.

1917 hæmatemesis once.

1918 hæmatemesis once.

1919 hæmatemesis once.

1920 hæmatemesis twice in Darjeeling.

1923 hæmatemesis twice in Vizagapatam.

1936 hæmatemesis once in Hyderabad.

1937 hæmatemesis once in Ootacamund.

March 1938 hæmatemesis twice on 4th and 15th in Darjeeling. At the time of hæmatemesis he used to feel faint and then 'up came the blood'.

There was nothing of interest in his family history. He was unmarried and no other member of his family had suffered from hæmorrhages.

On examination it was noted that he was an intelligent man, very thin, with a large abdomen. The spleen was enlarged below the umbilicus and the liver was not palpable. Ascites was present and the superficial abdominal veins were prominent. There was no enlargement of glands. A hæmic murmur was heard on auscultation of the pulmonary area of the heart.

The results of laboratory tests were as follows:—  
Blood—

Red blood corpuscles	..	2,690,000 per c.mm.
Reticulocytes	..	4 per cent.
White blood corpuscles	..	3,120 per c.mm.
Hæmoglobin	..	50 per cent.
Neutrophils	..	57 "
Eosinophils	..	3 "
Lymphocytes	..	34 "
Monocytes	..	6 "

There was a considerable reduction in the platelets.

Gastric analysis.—No free acid present.

Aldehyde and Chopra tests.—Both negative.

Splenic and sternal puncture.—No Leishman-Donovan bodies present.

Wassermann reaction.—Positive.

Blood fragility test.—

Hæmolysis started at 0.48 per cent.

completed at 0.35 per cent.

..

Treatment consisted of the administration of ferrous iron, liver, and a nourishing diet. Dilute hydrochloric acid was given in view of its absence in the gastric juice, and calcium was also given for hæmorrhages. The patient refused to consider splenectomy.

At first some improvement was noted. His red blood corpuscles rose to nearly  $3\frac{1}{2}$  millions and his hæmoglobin to 60 per cent. The white blood corpuscles also increased to 4,500 per c.mm. After two weeks his progress was arrested so he was given urea stibamine and later on arsenical injections (Mapharside).

About a month after admission the abdomen began to increase rapidly. The abdominal veins became very prominent and the spleen, which was hard and firm, floated about in a bag of fluid. His abdomen was tapped and 220 ounces of fluid were drained off slowly. A few days later he had a severe hæmatemesis and passed blood in his stools. Soon he began to pass pure blood in his stools and finally, following another large hæmatemesis, he died.

A post-mortem examination was made. The abdominal cavity was full of free fluid. The spleen which weighed 2 lb. filled a large part of the cavity. The capsule was wrinkled and adherent to the left lobe of the liver and surrounding structures. It was pale and had superficial hæmorrhages. There seemed to be an excess of fibrous tissue. The spleen was smaller than normal and weighed 2½ lb. It was very pale and had hæmorrhages on its surface. There were no obvious nodules but the substance felt hard in places suggesting increased fibrous tissue.

The stomach was full of clotted blood. The veins in the region of the lower end of the œsophagus were markedly enlarged, prominent, and varicose. The inner surface of the œsophagus presented two holes, one larger and one smaller than the head of a pin which communicated with veins.

The small intestine was congested and contained diluted blood. The bone marrow of the right femur was hyperplastic and smears made from it showed a reduction of the granular series of white cells.

Other organs showed no abnormality except the first part of the aorta which was slightly atheromatous.

### Summary

(1) A case of Banti's disease, including post-mortem examination, is described in detail.

(2) The differential diagnosis from Bengal splenomegaly is discussed.

### Acknowledgment

I wish to thank Major J. C. Drummond, I.M.S., Superintendent of the Presidency General Hospital, for permission to report this case.

# **New Facts about the Power of BOVRIL**

---

## **Remarkable Experiments at an English University**

As long ago as 1911, the late SIR WILLIAM THOMPSON of Dublin established that Bovril has a unique power of ministering to nutrition. During last year a series of remarkable experiments were conducted at an English University which provided physiological explanation and proof. A group of medical students volunteered to undergo scientific dietetic tests, so that accurate studies might be made of the effect of certain beef preparations. One of the substances investigated was Bovril. As a result of these experiments\* Bovril was proved to be "The most effective stimulant." Briefly, it was shown that Bovril increased the supply of gastric juices where there was a deficiency and restored it to normal. It is an accepted medical fact that a lowering of the essential gastric activity is found in people of sedentary habits and poor muscular development. Bovril helps to rectify this and, by facilitating the digestion of proteins, enables full nourishment to be gained.

\**B.M.J.*, 1937 August 28. Page 412.

The administration of **LIVOGEN** is particularly appropriate at the present time; not only do subclinical anæmias respond to Livogen treatment, but nervous debility and the more serious neurological conditions to which many patients are now particularly prone are overcome.

## MATERNAL MORTALITY IN CALCUTTA

THE strict definition of 'maternal mortality' would be deaths of women for the period of their lives during which they are capable of bearing children, but it is restricted to define the deaths of women directly or indirectly resulting from the functions of pregnancy and childbirth. It is obviously a very important factor in influencing the increase or decrease of a population, and as such it has given rise to much thought and inquiry all over the civilized world.

In India the problem is of extreme gravity and it has been the subject of several investigations in the last decade. Some of the more important of these are the reports by Sir John Megaw in 1933 as the result of a questionnaire, the object of which was to throw light upon certain aspects of public health in villages, among which was the death rate of women from childbirth. Then Dr. Margaret Balfour, working under the Indian Research Fund Association, first investigated the cause of maternal deaths in hospitals, by the study of hospital records all over the country, and later she studied the same problem among tea garden coolie women in a large district in Assam. Since that time the Association of Medical Women in India has continued to collect records of maternal mortality from hospitals. Although these various records are of great value it was thought by the special Advisory Committee on Maternal Mortality appointed by the Indian Research Fund Association that more information should be gathered and so in 1935 it was decided to inaugurate a special inquiry on the mortality among women who gave birth to children in their own homes, as this would add useful information to that already compiled from hospitals. This inquiry was based on the All-India Institute of Hygiene and Public Health in Calcutta, and was conducted for one year 1936-1937. The report of this inquiry has been published recently, and we give elsewhere in this number a short abstract from its pages.

The difficulty of acquiring accurate information on deaths from any cause in India is very great on account of the imperfect system of death registration and certification that exists almost everywhere, and in this report the shortcomings from this cause are taken into account but they seem to be fairly accurate on the whole, as a result of active co-operation of the local health authorities and painstaking system of house visiting by the persons conducting the inquiry.

On the whole the causes of death are similar to those in other parts of the world, and although the total deaths are higher in India, the deaths from sepsis are in about the same proportion as they are in the British Isles and the United States, and are actually slightly lower. This is very surprising when we consider the number of imperfectly-trained *dais* who still conduct a large number of births in this country. The training of midwives is now being actively pursued in many centres in India as so it may be reasonably anticipated that as more and more properly trained women become available this cause of death will be reduced.

The problem of anæmia which, when it was first noted as an important cause of maternal mortality, appeared to be caused by pregnancy *per se*, was stated by Dr. Margaret Balfour to be responsible for half the maternal mortality in the Assam coolie women she investigated. The present report finds that maternal deaths attributable to anæmia in Calcutta are about half as high as the Assam figures. Investigation of this subject in Assam has shown that a certain number of pregnancy anæmias is caused by iron deficiency from deficient iron intake and blood loss by hookworm infection, but that a balance of cases exists of macrocytic type the cause for which, apart from pregnancy, is not yet clear. Inquiry into the deaths from anæmia in Calcutta suggests that a number of them are caused by a deficient diet. In some of these cases there was a history of dysentery with consequent restriction of diet, which was continued for an unduly long period. Anæmia is also considered to be an important contributing factor in many of the deaths listed under other headings. This apparently serious cause of mortality among pregnant and parturient mothers has its bright side, for there are already indications that it can be largely overcome by appropriate treatment. Another not unsatisfactory aspect of the anæmia problem is that although it has been found necessary to add it to the international list of causes of maternal mortality on account of its frequency, if the deaths from this cause are deducted from the total it shows the figures for Calcutta in a much more favourable light in comparison with the maternal mortality rate in countries far ahead of India in their care of women during pregnancy, childbirth and the puerperium.

This report does not stop at a discussion of the causes of maternal mortality but it goes on to consider in detail how they may be best overcome, and it also discusses the extent of the properly organized maternity services in Calcutta. There is a final short chapter of recommendations based on the evidence produced by the inquiry: this we do not comment upon as we have reproduced it in full in our abstract of the report given elsewhere.

It is indicated that this is only the first of a series of inquiries which may be carried out by the Indian Research Fund Association in other

centres, both in town and country, and if they are conducted with the same care and energy as the one under review, they should add much further valuable information on how to deal with this problem. But, as practically everyone who writes on health problems concerning the whole of India is forced to remark, India is a vast country with many different climates and peoples with varied habits and religious beliefs with consequent differences in its local health problems; therefore if the investigation of

maternal mortality throughout the country is to be left to the sole efforts of the Research Fund Association it will be many decades before even the preliminary surveys are completed. It is accordingly suggested that now that this excellent report has been published it might be taken as a model for independent inquiries elsewhere, which could be profitably conducted by various local authorities, and in this way acquisition of the necessary preliminary information would be greatly speeded up.

## Special Article

### SOCIAL ASPECTS OF TUBERCULOSIS

By R. VISWANATHAN, B.A., M.D., M.R.C.P. (Lond.),  
T.D.D. (Wales)

Lecturer in Tuberculosis, Medical College, Vizagapatam

#### Introduction

Koch's discovery of the tubercle bacillus revolutionized the time-honoured conceptions regarding phthisiogenesis, but it has brought in its train new problems difficult of solution. Though the problem of tuberculous infection is adequately solved, a satisfactory explanation of tuberculous disease is still wanting. Bacteriology is considered by many as inadequate to clear up completely the ætiological problems of phthisis. Why, for instance, when the vast majority of urban populations are infected with tubercle bacilli consequent on its ubiquitous distribution, do only a small percentage of those so infected suffer from the ravages of the disease? Why should the disease take an acute course in some, resembling the conflagration in a forest fire, while in others it is chronic and slow, like a smouldering charcoal fire? Why should the pathological changes be so varied in different individuals? Why should some members of a tuberculous family suffer from the disease while others enjoy a relative immunity? The existence of such apparent discrepancies is sufficient testimony to the fact that the discovery of the tubercle bacillus as the causative organism in tuberculosis has only touched the fringe of the problem of phthisiogenesis. Attention has therefore been diverted to accessory non-parasitic causes of phthisis, both endogenous and exogenous. In the latter group of causes comes the important social factor including environmental peculiarities and economic conditions, such as occupation, housing, nourishment, etc., and also the geographical *milieu*.

#### Social factor in ætiology

Even in cities which boast of ideal methods of sanitation the incidence of infection with tubercle bacilli, as judged by the tuberculin test, is as high as in others less fortunately endowed. It has been shown that 90 to 98 per cent of urban

populations in Europe are infected with tubercle bacilli by the time they reach the age of 24. By no means yet known to man is it possible to prevent civilized mankind from coming into contact with tubercle bacilli. It is no doubt true that during infancy the well-to-do are shielded from contact with tuberculosis, unless one of the family or servants is affected with the disease, but when they reach the school-going age they come into contact with the outside world and hence are as liable to infection as those in the poorer strata of the population. Hence infection with tubercle bacilli is only slightly influenced by social and economic conditions. More important than infection is the question of morbidity due to tuberculosis. It has been statistically established beyond any possibility of doubt that tuberculosis is pre-eminently the poor man's disease. How does poverty increase the incidence of tuberculosis? This problem has to be looked at from various aspects. First and foremost is the question of malnutrition due to inability to buy the proper quantity, as well as quality, of foodstuffs. Stallybrass in 1931 says, whether it is through better nutrition or better housing or both it appears clear that if wisely expended and not wasted on alcohol, etc., rising wages produce a fall in tuberculosis. When therefore the incidence of tuberculosis morbidity is inversely proportionate to the wage-earning capacity its proportion among the unemployed will naturally be enormously greater. The tuberculosis mortality per 100,000 of population in the various parts of the city of Paris calculated by Bertillon is as follows:—

Age in years	..	1-19	20-39	40-59	Over 60
Very rich	..	61	129	159	105
Rich	..	79	205	241	168
Poor	..	168	526	641	340
Very poor	..	180	685	907	524

These figures are self-explanatory.

Apart from the question of malnutrition consequent on poor economic conditions, congestion of population is another equally important factor. It is a well-known fact that the incidence of tuberculosis is greatest in the slum areas

of every city where the poor live huddled together in insanitary and ill-ventilated dwellings. Besides poverty, overcrowding and filth may act by favouring contact infection.

In the city of Vizagapatam, where the writer has been working as Tuberculosis Officer for some years, the poor people live huddled together in huts of a peculiar picturesque construction. The average hut is built on a floor which is but 6 inches above the surrounding ground. The wall (there is only one wall as the structure is circular near the floor and tapers to a point at the top of the roof) is only 3 feet high made of bamboo poles and *tatties*. The roof descends from a central pole all over the wall giving the appearance of an occluded Buddhistic *stupa*. In each such thatched abomination live 5 to 8 people. Is it any wonder that the inhabitants of many of these groups of insanitary and ill-ventilated huts are infected with tuberculosis?

One other important socio-environmental factor which favours the development of the disease is the attitude of the mind. In tuberculosis, more than in any other disease, the mental factor, such as domestic worry and unhappy surroundings, is an important contributing cause to the onset of the disease. The joy of life not only emanates from within but also from happy environmental circumstances.

The writer had the opportunity to treat one of the princes of India who lived in an atmosphere of suspicion and distrust consequent on domestic infelicity, before he fell a victim to tuberculosis. Mental worry in that case was certainly a potent predisposing factor in the development of the disease. The writer has also known of three nurses who developed tuberculosis a few months after being disappointed in love. On systematically enquiring into the life and environment of 100 consecutive patients prior to the onset of the disease it was found that 75 per cent of them gave definite history of serious mental worry. Whatever be the nature of worry, be it a disappointment in love or unhappy married life, or sudden and serious financial loss, an unhappy state of mind is certain to undermine the health of an individual and make him more susceptible to tuberculous infection. Among mental patients the incidence of tuberculosis is great in those who suffer from the depressive type of mental aberration.

Another contributing social factor is the fairly rapid urbanization and industrialization which are taking place in India, without the sanitary conscience of the nation being fully developed. This naturally leads to increasing incidence of tuberculous disease. Nor are the rural areas in India free from the ravages of the disease. This is due to people in the villages in the neighbourhood of a town seeking employment during the day in the city and going back for the night to their homes. The result is that they carry infection from the town to the villages which have no modern sanitation.

In all the big cities of the world, owing to the growth of travelling that is entailed in getting daily to and from work, the lack of facilities for recreation in the open air and the sense of irritation and anxiety which is so frequently associated nowadays with vocations followed and circumstances encountered in such places, there is lowering of resistance and consequent predisposition to tuberculosis.

One other social factor which contributes to the spread of infection and disease is the excessive crowding of people during fairs and festivals and the extensive movement of pilgrims which is a peculiar feature in India. It is estimated that about 20 million pilgrims travel every year from one end of the country to the other carrying in their train acute as well as chronic infectious diseases. The writer has had occasion to treat several of the pilgrims suffering from tuberculosis in his wards, on their return home after a pilgrimage to Benares where they not only attained merit but also acquired the disease.

#### *Social factor in prevention*

It has been found that even in the most modern and the most civilized cities almost all the adolescents are infected with tuberculosis. Hence to prevent infection is not practicable. In infants of course it may be possible to do so by adopting the Grancher system of isolation of infants born of tuberculous parents. But after the period of infancy, especially with the commencement of the school-going age, it is almost impossible to prevent infection. Hence the only way to prevent the disease from developing is by increasing the resisting power of the community both individually and collectively. It is to be done by improving the social and economic status of the people and encouraging them to live in happy environments. This is easier said than done. Even the best of modern cities has its slum problem yet to be solved. The problem is extremely acute in India where appalling poverty is the rule rather than the exception. Unfortunately the socio-economic problem in India is intimately intertwined with the political problem. Hence prevention of tuberculosis is almost impossible in India at present, as it depends entirely on national prosperity.

A close study of the rigorous campaigns instituted in many civilized countries towards prevention of tuberculosis reveals that far from their succeeding in their misdirected though well-meant efforts, they have only created an intense phthisiophobia. Fishburg considers it 'a vain effort to let loose swooping social service workers, like so many prohibition agents on defenceless tuberculous patients, and not a few who never had tuberculous disease. Follow them up, push them from pillar to post, interfere with their employment, with contracting suitable marriage, etc., as has been done in many cases with a view to preventing infection of fellow

centres, both in town and country, and if they are conducted with the same care and energy as the one under review, they should add much further valuable information on how to deal with this problem. But, as practically everyone who writes on health problems concerning the whole of India is forced to remark, India is a vast country with many different climates and peoples with varied habits and religious beliefs with consequent differences in its local health problems; therefore if the investigation of

maternal mortality throughout the country is to be left to the sole efforts of the Research Fund Association it will be many decades before even the preliminary surveys are completed. It is accordingly suggested that now that this excellent report has been published it might be taken as a model for independent inquiries elsewhere, which could be profitably conducted by various local authorities, and in this way acquisition of the necessary preliminary information would be greatly speeded up.

### SOCIAL ASPECTS OF TUBERCULOSIS

By R. VISWANATHAN, B.A., M.D., M.R.C.P. (Lond.),  
T.D.D. (Wales)

Lecturer in Tuberculosis, Medical College, Vizagapatam

#### Introduction

KOCH'S discovery of the tubercle bacillus revolutionized the time-honoured conceptions regarding phthisiogenesis, but it has brought in its train new problems difficult of solution. Though the problem of tuberculous infection is adequately solved, a satisfactory explanation of tuberculous disease is still wanting. Bacteriology is considered by many as inadequate to clear up completely the ætiological problems of phthisis. Why, for instance, when the vast majority of urban populations are infected with tubercle bacilli consequent on its ubiquitous distribution, do only a small percentage of those so infected suffer from the ravages of the disease? Why should the disease take an acute course in some, resembling the conflagration in a forest fire, while in others it is chronic and slow, like a smouldering charcoal fire? Why should the pathological changes be so varied in different individuals? Why should some members of a tuberculous family suffer from the disease while others enjoy a relative immunity? The existence of such apparent discrepancies is sufficient testimony to the fact that the discovery of the tubercle bacillus as the causative organism in tuberculosis has only touched the fringe of the problem of phthisiogenesis. Attention has therefore been diverted to accessory non-parasitic causes of phthisis, both endogenous and exogenous. In the latter group of causes comes the important social factor including environmental peculiarities and economic conditions, such as occupation, housing, nourishment, etc., and also the geographical *milieu*.

#### Social factor in ætiology

Even in cities which boast of ideal methods of sanitation the incidence of infection with tubercle bacilli, as judged by the tuberculin test, is as high as in others less fortunately endowed. It has been shown that 90 to 98 per cent of urban

populations in Europe are infected with tubercle bacilli by the time they reach the age of 24. By no means yet known to man is it possible to prevent civilized mankind from coming into contact with tubercle bacilli. It is no doubt true that during infancy the well-to-do are shielded from contact with tuberculosis, unless one of the family or servants is affected with the disease, but when they reach the school-going age they come into contact with the outside world and hence are as liable to infection as those in the poorer strata of the population. Hence infection with tubercle bacilli is only slightly influenced by social and economic conditions. More important than infection is the question of morbidity due to tuberculosis. It has been statistically established beyond any possibility of doubt that tuberculosis is pre-eminently the poor man's disease. How does poverty increase the incidence of tuberculosis? This problem has to be looked at from various aspects. First and foremost is the question of malnutrition due to inability to buy the proper quantity, as well as quality, of foodstuffs. Stallybrass in 1931 says, whether it is through better nutrition or better housing or both it appears clear that if wisely expended and not wasted on alcohol, etc., rising wages produce a fall in tuberculosis. When therefore the incidence of tuberculosis morbidity is inversely proportionate to the wage-earning capacity its proportion among the unemployed will naturally be enormously greater. The tuberculosis mortality per 100,000 of population in the various parts of the city of Paris calculated by Bertillon is as follows :—

Age in years	..	1-19	20-39	40-59	Over 60
Very rich	..	61	129	159	105
Rich	..	79	205	241	168
Poor	..	168	526	641	340
Very poor	..	180	685	907	524

These figures are self-explanatory.

Apart from the question of malnutrition consequent on poor economic conditions, congestion of population is another equally important factor. It is a well-known fact that the incidence of tuberculosis is greatest in the slum areas

of every city where the poor live huddled together in insanitary and ill-ventilated dwellings. Besides poverty, overcrowding and filth may act by favouring contact infection.

In the city of Vizagapatam, where the writer has been working as Tuberculosis Officer for some years, the poor people live huddled together in huts of a peculiar picturesque construction. The average hut is built on a floor which is but 6 inches above the surrounding ground. The wall (there is only one wall as the structure is circular near the floor and tapers to a point at the top of the roof) is only 3 feet high made of bamboo poles and *tatties*. The roof descends from a central pole all over the wall giving the appearance of an occluded Buddhistic *stupa*. In each such thatched abomination live 5 to 8 people. Is it any wonder that the inhabitants of many of these groups of insanitary and ill-ventilated huts are infected with tuberculosis?

One other important socio-environmental factor which favours the development of the disease is the attitude of the mind. In tuberculosis, more than in any other disease, the mental factor, such as domestic worry and unhappy surroundings, is an important contributing cause to the onset of the disease. The joy of life not only emanates from within but also from happy environmental circumstances.

The writer had the opportunity to treat one of the princes of India who lived in an atmosphere of suspicion and distrust consequent on domestic infelicity, before he fell a victim to tuberculosis. Mental worry in that case was certainly a potent predisposing factor in the development of the disease. The writer has also known of three nurses who developed tuberculosis a few months after being disappointed in love. On systematically enquiring into the life and environment of 100 consecutive patients prior to the onset of the disease it was found that 75 per cent of them gave definite history of serious mental worry. Whatever be the nature of worry, be it a disappointment in love or unhappy married life, or sudden and serious financial loss, an unhappy state of mind is certain to undermine the health of an individual and make him more susceptible to tuberculous infection. Among mental patients the incidence of tuberculosis is great in those who suffer from the depressive type of mental aberration.

Another contributing social factor is the fairly rapid urbanization and industrialization which are taking place in India, without the sanitary conscience of the nation being fully developed. This naturally leads to increasing incidence of tuberculous disease. Nor are the rural areas in India free from the ravages of the disease. This is due to people in the villages in the neighbourhood of a town seeking employment during the day in the city and going back for the night to their homes. The result is that they carry infection from the town to the villages which have no modern sanitation.

In all the big cities of the world, owing to the growth of travelling that is entailed in getting daily to and from work, the lack of facilities for recreation in the open air and the sense of irritation and anxiety which is so frequently associated nowadays with vocations followed and circumstances encountered in such places, there is lowering of resistance and consequent predisposition to tuberculosis.

One other social factor which contributes to the spread of infection and disease is the excessive crowding of people during fairs and festivals and the extensive movement of pilgrims which is a peculiar feature in India. It is estimated that about 20 million pilgrims travel every year from one end of the country to the other carrying in their train acute as well as chronic infectious diseases. The writer has had occasion to treat several of the pilgrims suffering from tuberculosis in his wards, on their return home after a pilgrimage to Benares where they not only attained merit but also acquired the disease.

#### *Social factor in prevention*

It has been found that even in the most modern and the most civilized cities almost all the adolescents are infected with tuberculosis. Hence to prevent infection is not practicable. In infants of course it may be possible to do so by adopting the Grancher system of isolation of infants born of tuberculous parents. But after the period of infancy, especially with the commencement of the school-going age, it is almost impossible to prevent infection. Hence the only way to prevent the disease from developing is by increasing the resisting power of the community both individually and collectively. It is to be done by improving the social and economic status of the people and encouraging them to live in happy environments. This is easier said than done. Even the best of modern cities has its slum problem yet to be solved. The problem is extremely acute in India where appalling poverty is the rule rather than the exception. Unfortunately the socio-economic problem in India is intimately intertwined with the political problem. Hence prevention of tuberculosis is almost impossible in India at present, as it depends entirely on national prosperity.

A close study of the rigorous campaigns instituted in many civilized countries towards prevention of tuberculosis reveals that far from their succeeding in their misdirected though well-meant efforts, they have only created an intense phthisiophobia. Fishburg considers it 'a vain effort to let loose swooping social service workers, like so many prohibition agents on defenceless tuberculous patients, and not a few who never had tuberculous disease. Follow them up, push them from pillar to post, interfere with their employment, with contracting suitable marriage, etc., as has been done in many cases with a view to preventing infection of fellow

workmen'. Again Baldwin as early as 1913 said 'Adults are very little endangered by close contact with open tuberculosis, and not at all in ordinary association. . . . It is time for a reaction against the extreme ideas of infection now prevailing. There has been too much read into the popular literature by health boards and lectures that has no sound basis in facts and it needs to be dropped out and revised'.

Anti-tuberculosis campaigns with glaring posters and popular lectures have certainly produced an unnecessary scare in the minds of the lay public who naturally begin to shun the unfortunate people who are afflicted or suspected of being afflicted with phthisis. This phthisiophobia is itself an indirect danger as is so clearly expressed by the American historian Garret Brown. 'Known and recognized and decently entreated, we are not dangerous. Victims ourselves of this same regime of ignorant and self-deceiving inhumanity we are called on every hour of our lives for a magnanimous consideration of others. Society can hardly find it surprising or a grievance if our human nature should sometimes weaken under the strain of the incessant provocation it endures from this strange working of human nature in general. . . . If the public is to be safe from us, if the public is to continue to have our protection from that against which it failed to protect us, then the public must make it possible for us to get what we must have to live. We are neither criminals nor mendicants. We do not ask favours, we merely revolt against a mean and stupid oppression. We revolt against ignorance and against a lie. The public would get rid of us, and thereby make us inescapable. It would pretend, and would have us pretend, that we are nowhere. It thereby ensured that we shall be everywhere. It proscribes us and thereby admits us'.

These methods of phthisiophobia ought to be avoided as they are not only unnecessary but positively dangerous. The patients are to be told that they are a menace only to infants and not at all dangerous to adults. They are sufficiently philanthropic to take proper precautions against infecting those who may be harmed by it. On the other hand, if these unfortunate victims of phthisis are goaded to desperation by subjecting them to unwarranted social ostracism and obloquy for no fault of their own, the problem of control will be rendered all the more difficult. Hence, it is the opinion of the writer that no kind of social disability or stigma should exist with respect to tuberculosis, as otherwise many of the patients will be driven underground and live in promiscuity, in which state they will be a potential danger as they will not be actuated by 'magnanimous consideration for others'. From the therapeutic point of view also, social disabilities of the tuberculous should be wiped out as the inferiority complex engendered thereby will have a depressive effect on the minds of the patients.

### *Social aspect of treatment*

If the community can demand of the consumptive to shape his life in such a manner as to prevent the dissemination of the disease, the consumptive has in his turn every justification to expect the community to be mindful of its own duties towards him, who is suffering to a great extent because of conditions which the authorities have permitted to prevail. They should not only see that conditions favouring development of phthisis should be eliminated but also provide shelter, proper nourishment and medical attendance for those patients who are not in a position to procure it at their own expense. It is the duty of the state to maintain an adequate number of tuberculosis clinics and provide accommodation for patients in hospitals and sanatoria. The conditions in India are indeed appalling. With a population of 370 millions out of which a moderately estimated 5 million are suffering from tuberculosis there are only 2,703 beds available in hospitals and sanatoria for the whole of India. It will not be out of place to remark, however, that the appeal for funds for an Anti-Tuberculosis Campaign made recently by Lady Linlithgow is extremely opportune and it is hoped that something tangible and substantial will be done in the near future to bring this disease under control in India.

Social and environmental conditions have an extremely important bearing on the treatment of tuberculosis. Experience as well as a general impression testify that in good social circumstances and in good living conditions tuberculosis takes a more favourable course than in a socially inferior environment. A patient who can afford to detach himself from his family and get treated for the proper period of time in an efficient institution, and subsequently to live the carefully regulated life prescribed under satisfactory conditions, with a good prospect of the benefit he has received from sanatorium treatment being consolidated, has a much better expectation of life than the one who is less fortunate in his social and economic level.

But there is one other aspect of environment which has not been adequately stressed. It has been found that too often men and women contract the disease even though their standard of living is high, their housing hygienic and their working conditions excellent. 'Not merely good material conditions, not merely physical exercise whether organized or otherwise, but a mental state . . . ' says Varrier-Jones. He also adds 'this mental state is of the utmost importance. It is produced by an imbalance of our endocrine system, and that imbalance somehow upsets and undermines resistance to disease'. In the actual treatment of the tuberculous patients the environment must have something psychological about it. There must be an atmosphere of encouragement. An attitude of hope and not despair, a quiet contentment engendered by

confidence in himself and those who look after him, and an optimistic cheerfulness will go a long way towards the arrest of the disease process. Material conditions alone cannot produce this result. The mind must be at ease too. The consequence of mental ease is certainly the restoration of endocrine balance. In the degree in which we can create the conditions for well being, in that same degree can we maintain our re-created resistance to disease.

When a small wage-earner, who is also the sole support of his family, falls a victim to tuberculosis, the source of income is suddenly stopped, unless his employer gives him leave for the sick period with full pay. This is extremely unlikely as it would be a financial loss to the employer who will have to pay not only the man on leave but also the man who is temporarily employed in his place. If it is only a question of a few weeks, it could possibly be adjusted. But the treatment of tuberculosis is a question of months and sometimes years. The state should therefore provide for free treatment for such individuals and for the support of their families during the period of their illness. Unless this is done the patients will not submit themselves for proper and prolonged treatment in state institutions, as they will naturally be anxious to get discharged as soon as they feel slightly better and go back to their work, as the life of their families depends on their working and earning. Even if they are compelled to stay in the hospital or sanatoria, their condition may not improve as their minds will always be in an anxious state with worry for their wives and children. Under both these considerations therefore the State should provide not only for the free treatment of the poor wage-earning consumptives but also for the adequate support of their families if they have no other source of income. The only other way by which the problem is to be solved is by insisting on an universal system of national health insurance by which the insurance companies are made to pay for the treatment of the insured person and also for the support of his family.\*

#### *Social aspect of after-care and rehabilitation*

The sanatorium form of treatment has come to stay. Collapse therapy and other therapeutic measures, in spite of the marvellous results produced, cannot replace institutional treatment but form an important and necessary ancillary to it. It was found, however, that though the immediate results of sanatorium treatment were promising, the follow-up statistics of Bardswell, Weickert and Brown showed the ultimate results

to be unsatisfactory. This was found to be due to the inability on the part of many of the patients to continue the same kind of regime for the prescribed period of time after discharge from the sanatorium. The after-care movement therefore is the logical outcome of sanatorium treatment.

The problem of rehabilitation can be considered from two aspects, firstly from that of the patient and his family and secondly from the point of view of social hygiene and prophylaxis by institutional segregation of the chronically sick.

The plea for an elaborate system of after-care from the point of view of the patients is itself a confession of our inability to effect complete cure in tuberculosis. The utmost one can hope for is the arrest of the disease process. The maintenance of the arrest necessitates, always a temporary and often a permanent, continuity of the regime of life prescribed and followed during the stay in the institution. Many of the return cases met with in sanatoria and hospitals are because of the sudden return to the old mode of life and environment immediately after discharge. This can in a good measure be avoided and the number of patients who can take their place in the open labour market can be considerably raised by means of long treatment supplemented by after-care.

According to Vos the after-care patients can be divided into three groups, namely, (a) those who after treatment varying in length are completely healed, (b) those who regain their full earning capacity through temporary after-care or those who retain it through permanent after-care and (c) those who cannot regain their earning capacity because their illness takes an inevitable and unstable course.

The creation of combined institutional and semi-institutional systems of treatment and after-care necessitates grouping together of different establishments which facilitates the easy passage of various grades of patients without discontinuity through the phases of convalescence (medical and social). This may be accomplished either by creating a series of separate institutions for each of the various phases connected with one another through a central organization or by building up multiple units, the various departments of which are adapted to the various stages of convalescence.

In most of the institutions intended for treatment and rehabilitation of tuberculous patients there is a threefold organization. The parts of the unit are :—

- (1) The sanatorium-hospital for treatment.
- (2) The after-care section as intermediary between clinical treatment and re-employment in normal or sheltered industries.
- (3) The village settlement with industries for sheltered employment.

\* [Note.—So far as the Editor is aware no country has hitherto provided for an universal national health insurance of its inhabitants. National Health Insurance Acts provide for wage-earners up to a certain level. Insurance companies insure for sickness and invalidity on payment of a premium. As such it cannot be a compulsory and universal procedure.—EDITOR, I. M. G.]

Economic and sociological laws govern the growth and determine the character of any rehabilitation scheme which also organizes the post-sanatorium life of the tuberculous.

A pertinent question that may be asked is whether such an elaborate system of after-care is warranted. The excellent results shown at the Papworth settlement are sufficient to justify the institution of after-care schemes. Even those who can be considered as completely arrested cases require prolonged convalescence in sheltered employment before they are allowed to go back to their old work and environment. There are others in whom the disease is stabilized but who are unfit to return to their previous employment but who are fit enough for working in other fields. These can easily be trained for their new jobs during their period of convalescence, living under a system of temporary sheltered employment. There are yet other sub-standard consumptives who can work only under constant supervision and who therefore have to live under a system of permanent sheltered employment. The remainder are chronic invalids who are permanently disabled and have to be segregated in these settlements.

The after-care schemes are directed towards the socio-therapeutic protection of the various

grades of ex-patients after their discharge from hospitals and sanatoria.

It may be asked why should the state concern itself with tuberculosis and the fate of tuberculous patients? It is because the state demands notification of the disease, to protect itself. But in protecting itself in this way it may be putting in peril the livelihood and the whole social status of the patient. His work and his home are liable to be prejudiced by notification. If the state demands protection at such a cost, it must accept the liability of providing sufficient compensation. The state should not only provide treatment but also see that the victim of the disease, if he cannot be cured, can be at least provided with employment in a suitable environment. The result of such efforts on the part of the state is threefold. The state is protected from infection; the patient's family also is similarly protected and finally 'a load of hopeless frustration is lifted from the shoulders of the patient himself'.

As tuberculosis is essentially a social disease, socio-economic considerations are of paramount importance in all the aspects of the tuberculosis problem. As with prevention so with after-care the problem of lessening the ravages of tuberculosis is again and again the problem of providing healthy conditions of living and working.

### BRITISH PHARMACEUTICAL PRODUCTS\*

TABLE I

*Showing foreign products of which there are British products with the same essential composition*

Foreign product	British product	British maker and/or supplier
Acecoline	Acetylcholine chloride	B. D. H.; B. W.; Evans.
Acidol	Pragmoline	M. & B.
Acidol pepsin	Betaine hydrochloride	Boots; B. D. H.; Evans.
Adalin	Betaine hydrochloride and pepsin	Boots; B. D. H.; Evans; Richter.
	Carbromal B. P.	A. & H.; Boots; B. D. H.; Evans; M. & B.; Richter.
	Planadalin	M. & B.
Afenil	Calcium chloride and urea	B. D. H.; Evans.
Agurin	Theobromine and sodium acetate	Boots; B. D. H.; Evans; M. & B.; T. & H. S.; Whiffen.
Airol	Bismuth oxyiodogallate B. P. C.	Boots; B. D. H.; B. W.; Evans; M. & B.; T. & H. S.; Whiffen.
Aluoin	Diamorphine hydrochloride B. P.	Evans; J. F. M.; M. & B.; T. & H. S.
Anæsthesin	Benzocaine B. P.	A. & H.; Boots; B. D. H.; Evans.
Aphrodine	Yohimbine	B. D. H.; Evans; Johnsons.
Aristol	Thymol iodide B. P. C.	A. & H.; Boots; B. D. H.; Evans; G. Chem.; Howards; M. & B.; Whiffen.
Arrhenal	Disodium methylarsenate	B. D. H.; Evans.
Atebrin	Mepacrine hydrochloride †	I. C. I.; M. & B.
	Quinacrine	M. & B.
Atebrin musonate	Mepacrine methanesulphonate †	M. & B.
	Quinacrine soluble	M. & B.
Atocin	Cinchophen B. P.	A. & H.; Boots; B. D. H.; B. W.; Evans; Howards.
Atophan	Cinchophen B. P.	A. & H.; Boots; B. D. H.; B. W.; Evans; Howards.
	Tophosan	Richter.
Atophan balsam	Ung. Agotan co.	Howards.
Atoxyl	Sodium arsanilate	Evans; M. & B.
	Soamin	B. W.
Avertin	Bromethol †	Boots; B. C.; B. D. H.; B. W.; I. C. I.
Bayer 205	Suramin †	B. D. H.
	Antrypol	B. D. H.

\* Reprinted from the *Pharmaceutical Specialities*, second edition, published by the Association of British Chemical Manufacturers.

† Name chosen for use in the *British Pharmacopœia*.

TABLE I—*contd.*

Product	British product	British maker and/or supplier
	Vitamin B <sub>1</sub>	A. & H.; B. C.; B. D. H.; B. W.; Evans; Glaxo; M. & B.; Richter; Roche.
	Berin	Glaxo.
	Thianin	Richter.
	Benerva	Roche.
hydro-	Benzamine hydrochloride B. P. C.	Boots; B. D. H.; B. W.; Evans.
	Vitamin B <sub>1</sub>	A. & H.; B. C.; B. D. H.; B. W.; Evans; Glaxo; M. & B.; Richter; Roche.
	Berin	Glaxo.
	Thianin	Richter.
	Benerva	Roche.
Antaemame	Inj. bismuth salicylate B. P.	A. & H.; Boots; B. D. H.; Evans.
Cantan	Benzamine	Boots; B. D. H.; B. W.; Evans.
	Ascorbic acid B. P. (Vitamin C)	A. & H.; Boots; B. C.; B. D. H.; B. W.; Evans; Glaxo; Roche.
	Celin	Glaxo.
	Planavit C	M. & B.
	Redoxin	Roche.
Cebion	Ascorbic acid B. P. (Vitamin C)	A. & H.; Boots; B. C.; B. D. H.; B. W.; Evans; Glaxo; Roche.
	Celin	Glaxo.
	Planavit C	M. & B.
	Redoxin	Roche.
Chinosol	Potassium hydroxy-quinoline sulphate B. P. C.	A. & H.; Boots; B. D. H.; Evans; J. F. M.; Pierson.
	Soloid hydroxy-quinoline sulphate.	B. W.
Chloretone	Chlorbutol B. P.	A. & H.; Boots; B. D. H.; Evans; M. & B.; Morson.
Creosotal	Creosote carbonate B. P. C.	Boots; B. D. H.; W. J. B.; Evans; M. & B.
Decholin tablets	Dehydrocholic acid	B. D. H.
Decholin ampoules	Sodium dehydrocholate	B. D. H.
	Suprachol	Richter.
Dermatol	Bismuth subgallate B. P. C.	A. & H.; Boots; B. D. H.; B. W.; Evans; M. & B.; Morson; T. & H. S.
Devegan	Acetarsol vaginal compound	Evans.
	Stovarsol vaginal compound	M. & B.
Digitaline	Digitalin granules	A. & H.; Boots; B. D. H.; Evans.
Nativelle	Digitoxin	Boots; J. F. M.
	Tabloid digitalin cryst	B. W.
Dionin	Ethylmorphine hydrochloride B. P. C.	A. & H.; Boots; B. D. H.; B. W.; Evans; J. F. M.; M. & B.; T. & H. S.
Doryl	Carbachol*	A. & H.; B. W.
Duotal	Guaiacol carbonate B. P. C.	A. & H.; B. D. H.; B. W.; W. J. B.; Evans; M. & B.
Esterol	Benzyl succinate B. P. C.	A. & H.; B. D. H.; W. J. B.; Evans; G. Chem.
Eugallol	Pyrogallol monoacetate	B. D. H.; Evans; Johnsons.
Eumydrin	Atropine methyl nitrate	B. D. H.; T. & H. S.; Whiffen.
Euphthalmine	Tabloid ophthalmic euphthalmine hydrochloride	B. W.
Euphyllin	Theophylline and ethylenediamine	Whiffen.
	Aminophyllin	A. & H.
	Cardophyllin	Whiffen.
Euquinine	Quinine ethyl carbonate B. P.	A. & H.; Boots; B. D. H.; B. W.; Evans; Howards.
Evipan	Hexobarbitone*	Boots; B. C.; B. W.; I. C. I.; M. & B.
	Hexamastab	Boots.
	Cyclonal	M. & B.
Evipan sodium	Soluble hexobarbitone*	Boots; B. C.; B. W.; I. C. I.; M. & B.
	Hexamastab sodium	Boots.
	Cyclonal sodium	M. & B.
Exalgin	Methylacetanilide B. P. C.	A. & H.; Boots; B. D. H.; Evans.
Perronyl	Citrated ferrous chloride B. P.	A. & H.; B. D. H.; B. W.; Evans; Howards; Johnsons.
Fibrolysin	Inj. thiosinamine and sodium salicylate B. P. C.	Boots; B. D. H.; Evans.
Fouadin	Stibophen*	B. W.; Glaxo.
Fraisse's ferruginous ampoules.	F. N. S.	A. & H.
Germanin	Suramin*	B. D. H.
	Antrypol	B. D. H.
Helmitol	Formamol B. P. C.	A. & H.; B. D. H.; Evans; H. & W.
Hydronal	Collumina	Evans.
	Alocol	Wander.
Hydropyryn	Lithium acetylsalicylate B. P. C.	A. & H.; Boots; B. D. H.; Evans; Howards.

\* Name chosen for use in the British Pharmacopœia.

TABLE I—*contd.*

Foreign product	British product	British maker and/or supplier
Hypophysin	Pituitary extract B. P.	A. & H.; Boots; B. D. H.; B. W.; Evans; Glaxo; P. & B.
Ichthyol	Glandutrin Ichthammol B. P.	Richter. A. & H.; Boots; B. C.; B. D. H.; Evans; J. F. M.; M. & B.
Iodeikon	Iodophthalein B. P. Stipolac	A. & H.; B. D. H.; Evans. B. W.
Iodipin	Opacol; Opacin Iodised oil B. P. Iodatol	M. & B. A. & H.; Evans. B. D. H.
Iod-Tetragnost	Neo-Hydriol Iodophthalein B. P. Stipolac	M. & B. A. & H.; B. D. H.; Evans. B. W.
Lenigallol	Opacol; Opacin	M. & B.
Lipiodol	Pyrogallol triacetate Iodised oil B. P. Neo-Hydriol	B. D. H.; Evans; Johnsons. A. & H.; Boots; B. D. H.; Evans. M. & B.
Lipolysin	Iodatol (iodised oil 40%)	B. D. H.
Luminal	Anobesc Phenobarbitone B. P.	P. & B. A. & H.; Boots; B. D. H.; Evans; J. F. M.; M. & B.; T. & H. S.
Luminal sodium	Gardenal Soluble phenobarbitone B. P.	M. & B. A. & H.; Boots; B. D. H.; Evans; J. F. M.; M. & B.; T. & H. S.
Lutren	Gardenal sodium Lutcostab Progesterin Glanduantin	M. & B. Boots. B. D. H. Richter.
Magnesium perhydrol	Magnesium peroxide	A. & H.; Boots; B. D. H.; Evans; G. Chem.; H. & W.; Laporte; M. & B.
Medinal	Magnozon Soluble barbitone B. P.	Richter. A. & H.; Boots; B. D. H.; Evans; J. F. M.; M. & B.; Richter; T. & H. S.
Merkozone	Tabloid soluble barbitone Hydrogen peroxide 12 vols.	B. W. A. & H.; Boots; B. D. H.; Evans; G. Chem.; Laporte; M. & B.
Mercoloid	Collosol mercury sulphide	B. C.
Meta-Sympatol	<i>m</i> -Oxyphenyl-ethanolmethylamine hydrochloride	Light.

## ERRATUM

We regret that owing to an error 'Calsiod' on pages 176 and 179 of our March issue (wrongly spelt 'Calsoid' on p. 176) is listed as a foreign product. This is not the case, and we are informed that Messrs. Menley and James are the sole manufacturers of this product.

## Medical News

## MEDICO-SOCIAL QUESTIONS ARISING OUT OF THE MOVEMENTS OF CIVIL POPULATIONS

*Abstract report of the Emergency Sub-Committee of the Health Committee (League of Nations, Health Organization, Geneva, 4th to 7th March, 1940)*

AN attempt is made to state the principles and enumerate the measures which should be applied to control epidemic diseases and to protect the health of civil populations compelled, through hostilities or otherwise, to move from one area to another.

Displacement of a population may be compulsory or voluntary and, in addition, may concern only the native inhabitants of a given country or may include newcomers. The term therefore covers partial or complete evacuation of an indigenous population as well as the influx of refugees into a country from outside.

The following scheme is designed for a transfer of population under the most favourable conditions. Where speed is essential, however, whatever less elaborate action may be possible in the circumstances will obviously have to be accepted as sufficient.

The transfer of a population also raises a series of problems which are either purely social or have a bearing on economic policy or labour organization.

## I. MEASURES PRECEDING THE TRANSFER

The health authorities of the evacuated area and those of the reception area should make preliminary arrangements to facilitate co-ordination. Liaison should,

in particular, be established between the various medico-social services, especially those responsible for the reception, the isolation and the medical supervision of open cases of tuberculosis, other infectious cases and persons in need of special care.

The medical profession and the nurses and social workers should be familiarized beforehand with the work to be allocated to them. The social workers, for instance, will be responsible for explaining to the heads of families what rations, kit and other necessities are required and how these can best be carried.

In this connection, stress should be laid on the importance of the visiting nurses and social workers previously in charge of families of a locality population group remaining with that group both during the move and after arrival in the assigned reception area.

If it is necessary to spread the evacuated population over considerable areas, every effort should be made to regroup the families or even larger social units in order thus to reconstitute the transferred community as an entity with its administrative services.

Provision should be made for an order of priority in the execution of the plan, which should be determined by the existing circumstances, and should apply in particular to children and expectant mothers.

It is of importance that every person transferred should be provided with an identity document—i.e., identity discs (particularly for infants and children), individual or family evacuation booklets. Such a system is essential, not only in the interests of the individual, but also to apply all necessary supervision.

Preliminary propaganda and instructions should be undertaken among the population to be transferred as well as in the reception areas. This should include the education of women for the duties which will fall upon them. In this work, the co-operation of women's organizations may be extremely valuable. Teaching staffs can similarly play an important part—e.g., in preparing children for adaptation to life in a rural environment.

Propaganda in favour of voluntary evacuation may usefully be undertaken before compulsory evacuation becomes necessary.

The requisite measures are:

#### A. In the areas to be evacuated

Strict enforcement of existing or supplementary measures for the prevention of infectious disease and the protection of public health generally.

Propaganda by all available means (pamphlets, wireless, press, etc.) to promote vaccination against smallpox, diphtheria and the enteric fevers.

Registration, prophylactic medical examination and, when necessary, compulsory vaccination of persons to be evacuated.

Census of patients being treated in their homes.

Census of expectant mothers; classification according to the stage of pregnancy.

Ascertainment of open cases of tuberculosis, cases of venereal and other communicable diseases, 'carriers', cripples, mental cases, abnormal persons, etc.

#### B. In the transit areas

Provision of general and special means of transport (hospital trains, motor rail-cars and motor coaches fitted for stretcher cases, ambulances, etc.).

Provision of medical and nursing staff during the journey.

#### C. In the reception areas

##### 1. Choice of a reception area in relation to:

(a) Climatic conditions, local customs and the type of work of the transferred population.

(b) The health survey of the area.

Qualitative and quantitative survey of the water supply. Application of emergency methods of water purification.

General sanitation with particular reference to sewage and refuse disposal. Completion of any constructional work in hand and inauguration of essential supplementary schemes.

(c) The survey of available living accommodation.

Newcomers to a reception area may be billeted on the local inhabitants or housed in collective accommodation provided by existing buildings, reconditioned where necessary, or by hutments or camps. Due consideration should be given to the relative advantages and costs of each of these systems.

In the case of camps, important factors are the layout, internal equipment and the time required for erection.

In the accommodation survey, special provision for certain categories must not be overlooked—e.g., infants, children of school age, expectant and nursing mothers, old people, sick, cripples, mental cases and abnormal persons.

##### 2. Organization of reception.

Provision of:—Local services in charge of billeting; reception committees and headquarters; co-ordinating agencies between the various services; social centres and homes.

Arrangements should be made with a view to maintaining family and community life.

##### 3. Provision of medical and health services, including equipment.

(a) Arrangements for the maintenance in the reception area of the existing public health personnel and social workers and of an adequate number of doctors and nurses.

(b) Provision of adequate means of transport for doctors, nurses and midwives.

(c) Reinforcement of the hospitals and other institutions (maternity homes, hostels, crèches, milk dispensaries, etc.) either by enlargement of existing buildings or by the creation of new institutions in accordance with a general scheme of co-ordinated development.

Such a plan includes, in addition to general hospitals, sick bays for mild cases (infectious or non-infectious) and minor injuries, together with accommodation for unbillable children. Adequate provision is required of beds, drugs, dressings, sera and vaccines (including convalescent sera) as well as facilities for carrying out biological and bacteriological analyses.

The necessary preparations also include the provision of health centres, specialized dispensaries, infant welfare centres, bathing establishments, disinfection and disinfestation ovens, and their distribution according to a predetermined plan.

4. Survey of the available supply of food and milk and calculation of probable requirements.

5. Survey of available transport and estimated requirements.

#### II. MEDICO-SOCIAL WORK DURING THE TRANSFER

A. Assistance should be provided under medical supervision by nurses accompanying the population and by supplementary first-aid personnel.

B. Emergency hospital accommodation, canteens and milk kitchens, together with adequate sanitary conveniences (washing facilities and water-closets) should be provided at suitable points *en route*.

#### III. MEDICO-SOCIAL WORK IN THE RECEPTION AREAS

##### A. Medico-social supervision of evacuees

##### 1. Personnel:

Public health officers, medical practitioners, dental personnel, sanitary inspectors, midwives, nurses, health visitors, social workers, personnel of the Red Cross and first-aid organizations.

It is of fundamental importance that, as far as possible, the personnel should be that previously in charge of the transferred population. It is essential, for instance, that a social worker attached to a population group should accompany it during transit and remain with it in the reception area. It should, however, be supplemented, so far as may be necessary, by personnel recruited locally or requisitioned from another district.

Apart from its contribution to the general and social supervision of the population, the medical staff can in particular undertake prophylactic examinations (where these could not be carried out prior to departure), the detection and isolation of infectious cases, vaccinations, etc.

In every case, care should be taken to use, as far as possible, medical and social personnel who understand the language and habits of the transferred populations.

##### 2. Health centres and specialized dispensaries.

##### 3. Admission to hospital.

Adjustment of rules and financial conditions for admission.

##### 4. Mobile medical units.

General or specialized units (obstetrics, pediatrics, venereal disease, tuberculosis, dental care, laboratory examinations, etc.).

##### B. Hygiene of the reception area

Inspection by qualified personnel of the living accommodation provided.

Improvement of the prevailing sanitary standards of the billeting areas.

Periodic examination of drinking-water and supervision of sewage and household waste disposal, including fly, mosquito and rat control.

Maintenance of an adequate diet (collective feeding, school canteens, etc.).

Control of the purity of foodstuffs.

### C. *Special problems*

Enuresis and its prevention by education.

Pediculosis and scabies.

Psychological problems, including measures to counteract the ill-effects of the sudden change of environment.

### D. *Importance of general education in hygiene amongst the transferred population*

The measure of success achieved in the medico-social protection of the transferred populations will be to a great extent determined by the standard of public health organization already existing in the reception area.

In these circumstances, the raising of public health standards, and the strengthening of the medico-social machinery and equipment would appear to be the most logical and efficient method of preparing for the possible evacuation of populations and for their reception in other areas.

In this connection, general indications for guidance have been given by the Health Organization in the studies carried out in 1933 on the best methods of safeguarding the public health in times of emergency. Among these methods, one was particularly stressed—namely, the necessity for the thorough co-ordination of all the services and agencies, central and local, concerned. In view of the intricacy of the problems connected with extensive population movements, this recommendation is of particular importance. It is essential, therefore, that an endeavour should be made to secure agreement and unity of direction among the various ministries concerned and at the same time to enlist the active support of all public and private organizations (Red Cross societies, women's organizations, boy scouts, first-aid societies, etc.). Such co-ordination alone will yield the maximum of results with the minimum of expenditure.

### SCOPE FOR MANUFACTURE OF PAPAIN IN INDIA

THERE is ample scope in India for papain manufacture. With the world demand increasing and cultivation of the plant which yields it comparatively easy, and sites with requisite conditions of climate and soil numerous, the drug, at its present attractive price, offers promising possibilities for a large-scale industry in India.

### THE NAIR HOSPITAL DENTAL COLLEGE

#### *Announcement*

THE Nair Hospital Dental College is affiliated to the College of Physicians and Surgeons, Bombay, and is recognized to prepare students for L.D.S., C.P.S., Diploma Course.

Entrance requirement—Inter Science (B. group, same as medical students).

Course—Four years.

BOMBAY.

V. M. DESAI, D.D.S., F.I.C.D.,  
Dean.

### HILSA FISH IN THE RIVER HOOGHLY

#### *Extensive breeding grounds discovered*

STUDIES of the life-history of the *hilsa*, which is one of the most important edible fish found in Bengal, are being made by the Zoological Survey of India.

While carrying out biological investigations, at the Pulta Water Works on the river Hooghly, the Zoological Survey of India discovered fairly extensive breeding grounds of the *hilsa*, which is sometimes known as the Indian *shad*. Studies made since then indicate that the fish breeds in the Hooghly throughout the year, the peak period being July to August with a second low peak in May.

The upstream migration of *hilsa* on which the main fishery of this species depends, is believed to be due to the flooding of the rivers during the monsoon and the state of sexual maturity of the migrating individuals. Fluctuations are noticed in the year-to-year fishery, and it is surmised that a five-year cycle exists as in the case of the European herring.

### CINEOL CONTENT IN EUCALYPTUS OIL

#### *(Press communiqué)*

THE necessity of reducing cineol content in eucalyptus oil from 70 per cent as in the B. P. 1914 to 55 per cent, and introducing the change in the new edition of British Pharmacopœia to be published in 1941, has been suggested by the Indian Chemical Manufacturers' Association to the British Pharmacopœia Commission, London. The Association states that the examination of several samples of eucalyptus oil in India has shown that the cineol content is not more than 60 per cent and therefore the higher standard has been not only working as a severe handicap in the way of the development of the eucalyptus oil industry in India, but also precluding the manufacturers of pharmaceutical preparations in this country from using the Indian eucalyptus oil in the preparations of B. P. Products. It is pointed out that eucalyptus trees grow on a large scale in the Nilgiris and to a small extent in U. P., Bihar and other places in India and the Madras Government have expressed an opinion that if the cineol content is reduced to 55 per cent it would greatly benefit planters, distillers and merchants in the Nilgiris. The reduction of cineol content, it is stated, will greatly encourage the cultivation of eucalyptus and its utilization for oil which will enable India to produce considerable quantities of this oil and export it to foreign countries. As regards the effect of the change in the cineol content on medicinal value, the Association points out that Brevet-Colonel R. N. Chopra, Director, Biochemical Standardization Laboratory, Calcutta, is of the opinion that the reduction to 55 per cent would not be of great therapeutic significance. On the other hand Indian eucalyptus oil has several advantages over oils from other countries on account of its being free from obnoxious constituents.

## Special Report

### Health Bulletin No. 27. Abstract of the Report of an Inquiry into the Causes of Maternal Mortality in Calcutta

By M. I. NEAL EDWARDS, M.D., W.M.S.

Professor of Maternity and Child Welfare, All-India Institute of Hygiene and Public Health, Calcutta

[In the introduction to this valuable report it is made clear that Calcutta was selected for this inquiry by the Maternal Mortality Advisory Committee of the

Indian Research Fund Association because of the facilities offered by the All-India Institute of Hygiene and Public Health and it does not mean that in the other cities (and the country districts) throughout India this subject is not of just as much importance. This is only the first of a series of such inquiries which it is the intention of the Research Fund Association to conduct as opportunity occurs, and no doubt other cities and rural centres will be selected for future inquiry.]

The object of this inquiry was to inquire into the number and investigate the causes of maternal deaths in Calcutta. The period during which follow-up of

deaths took place was 15th June, 1936, to 14th June, 1937.

The area chosen was that which is under the control of the Health Officer of the Calcutta Corporation.

The definition of 'maternal death' which has been adopted for the purpose of this inquiry was that used in the inquiry into maternal mortality made by the Department of Health for Scotland a few years ago and is expressed as follows:—

'Maternal deaths which occurred during pregnancy or within four weeks after the termination of pregnancy, or later if illness originated during pregnancy, childbirth or the puerperium.'

The registration cards in use provide no information regarding any relationship there may have been with pregnancy and childbirth, so cards were prepared identical with those in regular use by the sub-registrars but with the addition of the name of the inquiry and the following questions:—

Was she pregnant at the time of death?

Did she die during labour or abortion?

Did she die within three months after labour or abortion?

The health officer was kind enough to issue orders that these duplicate cards should be filled up for all female deaths between 10 and 50 years and that these cards should be returned with the ordinary registration cards.

We arranged to collect the duplicate cards daily from the health office and thereby obtained notice of deaths within one to three days of their occurrence so that investigation was possible with very little further delay.

Arrangements to receive the duplicate cards were made about three months before the inquiry actually started and cards were coming in regularly when the investigation of deaths began on 15th June.

It is impossible to say how accurately our findings represent the true maternal mortality in Calcutta during the year of the inquiry. The following are possible sources of error:—

1. Failure to register deaths.
2. Failure to receive duplicate registration cards in all cases.
3. Incorrect information obtained by sub-registrars regarding association with pregnancy or childbirth.
4. Failure on the part of sub-registrars to obtain information relating to pregnancy and childbirth.
5. Inability to trace cases of death in which the association with childbearing was definite or doubtful.

The omissions from amongst registered deaths which may have arisen in the ways suggested above are probably few.

A number of women come to Calcutta from rural districts and distant places for confinement and a proportion of these come on account of some complication of pregnancy or childbirth. Amongst the 887 deaths followed up there were 203 imported cases.

Two women doctors were appointed by the Indian Research Fund Association for the work of following up the deaths.

A weekly meeting between the investigators and the officer in charge of the inquiry was held for the purpose of reaching a conclusion regarding the cause of death and the avoidable factors present in all cases for which schedules had been completed within the previous week. In this way each case was discussed while the circumstances were fresh in the minds of the investigators and further details could be elicited or further inquiries made, if considered necessary.

The accurate estimation of the maternal mortality rate in Calcutta is not possible on account of defective birth registration and the fact that our series of maternal deaths unfortunately cannot be claimed to be complete.

The total number of registered live births which occurred during the period of the inquiry, from 15th June, 1936, to 14th June, 1937, was 28,714 and in addition 2,839 stillbirths were registered. The registration of stillbirths is believed to be even less accurate than

that of live births. It seems better therefore to express the rate per live births. The figures at our disposal, viz, 28,714 live births and 701 maternal deaths due directly to childbearing causes, give a maternal mortality rate of 24.41 per 1,000 registered live births. If imported cases are excluded the rate becomes 17.90 per 1,000 live births but the births in connection with some of the imported cases of maternal death were registered in Calcutta. The exact number of these births could not be estimated and excluded from the total registered births of the city. The rate of 17.9 must therefore be considered an under-estimate. The true maternal mortality rate in Calcutta remains unknown.

In classifying the cases according to the cause of death the *International List of Causes of Death* (1929 revision) has been followed as closely as possible. It has been found necessary, however, to make an additional heading for 'anæmia'. The relationship between the severe anæmias and pregnancy in India is probably an even more intimate one than exists between cardiac disease and pregnancy.

It was found that in the series of 887 maternal deaths there were 656 or 74 per cent of the total in which the registered and ascertained cause corresponded while in 231 or 26 per cent a different conclusion as to the cause of death was reached after investigation.

The 887 maternal deaths investigated have been divided into two classes:—

#### Cases

Class I.—Deaths due directly to childbearing 701

Class II.—Deaths due to an independent disease concurrent with pregnancy or childbirth .. .. 186

*Puerperal sepsis.*—In countries where registration of maternal deaths is carried out and where special maternal mortality surveys have been made, puerperal sepsis has been consistently found to be the most important cause of maternal death.

The small amount of evidence which is so far forthcoming in India, and all this evidence relates to urban conditions, goes to show that while the mortality rate in India is several times as high as in Western countries, the proportion of deaths from sepsis is not more than a third of the total and this in spite of the fact that a far larger number of deliveries in this country are attended by untrained women, who make no use of modern methods of asepsis and antisepsis.

*Anæmia.*—The inclusion of the anæmia deaths amongst 'childbearing' and not 'associated' causes needs further explanation. In the first place, whenever anæmia was clearly associated with other conditions such as kala-azar, epidemic dropsy, malaria, tuberculosis, the death has been assigned to the 'associated' group under the appropriate heading. Similarly all cases of anæmia in which other complications of childbirth were present have been assigned to their respective groups. Thus the sepsis, toxæmia, hæmorrhage and accidents of labour groups contain certain cases in which anæmia was probably the more important cause of death, the other condition being secondary or terminal. The anæmia cases which remained after exclusion of the above, have had to be classed with the limited information at our disposal, as due to anæmia *per se*.

Such evidence as we have collected in the course of this inquiry suggests that in Calcutta severe anæmias of both the macrocytic and microcytic type, and also mixed forms, are extremely common and that while many cases are associated with poverty and malnutrition, others occur amongst the well-to-do in families that seem healthy and well-nourished.

The association between a history of dysentery or diarrhoea and a severe pregnancy anæmia in the Calcutta series of cases was noticeable and the suggestion is put forward that the development of anæmia in these cases may often be the result not only of the intestinal infection but of the diet which is commonly prescribed in these cases, and often taken for long periods afterwards.

TABLE I  
Maternal deaths. Distribution by cause (International List, 1929 revision)

Deaths due directly to childbearing	Calcutta cases	Per cent	Imported cases	Per cent	Total	Per cent
Abortion (septic) .. ..	25	4.86	8	4.28	33	4.71
Abortion (non-septic) .. ..	2	0.30	2	1.07	4	0.57
Ectopic gestation .. ..	4	0.78	2	1.07	6	0.86
Other accidents of pregnancy ..	..	..	7	3.74	7	1.00
Hæmorrhage .. ..	65	12.65	9	4.81	74	10.56
Puerperal sepsis .. ..	172	33.46	52	27.81	224	31.95
Albuminuria and convulsions ..	75	14.59	51	27.27	126	17.97
Other toxæmias of pregnancy ..	11	2.14	4	2.14	15	2.14
Thrombosis and embolism ..	11	2.14	..	..	11	1.57
Accidents of labour and operative shock.	15	2.92	11	5.88	26	3.71
Other and unspecified puerperal conditions.	10	1.95	..	..	10	1.43
Anæmia .. ..	124	24.12	41	21.93	165	23.53
	514	100.00	187	100.00	701	100.00
Deaths due to associated diseases ..	170	..	16	..	186	..
TOTAL MATERNAL DEATHS ..	684	..	203	..	887	..

We have no evidence of how large a part hookworm infection plays in the causation of pregnancy anæmias in Calcutta.

**Eclampsia.**—Primigravida predominated and half the deaths from eclampsia occurred in women under 20 years of age. It was found that the women who died from eclampsia were relatively more from the middle class than the poor. Their diets were better, and fewer of them worked during pregnancy. It is the young newly-married woman in her first pregnancy, taking little exercise, living on a good diet, who seems more liable to develop toxæmia of pregnancy.

The most striking thing about this series of cases is the almost total lack of antenatal supervision which these women received and the failure on the part of the patients, doctors and relations alike to realize the serious nature of the warning symptoms which were present in a large proportion of cases and, in many, were of long standing.

**Hæmorrhage.**—Many of these deaths were undoubtedly preventable. The group includes some of the worst cases of mismanagement, delay in getting skilled assistance and failure to treat the blood loss, that were met with during the course of the inquiry. Warning hæmorrhages were present in half the cases of death from placenta prævia, but in no case were adequate steps taken to ensure safe delivery.

Amongst the deaths from postpartum hæmorrhage the number delivered by trained attendants was rather high which raises the question as to whether such attendants are inclined to try to hurry the third stage of labour.

**Abortion.**—All the women who died of septic abortion were either admitted to institutions or were seen by doctors at home and it is therefore highly probable that there were other deaths from abortion which we failed to discover during the year of inquiry.

**Accidents of labour.**—Deaths due to accidents of labour, i.e., due to the shock of labour itself, apart from hæmorrhage, made up a small proportion of maternal deaths in our series, and one is led to the conclusion that neglected cases of obstructed labour are rare in Calcutta.

**Tuberculosis.**—Tuberculosis was of outstanding importance in the 'associated' group and caused 41 per cent of all maternal deaths due to intercurrent diseases.

[Following this chapter there is a short one devoted to preventability, chapter 3 discusses the factors that were found to affect mortality and chapter 4 is a review of the hospitals and institutions where women can obtain help in childbearing as well as the organizations for home visiting and treatment. Unfortunately this chapter is headed 'The Military Services in Calcutta' which according to the index should read 'The Maternity Services in Calcutta'. Chapter 5 is given in *extenso*.]

#### CHAPTER 5.

##### *Recommendations suggested by the findings of the inquiry*

(1) **Vital statistics.**—Registration of births is very defective in Calcutta, more especially in some areas and amongst certain sections of the population. The possession of accurate information regarding the total number of births, live and still, is a basic requirement in drawing up adequate schemes for maternal care and it is therefore urged that steps be taken to enforce the Calcutta Midwives Act, 1923, Section 451 (which requires registration of births within eight days), if necessary by means of prosecutions for contravention of the law.

Information with regard to the age and parity of the mother, the place of delivery and the attendant at delivery, are additional facts which could be collected at the time of registration of births and if available would provide most valuable information for the further elucidation of facts relating to childbirth in the city. The possession of such information would greatly facilitate the registration and control of private midwifery practice, private maternity homes and the work of the untrained *dai*, and is a most desirable supporting measure for the Bengal Nurses and Midwives Act, 1934.

In the interest of greater accuracy in the registration of deaths, it is suggested that the primary and secondary causes of deaths should be stated on the death certificate and that the annual reports of deaths by cause should be prepared according to the International List of causes of death with an additional heading for anæmia in the childbirth group.

(2) **Organization.**—In the interest of better co-operation between the existing services, and of developing plans for future extension and improvements, it is

suggested that a co-ordinating body should be formed of representatives of (1) hospitals admitting maternity cases, (2) the department of the municipal public health service concerned with maternal care, (3) the voluntary organizations which are carrying on maternity work in Calcutta, (4) the anti-tuberculosis service and other allied services. It should be the function of such a body to obtain in the first place complete information regarding existing facilities and then armed with accurate knowledge of the total number of deliveries per annum in the city, to consider means of increasing the efficiency of the existing services and making plans for their future development.

The recommendations which follow make no pretence to completeness. They are outstanding points noted during the course of this inquiry and arising out of its findings and they are such as might be taken into consideration by a co-ordinating body, such as that suggested above, in the course of its deliberations.

(a) *Staff*.—Doctors and midwives employed by public health authorities and voluntary organizations for maternity work should have had special training in the preventive aspects of maternal care. The medical training of the sub-assistant surgeon is by no means an adequate preparation for work of this kind and the same is true of the course for training of midwives in many institutions. The fact that several hospitals which train medical students and midwives in Calcutta have neither antenatal nor post-natal clinics is sufficient evidence of the truth of this statement.

More use should be made of the health visitor in the existing maternity services, both for follow-up work in the homes and for the supervision of midwifery. The trained health visitor is the backbone of the welfare centre system and at present, adequately staffed welfare centres are confined to the scheme of work of voluntary organizations in Calcutta.

The work of midwives should be adequately supervised and refresher courses should be arranged. The number of cases which the midwife takes in a month should not be greater than she can properly attend to in that time. The number will depend to some extent on the area in which she works, but it should not exceed 15 cases a month.

(b) *Antenatal care*.—1. Systematic antenatal care should be provided in connection with all hospitals admitting maternity cases, maternity homes, welfare centres and domiciliary maternity schemes. This antenatal care should include consultation clinics held by a doctor and follow-up work in the homes.

2. The system of booking for confinement should be introduced in institutions admitting maternity cases and annual returns should be made for booked and emergency cases.

3. The extension of the intensive type of welfare centre work which includes systematic antenatal care (as at present carried on in small circumscribed areas in Calcutta by the welfare centres of the Indian Red Cross Society, and the Institute of Hygiene centre), so that all areas are covered, is recommended. The desirability of domiciliary midwifery being carried on in connection with such centres is emphasized. This makes for continuity of work, and direct supervision of the midwives by health visitors becomes possible.

4. Milk and extra nourishment should be available for pregnant women in poor circumstances, who are unable to obtain proper food, and should be distributed as part of welfare centre antenatal care.

5. In view of the importance of the complications of pregnancy, especially anaemia, the toxæmias and tuberculosis, the need for a generous supply of beds for antenatal cases in institutions is of the greatest importance in Calcutta. It is necessary not only that the number at present available should be greatly increased, but that closer co-operation should exist between welfare centres, domiciliary schemes and the hospitals so that those cases found to require institutional treatment in pregnancy may have the means of obtaining it.

(c) *Intranatal care*.—1. More beds for confinements both in hospital and maternity homes, especially for women of the Mahomedan community, who at present take relatively less advantage of the facilities offered, are greatly needed. In addition a sufficient number of beds must be provided for those whose homes are entirely unsuitable for confinement.

2. Regulations for the control and supervision of maternity homes should be introduced. The prevention of overcrowding, the provision of an adequate and trained staff and the proper segregation of infected or potentially infected cases are the outstanding requirements.

3. More provision is necessary for beds for cases of puerperal sepsis delivered at home. Such beds should be in a separate block if possible, or at least in a separate ward, and arrangements for the care of the infant while the mother is in hospital should be made.

4. When a case of puerperal sepsis occurs in the practice of a midwife she should not be allowed to attend normal confinements as long as she is in attendance on the septic case.

(d) *Postnatal care*.—Postnatal clinics (with arrangements for gynaecological treatment if necessary) should be held in maternity hospitals, maternity homes and welfare centres. Birth control advice should be available for those women for whom rapidly repeated pregnancy is undesirable on health grounds.

(c) *Special considerations*. 1. *Anæmia*.—The diagnosis and early treatment of anaemia in pregnancy is such a vital one in Calcutta that special methods of tackling it, apart from ordinary antenatal care, are needed. It is suggested that (1) all antenatal clinics should have access to a central laboratory where examination of blood of anæmic women can be carried out; (2) that certain hospitals should provide special wards for the treatment of anaemia in pregnancy and (3) that the necessary treatment for milder cases as out-patients should be available free of charge to poor patients at welfare centres, hospitals and maternity homes. The lay public, the health worker, midwives and doctors should be taught to recognize the early symptoms and signs of anaemia and to know what steps are necessary in order to get adequate treatment in pregnancy.

2. *Tuberculosis*.—The problem of the tuberculous mother, when home conditions are unfavourable, is one that can only be properly dealt with by providing institutional accommodation for her and segregation for the infant. Until such time as facilities for this are available, the provision of extra nourishment during pregnancy and lactation, and the closest possible co-operation between the maternity services and the anti-tuberculosis service are required in order to reduce the ravages of this disease. This problem is undoubtedly the most complex of those relating to maternal mortality in Calcutta, and raises difficulties which seem almost impossible of solution.

The recommendations given are indications of the serious deficiencies, in the management of pregnancy and childbirth in Calcutta, revealed in this report; part II which follows is devoted to a detailed discussion of the causes of death, brought out in this inquiry.]

## Current Topics

### A Programme for Early Aggressive Treatment of Pulmonary Tuberculosis

By C. F. HEGNER, M.D.

(From the *Journal of the American Medical Association*, Vol. CXII, 14th January, 1939, p. 136)

PULMONARY tuberculosis is a chronic systemic disease with a decided tendency to heal. The chronicity, inherent tendency to heal and curability are due to a

beneficent auto-immunization. Were this not true the human race would long since have vanished. This chronicity, when the disease is untreated, inadequately treated or unrecognized, is responsible for its continuous contagion and universal distribution, for a reducible economic waste and disability and for a certain irreducible mortality rate.

A programme for early aggressive treatment of pulmonary tuberculosis is properly initiated by the diagnosis of the disease in the earliest possible stage. During the period of inception and the early stage more can be accomplished by less therapy than at any time thereafter.

The inception of tuberculosis is subtle, the onset insidious and the early progress stealthy and so devoid of symptoms that the host is taken unawares.

When the disease first becomes clinically manifest it is usually not in the early stage but is well developed, with focal tissue changes more or less advanced.

The earliest general clinical symptoms due to altered physiology are not positive. They are largely inferential. The earliest local signs dependent on pathologic changes are positive. These are differential.

The preclinical and early clinical stages are often overlooked even by expert examiners. Errors in diagnosis are more frequently made by the less expert and those who are not tuberculosis minded. Physicians must become tuberculosis minded and appreciative of their fallibility. The usual methods of examination for early tuberculosis have definite diagnostic limitations.

However experienced, one cannot place complete reliance on one's skill in auscultation and percussion. Additional corroborative methods of examination must be used; the tuberculin test must be used with children and in all suggestive cases fluoroscopic examination must be done and roentgenograms of the chest made. To be dependable x-ray examinations must be interpreted by experienced physicians or experts in pathologic changes of the lungs as depicted by x-ray examination.

In borderline cases the x-ray examination cannot determine the grade of activity of a tuberculous lesion. It does portray more accurately than any other diagnostic procedure the presence and extent of lesions.

It is obligatory to check the physical signs with those shown by x-ray examination.

The success of the antituberculosis campaign has been brilliant. Much remains to be accomplished before the disease is vanquished. The incidence of and the deaths due to pulmonary tuberculosis have decreased roughly 60 per cent in the last twenty years. The 40 per cent ratio of deaths to the number of cases has not changed materially, notwithstanding the tremendous increase in hospitalization and sanatorium care and the advances made in the active treatment of the disease. The causes of this constant death ratio warrant critical analysis. The ratio is a challenge. An aggressive programme of case and feeder finding by which the disease can be diagnosed and treated at its very inception, and isolation or control of those who, wittingly or unwittingly, are disseminators of the disease, offer a most potent answer to this challenge.

The antituberculosis programme in the past has been of necessity largely one of defence against active phases of the disease. One waited until the victims were well seeded with tubercle bacilli or for their lesions to become definite before beginning active treatment.

To wait for the disease to become clinically manifest is to wait too long. Procrastination compounds difficulties, augments the uncertainty of therapy, prolongs disability, increases expense, spreads infection and multiplies mortality.

Prophylaxis is certain, while cure is uncertain when the disease is fully developed and impossible in a fairly fixed percentage of cases. These facts are established by the convincing investigations and mass studies for case finding and tracing all contacts to the source of infection. Though it is not always possible to trace the infection to its source, these surveys reemphasize the fact that every case of pulmonary tuberculosis originates directly or indirectly from some previous

case. The reports further prove that early pulmonary tuberculosis, especially in adolescence and early adult life, the periods during which, in the majority of cases, the disease first becomes active, is commonly symptomless and hence frequently undiagnosed.

One must face facts. The antituberculosis campaign of the future to be fully effective must be not only one of defence but also one of offence. An aggressive campaign of case and feeder finding would attack the disease before the tubercle bacilli became seeded, and active therapy would be begun months or years before irreparable damage to the tissues had time to develop. It is easier to prevent than it is to cure destruction of tissue and complications.

The early recognition and treatment of the infected and control of the infectors is logical, economical and practical. Patients with open tuberculosis must be isolated whenever possible. If sanatorium isolation is impossible, then the utmost should be done by a course of sanatorium treatment and instruction to control or render them innocuous. The contacts must be treated before they in turn have active open tuberculosis.

By such a programme the incidence and life history of tuberculosis will become known and its methods of spread understood. Both the profession and the public will become sensitized to the importance of competent periodic health examinations, to the necessity of early diagnosis and to the advantages of early treatment. Thus fortified, many of the present problems in treatment and most of the weak points in the fight against tuberculosis will be overcome.

Tuberculosis is recruited from the ranks of those who are in apparent health. It is no respecter of class, creed or colour and knows no geographic, political or social boundaries. A competent, efficient antituberculosis programme must be one of stern defence and aggressive offence, coextensive with the distribution of the disease.

#### NECESSITY OF EARLY CASE FINDING

A campaign of early case finding, national in scope, and the isolation or control of bacilli breeders and disease disseminators will accomplish more than any other, if not all other, factors in the treatment and eradication of pulmonary tuberculosis.

This is a large and expensive programme beyond the authority and means of private enterprise. One can participate in appointing qualified commissions to study, and in organizing competent agencies to carry on this important work. Co-operation of the public with the profession is essential to the success of any health programme. An enlightened public sentiment will support and later demand public health projects. Success in the control and elimination of one disease reacts favourably and forcefully on campaigns for the control of other diseases. A national health department is indispensable for the coordination of complex public health activities.

Conservation of public health and control of communicable diseases are the province of the federal government and its various subdivisions. They have the authority to make and enforce health regulations.

A national department of public health should promptly take up and vigorously extend nationwide compulsory mass surveys for case and feeder finding. Small groups of investigators within their limited means and scope have proved the importance and value of such surveys on a voluntary basis. The trail has been blazed, the administrative set-up pioneered and the feasibility of the plan assured.

The treatment of the ill is not the jurisdiction of governmental agencies. This has been, is and should continue to be the prerogative of private physicians. The confusing of federal, state and civic obligations with private and professional affairs begets irresponsibility, inefficiency and distrust. This truth is more certain in the realm of therapy than in any other field of endeavour. Regimentation of doctors is possible though highly undesirable. Regimentation of therapy worthy of respect is impossible.

The requisites for an efficient aggressive programme for the control and eradication of pulmonary tuberculosis are:

First in point of time and importance, an authoritative mass survey, national in scope, of case and feeder finding.

Second, continuous maintenance by the medical profession of a true appreciation of the character of the disease. It is expedient to consider tuberculosis more serious than the clinical symptoms indicate.

Third, early treatment. The earlier appropriate treatment is begun, the more consistently enforced by the physician and the more conscientiously followed by the patient, the more rapid and certain will resolution ensue.

#### EXPECTANT TREATMENT

The passive or expectant treatment of pulmonary tuberculosis is founded on the time-tried and proved principles of general rest, fresh air and wholesome food. To this honoured triad, modern active treatment has added collapse therapy to secure local rest to the diseased lung. The therapeutic result will be proportionate to the degree, duration and timeliness of general plus local rest. This is true not only in the early stages of the disease but also in advanced stages and in cases in which the disease is resistant and demands some form of surgical aid.

Every patient differs in his local and general reaction to infection. The dose and degree of virulence of the infecting organism and the grade of susceptibility, which fluctuate from time to time, determine the clinical symptoms, the character and intensity of the pathologic changes and the course of the disease. The response to therapy likewise varies. The pulmonary lesions are an accurate index of the trend of battle between the tubercle bacilli and the resistance of the patient. The evolution of the local lesions must be as closely followed as is the general progress made by the patient in order to estimate, round by round, his ability to overcome the disease. The course and severity of the clinical symptoms do not constantly parallel the pathologic changes in the tissues. This lag in constitutional reactions is deceptive.

No one can deny the importance and value of expectant treatment in early stages or that in many cases it fails, without additional aid, to control the progress of the disease.

#### COLLAPSE THERAPY

General rest and expectant treatment should be tried for a reasonable time, a period expressed in terms of weeks. As long as favourable progress is made, one should defer active therapeutic measures. When favourable progress is not made or ceases, active measures to secure the added benefits of local rest by some form of collapse therapy are promptly indicated. Collapse therapy is not a substitute for any of the older forms of treatment; it is an invaluable supplement to these when after a reasonable trial they have failed, or in the light of experience are destined to fail, to reestablish a resistance balance against the disease.

The earlier a focus not controlled by expectant treatment is attacked by the appropriate measure for collapse, the more certain, rapid and favourable will be the effect and the fewer the complications.

One must obtain promptly the minimum collapse of the lung that is conducive to healing all the tuberculous infiltration and cavitation. A more extensive procedure than is needed to control the lesion should be avoided. Unnecessary destruction of tissue and of functioning lung parenchyma will be prevented.

A variety of mechanical procedures have been devised to control different stages of the disease. They all have definite indications and limitations. There is an optimum time for each procedure, which if not taken advantage of leads to more extensive operations.

Every patient who presents indications for more radical procedures of surgical collapse is a living example of failure; a failure of the physician to diagnose early, to appreciate the gravity of the disease and to institute promptly and continue rigidly appropriate conservative measures, a failure of the patient to cooperate or of the disease to respond to the expectant

treatment, or a failure of the physician to resort early to less radical measures for collapse therapy. A favourable opportunity lost renders the general condition of the patient more serious and permits the development of complications or extension of the disease to irremediable stages.

Surgeons have learned the necessity of early operations in the treatment of cancer, the advantage of operating during the rising tide of reserve in thyrotoxic states and the diminished hazard in multiple stage operations in the case of properly prepared patients with prostatic disease. These lessons are equally applicable in the surgical treatment of pulmonary tuberculosis. Timely surgical intervention is truly conservative. Late operations are always of greater magnitude and danger, and the results are not so satisfactory as those of early operations.

The purpose of collapse therapy is to secure local rest to the diseased lung, to prevent the development of restraining mechanical factors and to eliminate impediments to contraction of the diseased area of the lung. The objective of compression therapy is actively to compress the cavity or the cavity-bearing area of the lung and control resistant interposed lesions which interfere with contraction and healing. The advantages of timely collapse therapy are proved by the splendid results attained with progressive and otherwise hopeless conditions. Delay in the diagnosis of pulmonary tuberculosis has been and is the chief obstacle to the control of pulmonary disease. Delay in instituting graded collapse therapy compromises and may defeat all efforts to cure.

Successful collapse therapy for pulmonary tuberculosis is not merely a matter of technique. Important as this is, of greater importance is the choice of procedure, the time and the degree of collapse needed. There is no procedure yet devised that is universally applicable to the fluctuating phases of the disease. Each procedure must be graded to control the local lesion. This involves an understanding of the patient, who is always a substandard surgical risk, a grasp of the mechanics of the thorax and the physiology of respiration, an estimate of the cardiac reserve and a knowledge of the pathology of all stages of the disease.

A surgeon should approach a case of pulmonary tuberculosis from a medical no less than from a surgical point of view. He should collaborate with the phthisiologist and the radiologist, who must become surgically minded. They must understand all phases of the disease and the indications and possibilities of combinations of the two plans of treatment.

Competent surgical treatment without continued intelligent general medical care cannot cure. Adequate timely surgical treatment can and does render local conditions favourable for the orderly processes of healing to effect an arrest or cure.

Pulmonary tuberculosis demands medical supervision from its inception until it is clinically cured. Too often this fact is overlooked in the treatment of patients subjected to surgical collapse. The patient and sometimes his physician are deluded by the immediate improvement secured by surgical intervention. They relax in the care which is vital to making that improvement permanent. For a lasting cure it is obligatory that the patient continue for months after operation a graded rest regimen. Adequate prolonged collapse facilitates the permanent obliteration of cavities and the healing of pericavitary lesions by fibrosis. No operation can do more.

Before operative intervention is decided on, a review of the history and a careful complete examination of the patient should be made; a meticulous study of the evolution and the present status of the lesions in the lung, so graphically and chronologically recorded by a series of x-ray films, is imperative. The information obtained is of inestimable value in deciding what, if any, surgical intervention is indicated.

Select that procedure which will be most effective for the given stage. When possible employ revocable measures in ascending grades of severity, giving each procedure a reasonable period to prove its capacity to control the lesion. Note the progress by repeated

physical examination and x-ray study. With contralateral lesions, and these are always present in some degree, the responsibility is augmented in proportion to the extent and grade of activity; one must proceed with caution, keeping well within the limits of respiratory and cardiac reserve.

When revocable measures are not indicated or have failed to control the progress of the disease, then irrevocable measures for selective compression are indicated. The least extensive surgical operation that will secure adequate compression is the operation of election. In many cases a sequence of procedures is neither indicated nor advisable. The character, location and extent of the lesion determines an operation of necessity. The general condition of the patient may and often does demand that it be performed in multiple stages. Better regret doing too little than mourn the death of a patient.

#### PROCEDURES

The procedures for collapse therapy are (1) artificial pneumothorax—unilateral, alternating or simultaneous bilateral, (2) intrapleural pneumolysis, (3) interruption of phrenic nerve conduction, temporary or permanent, (4) scalenectomy, (5) extrapleural pneumolysis with or without filling of the extrapleural space, and (6) thoracoplasty, partial upper or partial lower, as single stages or in sequence, with or without extrafascial mobilization of the lung, or complete, in multiple stages. The first four procedures leave the thoracic wall intact and with one exception (permanent phrenic nerve interruption) are revocable; the last two are compressing operations which alter the osseous structures of the thorax and are irrevocable.

*Artificial pneumothorax.*—The introduction of artificial pneumothorax marked a transition from the time-honoured passive and expectant treatment to the modern active or aggressive therapy of pulmonary tuberculosis.

Wherever the efficacy of timely pneumothorax is fully appreciated it is recognized as the most valuable adjunct to phthisiotherapy. It has become a standard form of treatment in modern sanatoriums everywhere, curing or arresting the progress of the disease not possible by expectant treatment alone.

Induced pneumothorax is the spearhead of a line of surgical attack to secure added local rest to the diseased area of the lung by procedures graded from early relaxation and temporary collapse to firm irrevocable compression.

It is unfortunate that these gradations are not generally recognized and understood. An appreciation of the gradation principle of collapse therapy is of utmost importance in the modern treatment of pulmonary tuberculosis. The advantages of timely graded collapse therapy are proved by the splendid results obtained in the treatment of resistant progressive and otherwise hopeless cases.

Artificial pneumothorax decreases the volume of the lung by the injection of controlled amounts of air through a needle introduced into a free pleural space. It may be relaxing, collapsing or mildly compressive. The more uniform and continuous, the more effective it will be. Refills are necessary at more or less regular intervals over a long period, demanding prolonged co-operation of the patient, which, for economic, business, social, temperamental or other reasons, is too often interrupted or altogether neglected. This leads to intermittence, early loss or complications. To obviate these the injection of oils was introduced. The safe use of oleothorax demands a greater degree of experience and judgment than does the use of simple pneumothorax.

An early, continuous, uniform and moderately relaxing pneumothorax is a prophylactic pneumothorax. It separates the visceral from the parietal pleura, prevents the formation of adhesions, relaxes and rests the lung, is conducive to contraction of early, soft, thin-walled cavities and healing of soft exudative or mixed productive pericavitary zones. Massive repeated hæmoptysis may be stopped. In bilateral lesions of a similar type, though of different intensity, it may be

induced on the two sides simultaneously or alternately. An early pneumothorax is not more dangerous to induce or difficult to control than is a later pneumothorax. It may obviate further measures for collapse.

The practice of inducing high degrees of plus pressure in order to secure attenuation of restraining adhesions, desirable as this may seem, is neither wise nor safe and frequently causes complications. Obliteration of the pleural space precludes pneumothorax. Adhesions may prevent the induction and maintenance of a satisfactory pneumothorax.

An incomplete pneumothorax, while it may not collapse cavities, does exercise a salubrious effect on the pericavitary lesions. It renders the pleura less sensitive, and the mediastinum more rigid and gives the heart and contralateral lung time to become adjusted to the altered intrathoracic pressure. The patient is thereby fortified and will better tolerate the necessary more formidable procedures for collapse. These should not be delayed. Prolonged pneumothorax treatment without diminution in the size of the cavities or continuing improvement of the lesions in the lung is not good therapy. It wastes valuable time, courts complications, imperils the final results and withholds from the patient other measures when these give assurance of success.

*Intrapleural pneumolysis.*—Closed intrapleural pneumolysis is the severance of restraining and tethering pleuritic adhesions through a thoracoscope by means of the electrocautery or coagulation.

Pleuritic adhesions are the greatest impediment to successful artificial pneumothorax; once formed they are usually progressive. If restraining adhesions are narrow, like cords or bands, or fan shaped and are long enough to permit the manipulation of the necessary instruments, they may be severed by intrapleural pneumolysis. Thus may an inefficient or partial pneumothorax be made efficient or complete.

A knowledge of the character and content of the adhesions and of their relation to the lung, pericardium and great vessels, especially at the apex, and to the thoracic wall is important, not only because of the effect they may exercise in keeping the cavity open and the lung expanded but also because of the possible danger of puncturing large vessels and the pericardium, and of tearing or eroding the cavity wall or the diseased lung during or subsequent to coagulation.

The number and disposition of adhesions cannot be adequately determined by x-ray study. The thoracoscope is of positive value in the study of intrapleural adhesions. The restraining effect of adhesions must be established before intrapleural severance is attempted.

At the apex of the thorax, the commonest site of resistant adherent cavities, where intrapleural pneumolysis would be most helpful, it is frequently impossible.

Open intrapleural pneumolysis does not require that the operator have training to acquire proficiency in interpretation of adhesions and dexterity in the use of specialized instruments. Open intrapleural pneumolysis is a more difficult and extensive operation. It has a very limited field for broad, short, isolated, tethering adhesions. A satisfactory closure of the pleura is not easy to accomplish.

*Interruption of phrenic nerve conduction.*—This paralyzes the diaphragm. It may be made temporary by crushing the main and accessory nerves, which may be repeated to prolong its effect when, after two or three months, the diaphragmatic function returns. Should a permanent paralysis be desired the main and accessory nerves may be cut or 4 or 5 inches of the stem evulsed. Permanent paralysis is occasionally indicated, especially when the lesion has so seriously compromised the lung that a restoration to function is nil. Alexander has proved that repeated temporary interruption is preferable and usually should precede a permanent phrenic interruption. Paralysis of one-half the diaphragm, even if there is no appreciable elevation, secures a continuous uniform relaxation of the lung. It is more resting than a pneumothorax. The inconvenience of refills, the variable tension and the waning of a pneumothorax are eliminated. Phrenic

nerve operations, while simple, have attending dangers, especially evulsion.

The indications are practically those for pneumothorax. Some authorities give interruption of the phrenic nerve preference, especially when continuing co-operation of the patient is doubtful.

Early temporary paralysis of the phrenic nerve will hasten and assure the benefits of general rest in recent thin-walled cavities with a pericavitary zone of the exudative or mixed type. It is positively indicated when a satisfactory pneumothorax cannot be induced, controlled or continued. It may supplement or intensify a unilateral pneumothorax without increasing the pressure. In the case of bilateral lesions it may be performed concomitantly on the worst side. The greatest benefits are in basal lesions. Midfield and infraclavicular lesions are almost equally controlled. A temporary interruption of the phrenic nerve is of advantage to retard reexpansion of the lung on abandonment of pneumothorax. It is effective in reducing the size of empyema cavities and in relaxing the lung, favouring closure of bronchial fistulas by contracting fibrosis. Massive repeated hæmoptysis is controlled by operation on the phrenic nerve. As a palliative procedure in terminal stages to assuage an exhausting cough it is superior to sedatives.

**Scalenectomy.**—In this operation the scalene muscles are resected close to their insertions in the first and second ribs. The unopposed action of these muscles elevating and horizontally rotating the upper ribs is very great. However, when the ribs and intercostal muscles below the third rib are intact, the effect of the scalene contraction disseminated over the entire thorax is greatly reduced.

Scalenectomy does reduce excursions of the upper ribs and rest the apex of the lung, but to a degree so small that its effect on the lesions in the apex is uncertain and often negligible. It is recommended to control the upper part of the thorax as a supplement or sequence to operations on the phrenic nerve. What a successful operation on the phrenic nerve cannot accomplish alone usually requires more than a supplementary scalenectomy.

**Extrapleural pneumolysis.**—This is the formation of an extrapleural or fascial space overcircumscribing the area of a cavity by finger or blunt dissection through an incision in the periosteal bed of a resected short segment of an overlying rib. The pocket thus formed is filled with some material to maintain firm selective compression of the cavity-bearing area. The compressing effect is immediate. If sputum is abundant overflow infection is a possibility. Firm fusion of the endothoracic fascia to the ribs, rupture of the cavity or hæmorrhage prevents completion of the operation. No satisfactory filling material has been discovered. Gauze has to be replaced, frequently causing considerable pain. Muscle, if sufficient is available, requires a large fenestra for introduction and fixation. It atrophies and contracts. Air necessitates refills. Bags inflated with water or compressed air leave a projecting tube which is conducive to infection. Paraffin is irritating and heavy and may cause pressure necrosis, erode and perforate the cavity wall or a free pleural space, shift or migrate out of position or be extruded through the incision. Theoretically ideal, practically it is uncertain. The presence of any foreign material in a wound is a menace. Its use is indicated for the very ill who cannot stand a limited or multiple stage thoracoplasty and have unilateral or bilateral disease with small to medium sized, chronic, thick-walled cavities in a dense fibrotic area with or without severe hæmoptysis.

Extrapleural pneumolysis with the use of gauze filling is most efficient in compressing dense residual fibrotic cavities that have failed to close by all other measures. Extrapleural pneumolysis occasionally is useful before a limited thoracoplasty. It is not easier to perform and is scarcely less shocking than a limited thoracoplasty. Though the compressive effect is selective and immediate, the delayed effect is uncertain.

**Thoracoplasty.**—The purpose of thoracoplasty is to secure collapse or active compression of a cavity-bearing area in the lung by means of the subperiosteal resection

of definite lengths of a variable number of ribs. It may be partial, limited to a few ribs, either the lower or the upper, or in stages including as many ribs as may be necessary to obtain adequate compression. The interval between stages is determined by the condition of the patient, time being allowed for the heart and lung to become adjusted to the altered intrathoracic condition and the diseased area in a measure to clear itself. The collapsing effect depends not so much on the length of the ribs resected as it does on the length of the stumps remaining, especially at the posterior aspect, where the resection must be made at the spine and may include the transverse processes. The number of ribs and the length of the segments to be resected are determined by the character, extent and localization of the disease in the lung, the stability of the mediastinum, the thickness of the pleura and the conformation and rigidity of the chest wall. In order to avoid secondary and difficult revision or corrective operations, total or subtotal resection of the first to the third or fourth rib should be performed in an upper stage, going well beyond the underlying diseased area of the lung. Whereas short segments and too few ribs may require additional stages, long segments of too many ribs may cause shock, too sudden and great a degree of compression, weakening of an extensive area of the thoracic wall, massive atelectasis seriously embarrassing respiratory and cardiac function, a dangerous degree of autotuberculinization and rapid local or wide dissemination of the disease.

Some excellent authorities, Casper, Semb and Overholt, at the time of thoracoplasty, especially in the upper stage, advocate and perform extensive mobilization of the lung. Casper leaves the wound partially open and firmly packs the area with gauze saturated with mild silver protein to secure firm compression. Redressing is required for a long time; convalescence is prolonged.

Carl Semb of Oslo, Norway, was the first to perform extrafascial apicolysis. He secures a concentric collapse and contraction of the entire cavity-bearing area of the upper part of the lung almost to the level of the hilus. In this operation resection of the upper rib segments is not so extensive as in the total or subtotal type of thoracoplasty. The extrafascial ligamentous attachments and adhesions to the lower cervical nerve roots, to the large vessels and to the anterior and posterior mediastinum are carefully severed by sharp and gauze dissection. The entire dome of the pleura is freed and then depressed. The first three intercostal muscle bundles are double ligated and then severed.

Extrafascial pneumolysis may be performed at the first upper stage or be a step in a revision or corrective operation for collapse of resistant cavities. The latter is more difficult but a safer procedure. With the total or subtotal resection of the upper ribs the collapse of apical and subapical cavities is more efficient and residual cavities are less frequent than in the resection of the limited segments of the former thoracoplasties.

Extrafascial pneumolysis is indicated in the case of apical and subapical cavities with dense fibrotic pericavitary zones without exudative foci.

The manipulation incident to mobilization of the lung and the too sudden and massive compression of an actively-diseased lung area are fraught with the danger of a local or widespread dissemination of the tuberculous process. The unsupported mobilized area of the lung beneath the limited deribbed upper portion of the thorax cannot be adequately supported. Paradoxical expansion, on coughing, of this unsupported lung is inimical to the clearing of the secretion from the diseased area. If the region should contain active foci or exudative areas, manipulation, displacement and active too sudden massive compression are prone to cause complications. The compressing effect is ideal, the greatest attainable. It is safer to do active forceful compression on a residual cavity in a densely fibrotic area with only low grade, if any, tuberculous infection by extrapleural gauze tamponade.

The indications for thoracoplasty are those for collapse therapy in general, when lesser measures have failed or the temporary collapsed cavities reopen and quiescent areas become reactivated. The degree of

fibrosis and contraction deformity is an index of the rigidity of the mediastinum and the local resistance of the lung tissue. A rigid mediastinum gives assurance of cavity compression and security against mediastinal flutter and displacement.

Contra-indications to collapse are fresh, recent exudative lesions in the opposite lung, especially near the base; severe asthma, emphysema, active or decompensated heart disease, uncontrolled diabetes and

tuberculosis in other organs are, in proportion to their activity, unfavourable complications. Severe anaemia, rapid pulse and low blood pressure are warnings of danger; they prejudice but do not preclude surgical collapse.

Delay in diagnosis has been and is the chief obstacle in the control of pulmonary tuberculosis.

Delay in instituting the proper procedure for collapse compromises and may defeat all efforts to cure.

## Reviews

**NEUROLOGY.**—By S. A. Kinnier Wilson, M.A., M.D., D.Sc. (Edin.), F.R.C.P. Edited by A. Ninian Bruce, F.R.C.P. (Edin.), D.Sc. (Edin.), M.D., F.R.S., Lieut.-Colonel, R.A.M.C. Volumes I and II. 1940. Edward Arnold and Company, London. Pp. xxxvi plus 752 in volume I and Pp. xxvii plus from 753 to 1838. Illustrated. Price, £4-4-0 for two volumes

THESE two volumes are the outcome of a life's work on neurology. Dr. Wilson died before his task was finished and Dr. A. Ninian Bruce has completed it for him.

As regards the general arrangement a complete table of contents is provided in volume one along with a list of abbreviations for nearly three hundred periodicals from which references are made. Volume two which is considerably larger is provided with a table of contents referring to it alone. The same list of abbreviations is provided, but in addition at the end of this volume there is an index of authors containing about five thousand names, and an extremely useful subject index of seventeen pages.

The volumes are divided into ten parts. The first deals with toxic-infective diseases of the nervous system, and includes meningitis, fevers, disseminated sclerosis, and neuritis in its many forms. In the treatment advocated for epidemic cerebro-spinal meningitis, serum by the intrathecal route supplemented by vaccines is recommended, but there is no mention of treatment by sulphonamides. This is rather surprising in view of the increasing number of successes reported by the use of chemotherapy alone.

Part two deals largely with neuro-syphilis, but there are also chapters on chorea, tetanus, and diphtheria. Subjects of more tropical interest such as leprosy, rabies, and malaria, are also included. Boerhaave's account of 'dog madness' or hydrophobia written two hundred years ago is reproduced in the chapter on rabies and is remarkable for its accuracy of observation.

Part three concludes volume one with chapters on poisoning by morphia, cocaine, alcohol, and lead. The final chapter on heat stroke is very brief.

Parts four, five and six deal with degeneration or toxic-degenerative disorders, diseases of vascular origin, and tumours of the nervous system respectively, and are masterpieces of completeness and lucidity.

*Metabolic and deficiency disease states* is the title of part seven. It includes subacute combined degeneration of the spinal cord, pellagra, and beri-beri. The chapter on pellagra is not up to date. There is no mention of nicotinic acid treatment or of any of the recent work in the United States from 1937 onwards, and no reference of later date than 1935.

The last three parts are devoted to congenital anomalies, diseases of uncertain nature, and the neuroses, all of which are excellent.

One cannot help admiring the labour, patience, and skill which were necessary for the preparation of the material for these two volumes, and Dr. Wilson must have possessed, as stated in the foreword, 'an encyclopaedic mind'. They contain a wealth of detail which can be found nowhere else. Unlike many reference books the subject is presented in an interesting way

with numerous quotations from personal experience. In the next edition more reference should be made to recent work. The many excellent photographs add greatly to the value of the work which will be welcomed not only by neurologists but by those in general practice as well.

J. G.

**LEPROSY.**—By Sir Leonard Rogers, K.C.S.I., C.I.E., M.D., F.R.C.P., F.R.C.S., F.R.S., I.M.S. (Retd.), and E. Muir, C.I.E., M.D., F.R.C.S. (Edin.). Second Edition. 1940. John Wright and Sons, Limited, Bristol. Pp. xii plus 260. Illustrated. Price, 15s.

THE first edition of this book appeared in 1925. At that time there was no good up-to-date book on leprosy in English or in any other language, and this book went a considerable way towards filling the need. It summarized knowledge of the subject up to that time, and it helped to stimulate interest in leprosy all over the world. It had certain shortcomings, the chief of which was the absence of any list of references or bibliography.

The last fifteen years have seen a great increase in knowledge of all aspects of leprosy, and to this the two authors have made considerable contributions. During this time no other book covering the same ground has appeared in English, and it is therefore natural that a new and revised edition should be called for.

The new edition contains forty pages less than the old one, and like the old one it is divided into six sections, headed 'history and distribution', 'epidemiology and communicability', 'prophylaxis', 'aetiology', 'clinical' and 'treatment'.

To the first three sections only minor alterations have been made and some data have been added, particularly concerning the distribution of leprosy in the world. The main arguments and conclusions remain the same. Some people may consider that the comments made on the policy of anti-leprosy work adopted in the past in some countries are unnecessarily critical. The author of these sections, however, often expresses satisfaction with recent modifications of such policy. He stresses the importance of isolation of infectious cases, of limiting the use of compulsion as far as possible, and of treatment of isolated and other patients, in order to make measures of prophylaxis more popular and effective.

On reading a book like this, one naturally reads with special care statements about the country in which one's work lies. We would agree with most of the statements made about leprosy in India but there are certain statements which appear to us to be misleading. The estimated number of lepers in India is given as 500,000. Most recent estimates based on actual surveys are much higher than this. The map on pages 24 and 25 does not make clear the distribution of leprosy in India, nor does the discussion on leprosy in India which follows. The statements quoted from Santra regarding fish eating in Bankura (Bengal, not Bihar as stated) and parts of Burma where leprosy is very common appear to us to be misleading for we have found that fish eating is equally common in other

# Persistent Antisepsis for normal skins . .

Recently investigations have shown that the dried film left on the hands after treatment with 30% 'Dettol' renders them insusceptible to infection by Haemolytic Streptococci for at least two hours (vide '*British Medical Journal*', 21st October, 1933, page 723). 'Dettol' can be employed at high concentration, except on sensitive skins. The Rideal-Walker test proves it three times more potent than phenol. A two per cent. solution very rapidly kills Haemolytic Streptococci and B. coli even in the presence of pus.

Non-poisonous

adjacent areas where leprosy is much less common. Santra's report, that leprosy is less common in single-caste villages, is interpreted as indicating the influence of promiscuity in spreading leprosy in villages with several castes; but it appears to us that in single-caste villages, the people will mix more freely, because of the absence of caste restrictions.

In the section on prophylaxis on page 122 the following statement is made; 'The only way to reduce the incidence of leprosy rapidly is to trace and examine every few months over a period of at least five years, any person who has been in close contact with any known infective leper. A large proportion of the infections from each case so discovered in the earliest stage can be cleared up and prevented from going on to an infective stage.' This statement is made as though it were a generally accepted opinion, and neither in this section nor elsewhere is any mention made of the opinion of some experienced workers in certain countries (e.g., Rodriguez) that treatment will not prevent non-infectious cases from becoming infectious.

The other three sections, 'aetiology', 'clinical' and 'treatment', have been much more thoroughly revised along the lines of Muir's other publications, since the last edition. The system of classification and the terminology of the International Leprosy Congress, Cairo 1938, have been adopted throughout.

These three sections, which in the old edition occupied 147 pages, now occupy only 106. This condensation does not prevent them from being really useful surveys of these subjects. We think, however, that the descriptions of the clinical appearances and distribution of the different types of lesions, and of histopathology might have been better arranged, and the importance of the patient's age in prognosis might have been more fully discussed and emphasized.

Certain criticisms might be made regarding the description of the bacillus of leprosy. For example, it is stated that apart from its appearance in acute exacerbations of the disease the bacillus is a uniformly stained rod. Our experience is that diphtheroid forms, 'sporelike' forms, etc., are seen in all phases of the disease, although perhaps in somewhat varying proportions.

On page 167 the census figures of India are quoted as indicating that 0.4 per cent of cases of leprosy are under the age of three, and while some doubt is expressed on this point, an argument is based on the possible truth of this finding. In our experience leprosy is rare in such young children.

Seventy excellently reproduced photographs are printed in 34 plates at the end of the book, an arrangement which facilitates the binder's but not reader's task. We know, however, the difficulty of printing art plates opposite to, or near, the page of the book which they illustrate, and there is much to be said for the arrangement adopted here. The book contains a good index.

Although numerous authors are quoted by name, sometimes with the date, there are very few complete references given. In a book of this kind a complete list of references would be very long, but we think that its value as a work of reference would have been considerably enhanced by the insertion at the end of each chapter of a select bibliography indicating the most important publications on the subject of the chapter.

The book is a very useful general survey of leprosy, the only one in the English language which attempts to cover the whole field of leprosy. It is excellently printed and bound.

**A TEXTBOOK OF OCCUPATIONAL DISEASES OF THE SKIN.**—By Louis Schwartz, M.D., and Louis Tullipan, M.D. 1939. Henry Kimpton, London. Pp. 799. Illustrated with 116 photographs. Price, 45s.

ALTHOUGH references to industrial skin diseases can be traced back to Paracelsus, according to the opening paragraph in chapter 1 of this book, it is only in

relatively recent times that the endless possibilities in this respect have been fully recognized. The importance of skin eruptions from contact with chemicals and other substances used in industry is steadily expanding, as new discoveries in processes of manufacture lead to the establishment of new industries.

This publication is an extremely valuable one as a book of reference for dermatologists, medical officers of health, and doctors engaged in the care of employees of large industrial concerns, because in it they are almost certain to find a reference to any problem of industrial dermatosis they are likely to encounter. Simply reading the contents list of the 45 chapters is an education in itself in revealing the innumerable possibilities in this special aspect of dermatology.

P. A. M.

**SURGERY OF THE EYE.**—By M. Wiener, M.D., and B. V. Alvis, M.D. 1939. W. B. Saunders Company, Philadelphia and London. Pp. 445, with 396 illustrations. Price, 37s. 6d.

THE book is written primarily to supply a handy atlas for the student of ophthalmology and the practising ophthalmologist to which to refer for information on the surgical treatment of ocular defects and disease. As most surgical books on the eye are insufficiently illustrated the authors have endeavoured to bear this in mind and all the operations selected have therefore been clearly and profusely illustrated by serial drawings and diagrams.

The book consists of 419 pages with as many as 396 illustrations. It is divided into 18 chapters in which the authors discuss general considerations, the preparation of the patient, anaesthesia, pre-operative preparation, post-operative care, paracentesis, cataract, glaucoma, operations on the retina and sclera, intra-ocular foreign bodies, operations on the cornea, removal of eye, operations on the conjunctiva, operations on the lids and socket, ptosis, operations on muscles of eye, and finally operations on the tear sac.

The chapters on cataract and glaucoma are excellent and will be of great interest to ophthalmic surgeons working in India. The book is excellently produced and the subject-matter is written in a simple, clear style and is easy to follow.

There is little to find fault with and the authors are to be congratulated on their production and we hope it will be extensively read. We strongly recommend the book, and as a help and guide to the ordinary eye operations we have yet to find its equal.

E. O'G. K.

**THE SEXUAL PERVERSIONS AND ABNORMALITIES.**—By Clifford Allen, M.D., M.R.C.P., D.P.M. 1940. Oxford University Press, London, Humphrey Milford. Pp. xli plus 193. Price, 7s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

THE trouble with sexologists, including the author of this book, is that they invariably omit to define or even consider what they mean by the terms 'normal' and 'abnormal' in relation to the sexual impulse. By informing his readers that he himself is 'fortunate to be normal', we see him disappear into the abyss into which so many other sexologists have fallen, including Freud himself. No one can deny that psychoanalysis has correctly understood the urgency of sexual needs and has perceived the possibility of cure through the reasonable satisfaction of these needs, but it has failed to realize the necessity for a revision of the ridiculous way in which our present conventions look upon the manifestations of sex. To attain a more scientific theory of sex, psychoanalysts have got to realize that the sexual mechanism is more important than the sexual object. A normal instinct is supposed to be one which leads the individual to a person of the opposite sex. But we know that this so-called normal object-choice is only necessary for the function of reproduction, and has nothing to do with the instinct of sexual pleasure which demands nothing more than its mechanical satisfaction. The nature of normal

sexual satisfaction is no easier to understand. The function of reproduction can scarcely be carried out except by coitus; but pleasure may be completely attained by any other method, sometimes even more completely. Like Freud, Dr. Allen appears to imagine that the sexual instinct puts itself at the service of reproduction. We might just as well say that taste puts itself at the service of the stomach to aid the function of nutrition. Like the majority of sexologists, Dr. Allen appears to be unaware of what any intelligent man-in-the-street knows, namely, that nine times out of ten, sexual pleasure pursues its own end and is not at all concerned with reproduction, is indifferent to it, and, in many individuals, is even compatible with a strong conscious desire to avoid reproduction. In the light of these considerations we are confronted with the solution of the problem as to what constitutes disease; what is 'normal' and what is 'abnormal'. As the author of that penetrating study of sex entitled, *Sex Life and Sex Ethics*, has pointed out, a mind that was not dominated by thousands of years of anti-sexual taboo would have no difficulty in answering this question, and in making the necessary distinctions without resort to any superfluous psychological complications. Such a mind, says the author of *Sex Life and Sex Ethics*, would very likely make the three following formulations: (a) That the exercise of the sexual organs for the avowed purpose of procuring sexual pleasure, and ultimately also for the purpose of reproduction, is natural, normal, proper, legitimate, and indeed necessitated by the demands of our constitution: (b) That failure to exercise these organs, as a consequence either of voluntary abstinence or of external circumstance (chastity, legal prohibition, etc.), is, on the contrary, an artificial, abnormal, unhealthy and unpleasant state: (c) That sexual pleasure, the immediate aim of sexual activity, is obtained through an appropriate mechanism. This mechanism presents certain variations; but, so far as the general principle is concerned, and except for possible differences in the degree of pleasure obtained, it is independent of the quality (and, above all, of the moral value) of the methods or the partners employed for setting it in action; it can function just as well without a partner (as in onanism), or with any kind of partner (as in homosexuality).

O. B-H.

**CANCER OF THE LARYNX.**—By Chevalier Jackson, M.D., Sc.D., LL.D., F.A.C.S., and C. L. Jackson, A.B., M.D., M.Sc. (Med.), F.A.C.S. 1939. W. B. Saunders Co., Philadelphia and London. Pp. x plus 309, 189 illustrations with 5 plates in colour. Price, 40s.

THE name of Chevalier Jackson is an honoured one in the annals of laryngology. No one is probably better fitted than he to write an authoritative treatise on carcinoma of the larynx. It is particularly gratifying that in this work he is assisted by his worthy son.

This book of 318 pages is very well planned and consists of three parts. Part I, comprising 12 chapters, deals with procedures. Great emphasis is laid on early diagnosis and all the diagnostic steps are clearly described. The difficult subject of treatment is presented in a masterly fashion. The choice of treatment for the particular case is clearly indicated but here, as in diagnosis, experience is likely to be the main deciding factor. Part II, dealing with general considerations, is replete with clinical facts, data and statistics which are not available elsewhere. The chapters on aetiology and its corollary prophylaxis are of particular interest. Part III deals with the history of cancer of the larynx, affording, in the authors' words, 'lighter reading for the reader', but in reality there is much food for serious thought in this section. The historic case of the then Crown Prince of Germany is discussed in some detail. The controversy regarding Sir Morell Mackenzie's responsibility in an unfortunate surgical episode is now discussed from the medical point of view.

This is an excellent book not merely for the specialist but also for the general practitioner. The printing, get-up and illustrations are all first rate. There is a complete bibliography in addition to a useful index.

P. N. R.

**POISONS: THEIR ISOLATION AND IDENTIFICATION.**—By Frank Bamford, B.Sc. 1940. J. and A. Churchill, Limited, London. Pp. viii plus 344, with 21 illustrations. Price, 18s.

THIS volume has been designed as a practical handbook for chemists dealing with the detection and identification of poisons in the laboratory. It is therefore full of practical details required in this connection, whilst theoretical considerations are included only where they are absolutely necessary. In the foreword written by such an eminent authority in forensic medicine as Professor Sydney Smith, Regius Professor in Edinburgh University, the volume has been described 'to be the product of a practical, highly skilled specialist in toxicological analysis, which can be recommended with complete confidence to analysts'. With this view we agree. The subject-matter is well arranged so as to be easily available for purposes of reference and the book is written in a lucid style. The different groups of poisons have been dealt with in detail and a section has been added on drugs of addiction. We can recommend this volume to those dealing with medico-legal problems in this country.

R. N. C.

**DISEASES OF THE DIGESTIVE SYSTEM: A TEXT-BOOK FOR STUDENTS AND PRACTITIONERS.**—By Eugene Rosenthal, M.D. 1940. Henry Kimpton, London. Pp. xii plus 394, with 234 illustrations including 104 in colour, and 16 plates. Price, 42s.

IN this volume a teacher of distinction in the University of Budapest presents a technique of teaching which is both novel and effective. The training of the medical student nowadays entails a great deal of strain, even for the most talented. In an appreciative preface, Dr. Pulvertaft, reader of Pathology in the University of London, speaks very highly of the author's method of instruction, with diagrams and geometrical forms of illustrations.

This book consists of five chapters the first of which deals with diseases of the oesophagus. Chapter 2, consisting of nearly 200 pages, is devoted to diseases of the stomach and intestinal tract. In chapter 3 the diseases of the liver and biliary tract are discussed in some detail. The treatment in each condition is very clearly indicated. In the two concluding chapters diseases of the pancreas and peritoneum are dealt with.

This is a most instructive book and it is written in simple English. The illustrations are excellent, numerous and original. The printing and get-up are very good indeed. This is a book which we can strongly recommend to the general medical practitioner. A useful index is appended.

P. N. R.

**MIDWIFERY: PRINCIPLES AND PRACTICE FOR PUPIL MIDWIVES, TEACHER MIDWIVES, AND OBSTETRIC DRESSERS.**—By R. Christie Brown, M.B., M.S., F.R.C.S., F.R.C.O.G., and Barton Gilbert, B.Sc., M.D., F.R.C.S., M.R.C.O.G. With the Infants' Section by Richard H. Dobbs, M.B., B.Ch., F.R.C.P. 1940. Edward Arnold and Company, London. Pp. viii plus 796. Illustrated. Price, 15s.

DESIGNED for midwives and the teachers of midwives this book adequately fulfils its purpose.

It is written in easily understandable syntax, and stresses the basic principles of biology as its most important factor.

A certain amount of elementary embryology, chemistry and physics is gone through and explained. This is a somewhat unusual departure, but it is

## SALPERN TABLETS

(Sodio Calcium Lactate with Vitamin D)

SALPERN TABLETS are specially recommended in the treatment of various forms of calcium deficiency such as chilblains, premature dental decay, rickets, and retarded bone development in children. They are easily administered, palatable, and do not upset the digestion.

SUPPLIED IN  
BOTTLES OF 50 TABLETS

## DÈCROSE

(Glucose with Vitamin D & Calcium Glycerophosphate)

DÈCROSE is of great value in the treatment of acidosis, cyclical vomiting in children, train, sea and air sickness, general nervous and physical debility, feverish conditions and liver damage.

DÈCROSE is especially suitable for expectant and nursing mothers, and is essential for growing children.

SUPPLIED IN  
1 lb. TINS

# Economise with Vauxhall

## 40 m.p.g!

Imagine getting 375 miles  
in every 1000 FREE!

Motorists whose  
present car aver-  
ages but 25 miles  
per gallon will  
quickly appreciate  
the ECONOMY  
of the new 40  
m.p.g. Vauxhall '10'. . . . For example:—

### Save with India Defence Bonds

Vauxhall '10' averaging 40 m.p.g. x 25 gals.	= 1000 miles
A car averaging 25 m.p.g. x 25 gals.	= 625 miles
Difference	375 miles

Briefly, based on 25 miles per gallon, that's over Rs. 20 per 1000 miles saved by driving a 1940 Vauxhall '10'.

Many motorists are buying this EMPIRE MADE PRODUCT because it is one of the roomiest Tens on the road—with a rear seat 42" wide.

Others because the petrol saving economy permits them to buy more India Defence Bonds—Regardless of the reason—all join together in acclaiming the Vauxhall '10'—The leading Ten of 1940.

# VAUXHALL '10'

## ALLEN MOTORS LTD., 24-B, Park Street, CALCUTTA

A PRODUCT OF GENERAL MOTORS INDIA LIMITED

included so that the midwife may find her studies made easier and more interesting when she has been taught principles of science.

In the section on eclampsia a dogmatic statement is made that the disease usually develops in women who eat excessively of meat. This statement, however, cannot be acquitted of error when it is a well-known fact that eclampsia is very common in India and China where the women are for the most part, entirely non-meat eaters. There are many diagrams in the book which, although of a simple nature, are well drawn and illustrate with clarity the conditions described.

An admirable book is the verdict on this volume.

**AN INTRODUCTION TO MEDICAL GENETICS.**—By J. A. Fraser Roberts, M.A., M.B., D.Sc., F.R.S.E. 1940. Oxford University Press, London, Humphrey Milford. Pp. xxiii plus 266. Illustrated. Price, 15s. Obtainable from Oxford University Press, Bombay and Calcutta.

This excellent book is a happy departure. Genetic inheritance is explained directly by showing the movements of the genes. The traditional cryptic symbolism has been kept out nearly throughout. It appears in an insignificant rôle towards the end where short is represented by *tt* as would have been better. The over-worked American fruit-fly and cruditè formulæ have also been kept out. Yet medical men interested in genetics have been presented with all they need.

The price perhaps could be lower. The granulated cloth of the binding to which insects are very partial is a disadvantage in the tropics.

S D S G

**AIDS TO PSYCHOLOGY.**—By John H. Ewen, M.R.C.P. (Edin.), D.P.M. Second Edition. 1940. Baillière, Tindall and Cox, London. Pp. vii plus 176. Price, 3s. 6d.

**AIDS TO PSYCHIATRY.**—By W. S. Dawson, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), F.R.A.C.P., D.P.M. Fourth Edition. 1940. Baillière, Tindall and Cox, London. Pp. vii plus 320. Price, 4s. 6d.

BOTH these little books are written by doctors for medical students—undergraduate or post-graduate. That medical training has reached a point whereat psychology is admitted to the rank of a 'subject', shows that the teaching of psychopathology and psychiatry is becoming a serious affair. Without undue optimism one is at liberty therefore to presume that in a generation or two the famous dictum of Trousseau, 'there are no diseases but only diseased persons', has a hope of attaining recognition. In the list of works to which the author of *Aids to Psychology* states in his preface he is under an obligation, it is remarkable to observe that he makes no mention of the work of Professor C. Spearman 'Psychology down the Ages', a book which is certainly the most eminent textbook of psychology in English and possibly in any other language. Dr Ewen is evidently a loyal disciple of the late Professor McDougall with the result his psychology is all-too-human. On page 55 we are told that one of the differences between Natural Man (whatever the term 'natural' may connote) and other Mammals is that man has 'foresight of the future in accordance with the past'. The present situation in Europe would hardly support this statement. To the researches of animal psychology no reference is made. 'Gestalt' psychology is considered and dismissed in two paragraphs on the last page in the book, but in such a fashion as to leave the reader with a vague notion that 'there is something in it'. In case Dr Ewen has overlooked Professor McDougall's opinion on Gestalt psychology, it is as follows—'I would submit that no one of the principles of Gestalt psychology is new, except one (isomorphism), which is, I think, demonstrably false'. In other words, the medical student who reads this book is not getting a fair deal. Of course, it is possibly beyond human achievement to give any one a fair deal in psychology in what is no more than a cram-book. This remark applies more or less to the book of Dr Dawson which in spite of the

fact it is in its fourth edition, is lamentably behind the times. It is even more of a cram-book than the book of Dr Ewen, and as such its sale should be prodigious. That the book is particularly devised to help students to pass the examination for the Diploma of Psychological Medicine and is now in its fourth edition, seems rather to reflect on the scope of the D.P.M. Dr Dawson appears to regard Kraepelin's work on dementia praecox to be still of practical value, although Kraepelin's original conception is now held to be more or less bankrupt. Dr Dawson makes no mention of 'psychobiology' nor of the concept of the somatopsychoses. In the matter of therapy, occupational therapy is hardly touched on while in regard to mental hygiene the name of Clifford W. Beers is not even mentioned. If Dr Dawson is representative of psychiatry in Australia, Australian psychiatry has a good deal of lee-way to make up.

**THE PHYSIOLOGICAL BASIS OF MEDICAL PRACTICE: A UNIVERSITY OF TORONTO TEXT IN APPLIED PHYSIOLOGY.**—By Charles Herbert Best, M.A., M.D., D.Sc. (Lond.), F.R.S., F.R.C.P. (Canada), and N. B. Taylor, M.D., F.R.S. (Canada), F.R.C.S. (Edin.), F.R.C.P. (Canada), M.R.C.S. (Eng.), L.R.C.P. (Lond.). Second Edition. 1939. Baillière, Tindall and Cox, London. Pp. xvi plus 1872. Illustrated. Price, 55s.

THE fact that this book, which was first published in 1937, was reprinted four times is in itself a sufficient proof of its popularity and utility. The second edition appeared in September 1939 and has been thoroughly revised and enlarged. A new section has been added on the physiology of the special senses and the whole of the subject matter has been brought up to date. This is a most excellent book which puts in very simple and easily comprehensible language the applicability of modern concepts of physiology in the treatment of disease. We strongly recommend it both to students and practitioners in this country as a perusal of it will enable them to understand the physiological basis of scientific medical practice which is the only way they can equip themselves for successful careers.

R N C

**AIDS TO MATERIA MEDICA.**—By G. H. Newns, M.D. (Lond.), M.R.C.P. (Lond.). Second Edition. 1939. Baillière, Tindall and Cox, London. Pp. vii plus 171. Price, 3s. 6d.

THE students aid series is designed with the object of assisting medical students reading for examination. The second edition of *Aids to Materia Medica* has been thoroughly revised and includes the new drugs contained in the British Pharmacopœia Addendum 1936. The preparations of the drugs are clearly given and their pharmacological actions are concisely stated. The book is reasonably priced and will be useful to Indian students.

R N C

**AIDS TO PRACTICAL NURSING.**—By M. Houghton, S.R.N., S.C.M., D.N. (Lond.). Second Edition. 1940. Baillière, Tindall and Cox, London. Pp. xii plus 308, with 36 figures. Price, 3s. 6d.

THIS book is essentially practical and is of everyday use to nurses in training. If the other parts of this 'Aids' series is of equally high standard, I shall have no hesitation in recommending my pupils to collect this inexpensive series for their progressive studies.

R C

**A POCKET MEDICAL DICTIONARY.**—Compiled by Lois Oakes, S.R.N., D.N. (Lond. and Leeds). Assisted by Thos. B. Davie, B.A., M.D. (Liverpool), M.R.C.P. (Lond.). Fourth Edition. 1940. E. and S. Livingstone, Edinburgh. Pp. xx plus 409. Illustrated. Price, 3s. 6d. Postage, 2d.

THIS dictionary should be in the possession of every training and post-graduate nurse. Its definitions are simple and comprehensive, and the book is completely up to date with the revised medical terminology.

R C

**LIPPINCOTT'S QUICK REFERENCE BOOK FOR NURSES.**—Compiled and arranged from Various Sources. By Helen Young, R.N. With the Assistance of G. A. Morrison, R.N., and M. Elliot, R.N. Fourth Edition. 1939. J. B. Lippincott Company, Philadelphia and London. Pp. 557. Price, 9s.

THE book comprises a very well-thought-out scheme for grouping nursing procedures, thus providing a time-saving guide for the busy nurse.

R. C.

**HORMONES IN INVERTEBRATES.**—By Bertil Hanstrom. 1939. Oxford University Press, London. Pp. ix plus 198, with 13 plates. Price, 12s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

THIS is the first volume to appear in the new series of monographs on animal biology which are being published by the Oxford University Press under the general editorship of Dr. G. R. De Beer. The importance of hormones in man and higher animals has received particular attention during recent years, and the part which they play in the proper functioning of the organism by chemical correlation has been fully appreciated. Lately, attention has also been paid to the part the hormones play in the economy of the invertebrates, and biologists will be grateful to Professor Bertil Hanstrom, whose work in connection with invertebrates is well known, for presenting a summary of the present knowledge on the subject. The difficult task before him has been accomplished with great skill and he has given in very lucid and easily comprehensible language the various functions which these hormones perform. An account of the anatomy and physiology of the excretory organs in different invertebrates is given and their connection with different hormones is indicated. There are interesting sections on the influence of vertebrate hormones on invertebrates and invertebrate hormones on vertebrates. Other sections which will be of interest to the biologist are hormonal regulation of colour changes, retinal pigment migration and neuro-secretory organs. A comprehensive list of references is given at the end. The book is priced low and will greatly interest biologists.

R. N. C.

**COMMON MISTAKES OF SURGERY IN INDIA AND HOW TO AVOID THEM.**—By Lieut.-Colonel A. N. Palit, O.B.E., F.R.C.S. (Edn.), M.R.C.O.G., I.M.S. (Retd.). 1940. Book Company, Calcutta. Pp. xx plus 382. Illustrated. Price, Rs. 5

THIS book is intended to be a practical handbook for the young surgeon, the general practitioner, the hospital medical officer and the surgically-minded student. The author has written the book with a laudable object and we hope that his desire may be fulfilled. It contains an appreciative foreword by Major-General Mills, the present Surgeon-General with the Government of Bengal.

## Abstracts from Reports

### ANNUAL REPORT OF THE KASHMIR MEDICAL MISSION OF THE CHURCH MISSIONARY SOCIETY FOR THE YEAR 1939

THE beginning of medical missionary work in Kashmir was made by Mrs. Robert Clark, wife of Rev. Robert

Clark, just seventy-five years ago in the summer of 1864. The urgent need for medical relief may be judged by the fact that Mrs. Clark, though not a doctor, often treated as many as a hundred patients in a day in Srinagar. The following year, Dr. Elmslie our first mission doctor was appointed, and since then there has been a continuous succession of doctors to carry on the work.

The past year has been a difficult one for our hospital, but the work has been well maintained in all departments: medical, surgical, pharmaceutical and evangelistic. That the hospital has kept up its popularity is shown by our statistics, showing the numbers of in-patients admitted to this hospital for the last 58 years.

As usual we had to treat a great variety of medical and surgical cases, many of them suffering from grave and serious disease. Of various medical diseases, heart disease is one of the most prevalent with which we have to deal, and a large proportion of those who seek our aid for this trouble come in an advanced stage of the disease and, to do any real good, admission to the wards is essential.

Of surgical troubles, bone disease is one of the commonest with which we have to deal. It is due largely to deficiency in diet. These patients occupy our beds for longer periods than any other class of sufferers. Often after a successful major operation in which all diseased bone is removed, it may be six months or more before the patient is fit to return home. There can I think be no doubt that many of these patients receive not only physical healing but a real moral and spiritual uplift while in our wards. A number of these patients before admission to hospital have had their disability for many months or even years, and prolonged treatment by 'Hakims' has failed them, and they come to us sad and dispirited.

At least some Kashmiris are grateful for the work of this hospital. It was only about a year ago that a relative of one of Dr. Rawlence's patients gave us two hundred or more young trees which were planted in our hospital grounds. A number of Kashmiris have for some years been giving subscriptions and donations to the hospital, and at least one well-known Kashmiri business man has given a banker's order for a monthly donation to our funds. On this very day, a Kashmiri has asked the writer to accept Rs. 500 for this hospital but he has stipulated that the gift must be kept anonymous.

One way in which our hospital has increased its usefulness in the last four years has been the thorough training of dispensers, not only for our own hospital but also for others. During the last four years eight candidates have passed the first dispensers' examination and five have completed the course and passed the second and final examination. Four young men who qualified as dispensers have left and are now well able to do useful and very responsible work in various parts of India.

There has been considerable progress in recent years in the prevention of epidemics by the public health authorities, and the widespread epidemics of smallpox, cholera, dysentery and typhoid, which used to occur, now no longer devastate the country. But tuberculosis is a modern plague which needs to be tackled on a widespread scale, and with great vigour. The Kashmiri has a poor resistance to tuberculosis, and it causes a heavy mortality, both among the young and old.

The solution to the health problem of Kashmir, like any other country, depends largely on its diet and food supply, and clean and healthy habits of its people, and there is no reason why in Kashmir the people should not be one of the healthiest in the world. The land is so fertile that almost any crops and fruit will grow abundantly. The climate is exceptionally good, and the natural resources are almost unlimited.

In the fight against disease, success depends largely upon having a supply of good and efficient drugs ready at hand for immediate use. In this hospital we endeavour to keep abreast with modern medicine and treatment, and in the past we have had every reason to be proud of its record. Owing to the war, it is becoming

A specialist in Tropical Medicine, addressing a meeting of eminent malariologists, recently stated :

*"I am definitely of the opinion that prophylactic quinine does prevent actual attacks of malaria. Once or twice the experiment was tried of withholding prophylactic quinine for a week or two from large groups of men. This was followed by such increases in the sickness rate from malaria that a rapid return to the prophylactic dose was made."*

But—the physician must be able to *rely* on the quinine so prescribed. Howards' Quinine is, and has been for over 140 years, guaranteed pure and fully up to the B. P. Standard. The physician may prescribe HOWARDS' Quinine with every confidence.

**CALCUTTA :: :: BOMBAY**

increasingly difficult to obtain certain drugs, partly owing to difficulties in transport from England, and partly on account of the large increase in cost. We hope that those who have supported us in the past, will do so with renewed generosity in the future, and help the medical and surgical work of the Kashmir Mission Hospital to be carried on in these difficult days.

#### THE NINETEENTH ANNUAL REPORT OF THE RAMAKRISHNA MISSION SEVASHRAM (CHARITABLE HOSPITAL), RANGOON, FOR THE YEAR 1939

Born in the indoor and outdoor sections there has been a rise in the number of patients. The following figures for the last five years will give an idea of the extent the public has used the hospital and there is every reason to anticipate further increases in the coming years.

Year	Indoor	OUTDOOR		Total
		New	Repeated	
1935	3,746	79,448	116,303	199,497
1936	4,083	85,423	137,829	227,335
1937	4,375	88,418	150,951	243,744
1938	4,701	98,190	160,634	263,525
1939	5,263	104,591	199,100	308,954

The death rate was 5.25 per cent.

The patients requiring x-ray examination were sent to the Rangoon General Hospital and to the tuberculosis clinic of the Corporation of Rangoon.

Wassermann and other important tests were done by the Pasteur Institute of Burma and the management takes this opportunity of offering the institute and its Director, its heartiest thanks for their co-operation. Besides these, 8,260 tests were carried out by the laboratory of the hospital.

With the addition of 18 beds in the Nanigram maternity ward and 12 beds in the segregation ward the total number of beds available is 200 of which 56 are for the females.

In the year under review there were 15 nurses for the female wards and 21 male workers did nursing in the male wards besides the *Swamis* and *Brahmacharins* of the Ramakrishna Order who held charge of nearly all the responsible posts so far as the indoor general management was concerned. Sister Anderson of the St. John Ambulance Brigade, with her band of devoted workers, helped in the female wards and out-patient departments; but for their help, it would have been difficult to manage the ever-increasing demand made on these departments and the management takes this opportunity of conveying its heartiest thanks for their labour of love.

The managing committee met every month for transaction of business. The attendance was very satisfactory.

The opening of the maternity and segregation wards marked a great improvement in the hospital. The maternity block with its clinic has become very popular and is rendering valuable service to the poor public of this locality. It was opened on the 20th November, 1939, by His Excellency the Governor of Burma.

#### THE SECOND PROGRESS REPORT OF THE SAIDAPET HEALTH PROJECT

The Second Progress Report of the Saidapet Health Project, recently published, gives a survey of 1939, along with detailed reports of the various activities of the association.

The fact that this is only the second report may suggest to some, that this work has been going on for only two years. It was actually started as long ago as 1932, but the promoters have been content to concentrate on making sure foundations before issuing a public report.

The report begins with a review of the spade-work, when decisions had to be taken as to how best the objective of Saidapet—'the cleanest and healthiest town in South India by 1950'—could be reached; which of the prevalent diseases most urgently required investigation in the actual situations where they occur; how public apprehension, if it were to be leprosy, could be disarmed; what staff would be needed to visit the 3,000 homes and correlate the information gained, and lastly but most important, how the scheme was to be financed.

It was decided to concentrate upon the relief of leprosy—the Silver Jubilee Children's Clinic was opened in 1937—and to seek the interest and co-operation of the people through an efficient maternity and child-welfare centre, which was opened in 1934.

#### Maternity and child-welfare centre

During the year ending 30th April, 1939, 1,575 women attended the antenatal clinic, though less than one-sixth of that number were delivered by a member of the staff; the reason for this is that many pregnant women, assured at the clinic that their case is normal, are at the last moment persuaded to accept the care of the traditional midwife. Of the 208 cases attended during childbirth (146 in the centre and 62 at home) six babies were still born or died, while the maternity mortality rate was *nil*. In July a whole-time lady medical officer was appointed.

#### Leprosy

With regard to the leprosy investigation, three main objects can be defined:—

(1) Causes of the development of leprosy in children.

(2) The types of leprosy in children.

(3) The significance of the various types of child leprosy, and a study of the factors which influence the development of the more serious types.

The report shows that the clinic is becoming increasingly popular, for parents bring their children with even the slightest blemish, to ask whether it may be due to leprosy, and it reveals the following interesting findings. Half the children in the observation group are 5 to 9 years of age and a third are 10 to 14 years, whereas in the treatment group two-thirds of the children are aged 10 to 14 years. When an attempt was made to trace the source of infection, divisions were made into intra-familial (room and house) and extra-familial (street and school) contacts. Space forbids reproduction of all the figures concerned, but nearly half of the sources of infection of the 284 neural cases were definitely traced, and nearly two-thirds of the lepromatous ones. The report frequently emphasizes that the greatest danger is contact with open cases, and that where this contact is maximum there appears to be the greatest risk of acquiring serious-type leprosy.

At the assessment made in July 1939, out of a group of 145 children under observation only, 64 were found to be improved, 66 stationary and 15 worse. This group does not contain lepromatous cases which are classified in a separate treatment group; of their total of 43, 17 became negative, 11 improved (while remaining positive or open), 2 were stationary and 13 worse, while the corresponding figures for 49 'N1' cases under treatment were 35 improved, 4 stationary and 10 worse.

An experiment was carried out to observe the effect of the addition of skimmed milk to the diet (1½ c.cm. per 10 pounds body-weight weekly). Analysis of the tables showed that it had little influence in hastening retrogression of lesions in the early neural cases, but the experiment is not yet sufficiently advanced for conclusions to be drawn. A further interesting observation made is that children who receive the maximum dose of *Hydnocarpus* oil appear to improve more rapidly than those on lower doses.

*Mambalam village survey.*—A survey of the *cheri* (Mambalam village) is described in detail in the report which shows that while the gross incidence of leprosy is only one-fifth of that in Saidapet proper, every definite case was shown to have had contact with an

open case of leprosy; for instance when a case of neural leprosy was discovered, somewhere near to his hut an open case would almost invariably be found. Indeed the distribution, of leprosy seemed to centre round five foci of infection, of whom three were alive and two dead. Six cases were traced to the three existing open cases, and 14 to the two deceased ones. Another feature was that the majority of cases were traceable to extra-familial sources of infection, largely because, for purposes of contact, the whole village may be taken as a single family group, whereas in Saidapet proper caste distinctions are more in evidence and so contact is mainly intra-familial. Lastly the evidence was all against the poor dietetic condition of the *cheri* predisposing to more widespread infection or resulting in a more serious type of leprosy.

#### *Tuberculosis*

The report contains an abstract of the tuberculosis survey and this reveals a most disquieting situation. Of 638 persons examined, 446 showed no physical signs of tuberculosis, but of the remainder, 186 required further examination; of these, 126 had physical signs in the lungs and were x-rayed, as were also 114 who showed a strong Mantoux but no physical signs of tuberculosis. In passing it may be said that 67.8 per cent of the adult population of Saidapet reacted positively to the Mantoux test and 41 per cent of children (under 12)—both high rates. The latter figure points to a serious home or school source of infection which should be urgently investigated. In all, 33 individuals were found to be suffering, without any doubt, from active tuberculosis requiring treatment. In addition 107 others required further observation and possibly treatment, because of physical and x-ray findings, and 54 of these were children under 12.

As in leprosy, the infection rate is much higher in those living in contact with open cases, and as a corollary, it was evident that overcrowding was a more serious factor than purely a poor economic condition. The tuberculosis mortality rate works out at 462 per 100,000 of the population; the corresponding figure in England is only 76 per 100,000 and the Saidapet numbers must all unfortunately be regarded as minimum figures. A survey has still to be made into the causes of the high tuberculosis infection, morbidity and mortality rates in Saidapet, and it is gratifying to know that a start is to be made later this year, in tackling the problems of further investigation and treatment.

#### *Social*

The report also contains an account of the social work carried out by the students of the Y. M. C. A. College of Physical Education, for it was early realized that the work to be carried on outside the clinic in the homes and streets would be almost as important as that of the laboratory. It has already been indicated how the initial fears of failing in the house to house survey proved to be groundless, and this is largely because of the way in which suspicion has been disarmed, through the school play programme and the maternity centre, etc.

The remainder of the report deals with the economic and sociological survey, and gives an outline of the future programme, which aims at the accumulation of further valuable statistics concerning the general health level of the children, in order that the right steps may be taken to raise that level. It ends with a complete clinical record of one child and is liberally illustrated with photographs, plans and tables.

There is a concluding note which reminds the reader that the results cannot but be secured slowly, for although the work is amongst individual cases, the information in the final analysis is concerned not with the individual cases only, but with the problem of how to control and eradicate leprosy and tuberculosis in a given district. Great satisfaction lies in the quiet revelations of the report that the research work of the association is acting as a lever to elevate the health level of the entire community, and thus it merits the interest and support of all progressive men and women.

### ANNUAL REPORT ON THE WORKING OF HOSPITALS AND DISPENSARIES IN THE PUNJAB, FOR THE YEAR 1938

DURING the year under report the total number of medical institutions was 974 (697 in rural areas and 277 in urban areas) against 968 in the preceding year. Two canal dispensaries were closed, but five more were opened in connection with the Haveli Project. The hospitals at Jhelum, Jhang-Mughiana, Batala and Rajanpur and the hospital for women at Beri in the Rohtak district were provincialized. The number of rural dispensaries remained the same, namely, 364; but their sphere of usefulness was widened. The scheme requiring medical officers in charge of these institutions to visit neighbouring villages within a radius of five miles on payment of a fixed travelling allowance of Rs. 10 per mensem which was introduced in 1937, was extended to ten other districts. In order to bring medical relief within easy reach of the rural population at a minimum cost to the exchequer and also with a view to encouraging the spirit of self-help, Government have given a new orientation to their policy. They have now embarked on a scheme of subsidizing private practitioners who will be encouraged to settle in villages with the promise of a subsidy of Rs. 1,200 per annum, half of which will be paid by Government and the other half by the villages themselves through co-operative societies or other similar collective organizations. The experiment was started recently and has been received with enthusiasm in several places.

The total number of patients treated both indoor and outdoor was 171 lacs against 162 lacs in the preceding year. The increase is most noticeable in the case of patients suffering from diseases of the eye and is an indication of the popularity of eye centres, where mainly cataract operations are performed. The phenomenal increase in the number of cholera patients from 139 to 4,251 is due to the importation of infection by pilgrims returning from the Kumbh fair at Hardwar. There was a decrease in the number of patients treated for malaria, which is attributable not only to the disease being less prevalent, but also to a growing tendency amongst the people to treat themselves with quinine without resorting to hospitals.

The total expenditure on hospitals and dispensaries maintained by Government or local bodies or by private organizations with a grant-in-aid by Government was Rs. 52.38 lacs against Rs. 51.18 lacs in the previous year, the principal increase being under the head 'Establishment' on account of the annual increments of the staff. The increase in expenditure on medicines and diet was due to the treatment of a larger number of patients. The income from fees and voluntary contributions rose from Rs. 2.62 lacs to Rs. 2.96 lacs. It appears that patients who can afford to pay for medical treatment are beginning to realize that any payment made by them will help to extend the facilities for medical relief to those who are too poor to pay. The Inspector-General of Civil Hospitals is not satisfied that local bodies are fully alive to the necessity of the proper maintenance of the institutions under their control. Government realize that unless a local body is able to raise additional funds by fresh taxation or from some other source, it is not in a position to expand its activities. But they trust that the standard which has already been attained as a result of several years' effort will not be allowed to fall.

Considerable attention was paid during the year under report to the supply of medical aid to women by members of their own sex. The female hospital at Beri in the Rohtak district which was constructed through the generosity of a public-spirited philanthropist, and the women's sections attached to the civil hospitals at Campbellpur and Jhang-Mughiana were provincialized. The hospitals for women at Bhakkar and Sirsa in charge of municipal committees which had been closed down were reopened. The number of beds available for women increased by 115, of which 59 were in women's hospitals. A sum of Rs. 60,000 was provided

## 'Elastoplast' and Minor Injuries

'Elastoplast' is of great value in dressing small injuries. 'Elastoplast' Dressings are elastic, adhesive and antiseptic; their elasticity helps to approximate the wound margins.

The 'ELASTOPLAST' DOCTOR'S SET is a black japanned box divided into separate compartments containing 105 assorted dressings and a roll of 'Elastoplast'

plaster. Refills can be obtained from your surgical supplier either for the complete outfit or for individual items.

The 'ELASTOPLAST' SURGERY CASE is a black metal box which contains 1-yard lengths of the 1½", 2½" and 3" widths of 'Elastoplast' Dressing Strips. To refill the Case, Dressing Strips can be had separately from your surgical supplier.

from the Government of India grant for rural construction to be spent on scholarships to encourage women from rural areas to be trained as *dais* and nurse-*dais*.

Government have still before them the ideal that there should be a separate hospital for women at the headquarters of each district and a separate female section in charge of a woman sub-assistant surgeon attached to each *tahsil* headquarters hospital. But the achievement of this ideal is still remote, for financial reasons. The other limiting factor was the insufficient supply of Punjabi women doctors. Now, however, this is not likely to present any serious difficulties, as medical education among girls is becoming increasingly popular. During the year under report there were 108 Punjabi women students studying for the M.B., B.S. degree and 209 were undergoing a training to qualify themselves as sub-assistant surgeons.

The principal institutions maintained by Government, namely, the Mayo Hospital, the Lady Willingdon Hospital, the Lady Aitchison Hospital, and the Dental Hospital at Lahore and the Civil Hospital, Amritsar, retained their usual high standard of efficiency. A new x-ray plant was installed at the Mayo Hospital at a cost of more than Rs. 1 lac. The construction of a Radium Institute in connection with the hospital has been made possible by the munificence of L. Tirath Ram who gave a generous donation of Rs. 50,000. A whole-time clinical pathologist was appointed at the Civil Hospital, Amritsar. The Lady Aitchison Hospital was so popular that there was a daily average attendance of 99.65 indoor patients for 100 beds and notwithstanding overcrowding admission had to be refused in many cases. The number of ante-natal cases at the Lady Willingdon Hospital increased from 203 to 306 and of surgical operations from 1,169 to 1,567.

A conference of civil surgeons was held at Lahore in April 1938, under the chairmanship of the Inspector-General of Civil Hospitals. The idea was well conceived and the conference proved a great success. Apart from providing an opportunity for establishing personal contacts, the deliberations of the conference resulted in important suggestions for economy and improvement in medical administration. Another noteworthy event of the year was the appointment of a committee to consider whether steps should be taken to provide for the registration of practitioners of the indigenous systems of medicine and whether anything could be done to secure better education in these systems.

#### ANNUAL REPORT OF THE MALARIA ADVISORY BOARD, FEDERATED MALAY STATES, FOR THE YEAR 1939. BY A. NEAVE KINGSBURY, CHAIRMAN

##### *An example of unsuccessful plasmoquine prophylaxis*

ALTHOUGH plasmoquine was introduced twelve years ago there is still no unanimity on its value in field prophylaxis. Under laboratory or hospital conditions the drug is a powerful gametocide, but attempts to utilize its gametocidal action for the control of malaria in the field have given very variable results. A renewed attempt to define the prophylactic value of the drug under plantation conditions was made by the Malaria Research Division, Institute for Medical Research, during 1938 and the early months of 1939.

In describing this experiment to the board, the senior malaria research officer stated that the plantation selected was one on which gametocidal prophylaxis might fairly have been expected to operate under conditions favourable to success. It was well isolated from outside sources of infection, both human and anopheline, while the population of about 700 men, women and children was under such control that the regular administration of the drug could be assured.

Prophylaxis started in March 1938, and continued for one year. The plasmoquine was given under personal supervision at a dosage of 0.02 gm. twice a week for adults and proportionately less for children. Control was regarded as unsatisfactory. The incidence of clinical malaria remained high, while many *P. vivax*

gametocyte carriers were found at routine blood surveys. There was, moreover, strong circumstantial evidence of continued transmission of infection, for wild-caught mosquitoes were found occasionally to be infected and most of the children born on the estate during the year developed malaria within a few months of birth. Two out of every three new-comers, the majority arriving without evidence of existing malaria, developed one or more attacks during the year. Most of the fresh infections that were observed during the period of prophylaxis were with *P. vivax*, but some fresh *P. falciparum* infections undoubtedly occurred.

At first, experimental attempts to infect mosquitoes from *P. vivax* gametocyte carriers known to have received plasmoquine regularly, were mostly unsuccessful: a few gut infections were obtained but no infections of the salivary glands. Later, however, gland infections were obtained. It appears that the discordant results reported in connection with plasmoquine prophylaxis may possibly be explicable by specific differences in response by *P. vivax* and *P. falciparum* to prophylactic dosage.

Dr. I. G. Cameron remarked that contradictory results were published as a result of investigations made on estates near Kuala Lumpur in 1928-29. (Then, the dosage of plasmoquine was twice that used in the present experiment, and now generally recommended for prophylaxis). Dr. B. Barrowman stated that when he was in charge of the estate where Dr. Field's experiments were carried out, and the population was under eighty, he had found that quinine and plasmoquine successfully controlled malaria but such effective control was not obtained whenever the population rose above approximately that number. The population was now 700 and the infection rate, despite prophylaxis, was 14 per cent per month. He considered that the possibility of control of malaria with drugs depended on the size of the population to be protected. He had observed that all reports of the failure of plasmoquine to control malaria had been where the numbers treated were large, while reports of success with the drug had been when the numbers treated were small, and he suggested that all experiments should be scrutinized with this point in mind. The senior malaria research officer pointed out that when, on the same estate, about 400 people were under observation, of whom one-third were subjected to atebirin prophylaxis, the results were regarded as highly satisfactory despite the presence of a large parasite reservoir in a comparable control group.

##### *Attempted prophylaxis with 'M.3'*

An Italian drug known as 'M.3', prepared by the State Biochemical Institute in Milan, has recently been introduced into Malaya. 'M.3' contains mercury and manganese as a double iodide combined with spleen extract and is said to be a valuable prophylactic against malaria. It is claimed that the drug stimulates immunity, improves anaemia and reduces the size of the spleen: administration in rising doses on alternate days for a month is said to confer an immunity which, in the tropics, lasts for six months. It is further claimed that the preparation is a better preventive of malaria than is quinine.

A test sample was recently supplied to the Institute for Medical Research by the courtesy of the local distributors. The senior malaria research officer reported that three hundred adults who had little malarial immunity and were exposed to fairly heavy transmission had been selected for observation; 100 were receiving a full course of 'M.3'; 100 were receiving 1.0 gm. of quinine sulphate weekly; and 100 were untreated controls.

There was little evidence at the end of the year, i.e., after 2½ months' treatment, of any significant reduction of malaria in the 'M.3' group, but a longer period of observation is necessary before definite conclusions can be drawn.

In addition to this brief account of drug prophylaxis the report contains a large amount of information which is mainly of local interest, nevertheless it might be read with advantage by those interested in malaria

control elsewhere, because they are sure to find many items that will be applicable to their own problems.—  
EDITOR, I. M. G.]

## ANNUAL REPORT OF THE MYSORE STATE MEDICAL DEPARTMENT, FOR THE YEAR 1938

THERE were 311 medical institutions working in the State at the close of the year 1938 against 291 at the end of the previous year.

Of the 311 institutions, 279 are classed as public, 26 as non-public (jail, military, forest, railway, etc.), and six as private-aided institutions. There are 32 maternity hospitals and female dispensaries exclusively for the use of women and children.

Including 13,078 parturition cases treated in the various hospitals and dispensaries 61,537 new in-patients were admitted during the year as against 53,251 in the previous year, showing an increase of 8,286 in the current year, i.e., an increase of 15.5 per cent.

During the year 5,612,993 new out-patients were treated as against 5,271,437 in the previous year. Of these 3,485,302 were adults and 2,127,691 children. 4,293,342 were Hindus, 1,060,174 Muslims and 259,477 others; 4,124,665 attended personally and 1,488,328 were represented by friends or relatives. The daily average number of out-patients treated was 25,663.84 against 26,256.91 in the preceding year.

A total number of 335 midwives were working during the year compared with 325 in the preceding year.

A total of 32,038 parturition cases were conducted during the year both in and outside the medical institutions against 30,355 in the previous year. Out of these 13,078 were done in institutions and 19,010 outside.

As in the previous year there were 32 maternity hospitals and female dispensaries. A total of 881 beds was provided in these institutions for the use of in-patients including parturition cases, against 772 in the preceding year.

## Correspondence

### OBSERVATIONS ON THE USE OF NICOTINIC ACID IN THE TREATMENT OF PELLAGRA AND ALLIED CONDITIONS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the May number of the *Indian Medical Gazette*, Dr. W. R. Aykroyd has criticized my statement that 'pellagra is quite common in Bengal'.

According to Sen Gupta *et al.* (1939), the Calcutta School of Tropical Medicine treats six to twelve cases of pellagra per annum. I myself have seen classical pellagra in parts of Bengal as far apart as Chittagong and Midnapore, and more recently in Calcutta.

I admit that in my experience advanced cases of classical pellagra are not common, but I believe that mild cases of pellagra and especially cases which respond well to nicotinic acid are quite common.

The truth of the matter is probably best expressed by Napier (1939) who wrote as follows 'If medical officers in India were more familiar with the signs and symptoms of pellagra it is probable that far more cases would be diagnosed'.

## BRITISH PHARMACEUTICAL PRODUCTS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Our attention has been drawn to the article on 'British pharmaceutical products' commencing on page 175 of your issue of March 1940, and the two tables which appear on the following pages.

The article is apparently an extract from a publication which appeared in England very shortly after the outbreak of war, which contains a certain amount of misleading information, a certain amount of information which is untrue so far as India is concerned, and which takes no note of developments that have occurred since the outbreak of war.

The items in which we are interested are as follows:—

**Knoll products**—The following Knoll products appear in the tables under the heading 'Foreign Product':—

Bromural	Iod. calcium diuretin
Calcium diuretin	Matronax (known in India as
Cardiazol	Klimakton).
Digipuratum	Styptol
Diuretin	Styracol
Euresol	Tannalbin

The position with regard to Knoll products is, that the trade-mark rights in the United Kingdom are owned by Messrs. Knoll, Limited, London, an English firm closely affiliated with Messrs. Savory and Moore Ltd., and immediately after the outbreak of war, arrangements were made to carry on the manufacture of these in England, and at the present time they are definitely English products, manufactured and marketed by an English company. Arrangements have been made for the English company to supply the requirements of India, and continuity of supply to India of these particular preparations is now assured.

**Argyrol**—This is given as a 'Foreign Product', but this is not correct so far as India is concerned.

For many years the requirements of India have been supplied by the Canadian factory, and Argyrol, in so far as this country is concerned, is definitely an Empire product.

**Veganin (Warner)**—This is starred as a 'Foreign Product' now manufactured in England.

So far as India is concerned, this has never been a foreign product. All supplies made to India since the first introduction of Veganin, have been manufactured in England, and this is definitely an English product.

We shall esteem it a favour if you will take any measures possible to correct any misleading impressions that may arise from the publication of this article.

Yours, etc.,

MESSRS. MARTIN AND HARRIS,  
LIMITED.

MERCANTILE BUILDINGS,  
LALL BAZAR,  
CALCUTTA,  
29th May, 1940.

## Service Notes

### APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL W. H. HAMILTON, C.B., C.I.E., C.B.E., D.S.O., K.H.P., to be Director of Medical Services in India. Dated 12th March, 1940.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff:—

To be Honorary Surgeon

Colonel D. F. Murphy, M.C., vice Colonel A. C. Munro, vacated. Dated 22nd October, 1939.

The services of Colonel D. H. Rai, M.C., have been placed at the disposal of the Government of the C. P. and Berar, with effect from 11th March, 1940, and he has been granted leave from 11th March, 1940, to 14th May, 1940, preparatory to retirement.

## HEADACHE IS DISABLING

Headache may be as disabling as a grave illness. In migraine particularly, the headache is of all degrees of intensity, at times so severe as completely to incapacitate the sufferer. It is noteworthy how quickly the patient can obtain relief with Veganin. Composed of minimum doses of acetylsalicylic acid, phenacetin and codeine, Veganin affords striking proof of the superior analgesic potency of this synergistic alliance over that of its components administered separately. Recurrent painful conditions, such as migraine and dysmenorrhœa, yield with impressive promptness to the efficacy of Veganin.

**VEGANIN** TABLETS

Supplied in tubes of 10 and 20. Veganin is not advertised to the public.

*A trial supply to Physicians on request.*

**MARTIN & HARRIS LTD.,** Mercantile Buildings, Lall Bazar, Calcutta.

Also at Bombay, Madras, Karachi and Rangoon.

Prepared by **WILLIAM R. WARNER & CO. LTD.,** LONDON, ENGLAND.

the satisfactory results. Many patients have been seen after operation, enjoying excellent health and highly satisfied with the result.

Further objections have been raised against subtotal gastrectomy in this country on account of the bulkiness of the Indian diet, but no fears need be entertained on this account. Another objection to the ulcer-exclusion operation, recently referred to by Lahey and Marshall (1939), is possible difficulty of drainage of the pyloric stump if stenosis is present at the site of the ulcer or if it develops later. I do not perform the operation in the presence of stenosis, and have not seen or heard of any after-effects of this kind.

As there is no reason as yet to suppose that the acid levels of Indian stomachs differ considerably from the European, the discrepancy in the results is not easy to explain. Recently Rokitsky's neurogenic theory of the origin of peptic ulcer has been revived and there is experimental evidence in animals that division of the vagus nerves results in considerable lowering of gastric acidity. It is possible therefore that in ligation of the blood vessels in the region of the cardia, these nerves are included. Wilson Hey has claimed that ligation of a large number of the gastric vessels is followed by lowering of gastric acidity, and this claim has been supported by Somervell (1940) among others. It is difficult to understand the mechanism by which this is brought about, for in the ulcer-exclusion type of gastrectomy an equal number of vessels is ligatured or divided. Wells (1939) has suggested that the results of vessel ligation might be due to inclusion of branches of the vagus in the ligatures, and I am inclined to agree with this suggestion. Moreover, in the operation which I practise, little of the pyloric antrum is left. This also may be an explanation of the satisfactory results.

In my opinion, the majority of cases, as seen to-day in India, are such that an ulcer-exclusion type of operation is all that can be done with safety. For those who consider or find the post-operative recurrence of a high acid level to be a danger, the original operation may be regarded as a *first stage* procedure, the pyloric stump being removed at a *second stage* operation some weeks or even months later.

#### *Management and technique*

*Pre-operative technique.*—Each patient is subjected to a careful general examination, special attention being paid to the state of the blood and to a search for intestinal parasites of which the most important is the hookworm. Every one of these patients shows some degree of anæmia. It is often very severe and many patients are admitted with a hæmoglobin percentage as low as 40. Such cases obviously require energetic anti-anæmic treatment to improve this state of affairs. A possible factor in the causation of this anæmia is the chronic gastritis from which nearly all these cases seem

to suffer. Stomach washes, iron, vitamin B, and injections of liver extract are our most potent remedies in the improvement of the anæmia in all cases, with in addition a course of appropriate anthelmintics where intestinal parasites such as the hookworm or the roundworm are found. Hookworm infestation is found to be very common and requires eradication before operative treatment can be proceeded with. The intravenous injection of large doses of Neohepatex (Evans) has been found a most valuable remedy in bringing about rapid improvement in the more severe cases of anæmia and has in fact proved life-saving in cases of acute anæmia following one or more severe hæmatemesis. Its effect is especially valuable for it is usually impossible in this part of India to secure donors for blood transfusion. Anæmia is the most serious complication with which we have to deal, for it has far-reaching effects on all the vital organs, and it is not inconceivable that some of the damage resulting from it is irreparable. We find it safe however to operate on all cases once the hæmoglobin percentage has risen to 70 per cent.

The teeth and mouths of practically all patients require attention, and in many gross caries and infection are present. It is very difficult, however, to persuade patients to submit to routine dental extraction and their reluctance to part with extremely carious and filthy teeth is truly amazing. The infection is often so bad that it is possible that the extraction of such teeth may actually have a deleterious effect in flooding the system with organisms to which the mouth and possibly the stomach have long become accustomed. We have to content ourselves usually with cleaning the mouth by frequent mouth washes during the period of treatment. No serious results, so far as the operation itself is concerned, have been observed through following this very conservative dental regime.

The diet given during the pre-operative period is the ordinary Indian hospital diet consisting mainly of rice, bread, country vegetables, potatoes, plantains, buttermilk and milk, with the usual flavouring ingredients. The diet contains approximately 71 gm. of protein, 20 gm. of fat and 560 gm. of carbohydrate with a caloric value of 2,780. It really requires fine clinical judgment to determine when the patient is fit for operation and this is the most difficult task of the pre-operative period. On it will depend the success of the operation.

*Operative technique.*—Spinal anæsthesia is used in all these cases. Of the many spinal anæsthetics on the market, I have found Percaine, Ciba (1 in 1,500 solution), to be the most suitable for all forms of upper abdominal surgery, and in an experience of some 5,000 spinal anæsthesias with this drug I have seen only two cases to which a fatal termination could be attributed to the drug. It fulfils especially all the requirements

of gastric surgery as it produces perfect relaxation and is sufficiently lasting to enable the operation to be concluded in comfort, both to the patient and the surgeon. The fall in blood pressure which always occurs with spinal anaesthesia is very rarely of sufficient severity to cause anxiety. A dosage of 10 to 11 c.c.m. has been found sufficient for Indian patients and while the majority experience nausea at some stage of the handling of the stomach this very soon passes off. The anaesthetic is administered according to the Howard Jones technique with the head of the table lowered 10 to 15 degrees, and with the patient curled up on his side. The dura is entered with a fine short-bevelled spinal needle between the 3rd and the 4th lumbar vertebrae or in some cases between the 2nd and 3rd. The injection is given slowly and the patient is turned over on to his face immediately after its completion. After 5 minutes in the prone position he is turned over on to his back. Not more than a few drops of cerebro-spinal fluid are allowed to escape before the injection is given. Headache following this technique is very rare.

I have found it necessary to stress our preference for spinal anaesthesia, for it is often stated that this type of anaesthesia is unsuitable for gastric surgery, and some even state that it is dangerous. It has not been so in my experience. Lahey and Marshall (*loc. cit.*) recently stated that, from their experience of Pereaie in upper abdominal surgery, it appeared to be the 'nearly ideal anaesthetic particularly for subtotal gastrectomy'. The patient is given morphia gr.  $\frac{1}{4}$  and scopolamine gr. 1/150 half an hour before operation.

The abdomen is opened by a right upper paramedian incision in all cases, except those in whom a gastro-jejunal ulcer is present, when a midline incision extending from the xiphoid cartilage to the umbilicus is employed. The midline incision in these cases is used mainly to avoid the paramedian incision of the previous operation. The right upper paramedian incision with reflection of the rectus outwards is used because not only can the gastrectomy be satisfactorily concluded through it but the appendix and also the gall bladder, if need be, can be dealt with easily. The appendix is invariably removed and in this country it is remarkable how often it is found diseased. It is nearly always thickened, kinked or adherent, and its removal through a midline incision extending down to the umbilicus or through a left paramedian incision of whatever length would often be difficult and require an undesirable degree of traction, even with the perfect relaxation secured by spinal anaesthesia. The gall bladder usually appears healthy but in a small proportion of cases it is obviously diseased and contains stones. Its removal is left as the last stage of the operation, and it is excised only if it is felt that the patient's condition will permit it. Patients

stand the gastrectomy so well that it has usually been found possible to remove the gall bladder when indicated.

Once the abdomen is opened the ulcer (almost invariably duodenal) is carefully examined. The neighbouring duodenum and the stomach are inspected and palpated in turn and the type of operation decided upon. The gall bladder, pancreas and liver next receive attention and after them the intestines. Finally, the appendix is delivered and excised.

Fig. 1.—Posterior view of stomach showing:—  
 A. Site of left gastric artery.  
 B. Site of right gastric vessels.  
 C. Site of distal division of stomach between the row of clips.  
 D. Site of proximal division of stomach.  
 E. Site of ligature of left gastro-epiploic vessels.  
 F. Site of ligature of right gastro-epiploic vessels.

The details of the operation are as follows:—The stomach and the transverse colon are delivered into the wound and the site of distal gastric section (figure 1) is selected 3 fingers' breadth proximal to the pylorus and marked by the application of a pair of Allis forceps to the greater and lesser curvatures, respectively. The gastro-colic omentum is put on the stretch and opened at an avascular portion. The stomach is drawn over to the right and the left gastro-epiploic artery is secured and divided between artery forceps. Proceeding from left to right, the gastro-colic omentum is further divided between artery forceps for a sufficient length to enable easy examination of the posterior wall of the stomach. The region of the pyloric antrum and pylorus is almost invariably slightly adherent to the serous covering of the pancreas and to the mesocolon, from which however it can usually be stripped readily with a sweep of dry gauze. The right gastro-epiploic artery is then clearly demonstrated and divided between forceps. We consider that unless the operation is proceeded with in this fashion ligation of the right gastro-epiploic artery is likely, on occasion, to endanger the middle colic artery or one of its

branches. The remainder of the gastro-colic omentum is similarly dealt with. At this stage all the divided vessels are ligatured. A feature of the operation, as described by Ogilvie, is the division and ligature of the vessels between the gastro-epiploic arch and the stomach. This I have given up, for these vessels are often so short that the ligature has to be tied almost on the main artery or so close to it as to introduce the possibility of converting the epiploic arch into a thrombosed cord. I have had, furthermore, an opportunity on two subsequent occasions of observing the omentum after the right and left gastro-epiploic vessels had been tied, and the conversion of the omentum into a fat-graft productive of adhesions, as predicted by Ogilvie, had not occurred. The vessels along the greater curvature having been divided the stomach is then drawn down and an opening is made in the gastro-hepatic omentum with the fingers. Of the leash of vessels which go to

Fig. 2.—The stomach has been turned up over the left margin of the abdominal wound and the aneurism needle (G) has been passed under the left gastric artery (A) close to its origin. The vessel is double ligatured at this site. The pyloric antrum has been doubly oversewn with 00 catgut.

supply the region of the pylorus and the first part of the duodenum one turns to the left, and it is secured near the point at which the stomach is to be divided. The Friedrich-Petz sewing machine is now applied and the stomach is divided with scissors between the double row of clips. The distal stump comprising the pyloric antrum is then doubly oversewn with 00 catgut.

The remainder of the stomach is then turned upwards and over the left margin of the wound so as to define the commencement of the left gastric artery, which has to be further

exposed by a little gauze dissection. When exposed it is underrun with an aneurism needle, double ligatured and divided (figure 2). This manoeuvre of high ligation of the left gastric artery, as pointed out by Ogilvie, greatly mobilizes the stomach and is considered essential for the better functioning of the proximal gastric stump. Before proceeding further with the resection numerous large vessels, which reach the stomach in the region of the cardia from the left gastric artery, require ligation at this stage. These vessels are particularly numerous on the posterior wall of the stomach. The site of proximal division of the stomach is then selected and marked by the application of Allis forceps. The line of division at the lesser curvature should be within  $1\frac{1}{2}$  inches of the cardia, and the line of division at the greater curvature should be above the site where the left gastro-epiploic artery reaches the stomach. The line of gastric section therefore lies almost at a right angle to the lesser curvature at the site of section. A long straight-bladed clamp is then applied to the stomach. I have had made for me a pair of clamps for application to the stomach and jejunum which hold lightly and do not crush. To avoid any possibility of the stomach receding out of the clamp a pair of Allis forceps are applied to the lesser and greater curvatures, respectively, just proximal to its site of application. The jejunum is then brought up so that the proximal loop joins the lesser curvature (figure 3). The jejunum is brought either through (retro-colic anastomosis) or in front of the mesocolon (ante-colic anastomosis) depending on the length of the mesocolon. In the latter case, a slightly longer loop is necessary. Considerable care must be taken in determining the length of the proximal loop and allowance must be made for the fact that once the anastomosis is complete and the stomach released it retracts back high up under the costal margin. The length of the loop which we find sufficient is that which reaches easily to the surface of the abdominal wound without any stretch whatever being applied to it. If the anastomosis is of the retro-colic variety the left leaf of the incised mesocolon is at this stage sutured to the under surface of the stomach proximal to the clamp. If the anastomosis is carried out with the proximal jejunal loop at the greater curvature (only two cases in the series) the length of loop required is somewhat less than that required for the more usual operation. The stoma is in all cases placed at the greater curvature and is always made sufficiently large to admit four fingers.

The seromuscular suture is commenced at the lesser curvature (figure 3) and is of the continuous Dupuytren type. When it reaches the greater curvature it is locked and held. The Petz clamp is applied and the stomach resected with scissors between the rows of clips. A sufficient number of clips is then

cut out to provide an adequate stoma, a few clips (in practice usually five) being left at the lesser curvature to form a spur. The jejunum is opened to a corresponding length. The hæmostatic layer is commenced at the greater curvature and is a simple running suture, six to the inch, and locked at every fourth stitch (figures 4 and 5). It turns at the lower end of the spur and is continued along the anterior wall of the stomach to end at the greater curvature where it is tied. In order to prevent undue pouthing of the gastric and jejunal mucosa, the stitch, which is passed from jejunal to gastric side, picks up a slightly lesser bite of jejunal and

If the anastomosis has been retro-colic the right leaf of the opening in the mesocolon is now affixed to the stomach with five or six interrupted catgut sutures. Figure 7 shows the completed ante-colic anastomosis.

I have used the Friedrich-Petz sewing machine for nearly all gastrectomy operations for over two years, and consider that it adds an element of safety to these operations. The suture line is absolutely water-tight. The machine, however, has to be used with discretion in cases of hypertrophied stomachs and, in my opinion, it is better not to use it at all in such cases. Such a state of affairs hardly exists in

Fig 3—The jejunum has been brought up with the proximal loop to the lesser curvature of the stomach. The clamps have been applied and the first seromuscular layer of sutures (M') commenced at the lesser curvature has been completed. The stomach is being cut away with scissors and the clips cut out at the site of the stoma. Five clips are left to form a spur at the lesser curvature. (In practice the stomach is cut away first and then the appropriate number of clips are cut out.) The jejunum has been opened.

gastric mucosa than it does of jejunal and gastric seromuscular coats

At this stage the clamp on the jejunum is removed. The seromuscular suture, which had commenced at the lesser curvature and was locked and held at the greater curvature, is then brought along the anterior surface of the stomach and jejunum and ends at the lesser curvature. The remaining clips forming the gastric spur are enfolded by jejunum only and are not oversewn separately and buried in the gastric wall (figure 6). 40-day catgut (00) is used for the seromuscular and 20-day catgut (00) for the hæmostatic layer of sutures.

the type of duodenal ulcer for which we perform gastrectomy, but it does sometimes exist in cases of gastro-jejunal ulcer, and also in stomachs at the site of a gastric ulcer situated close to the pylorus. In these instances, of course, an ulcer-exclusion type of gastrectomy would not always be done.

*Post-operative technique.*—The patient on return to the ward is given immediately 4 ounces of glucose water by mouth, one pint of coffee rectally, and after this continuous rectal saline is commenced and maintained for 48 hours. The Fowler position is adopted after 4 hours.

Fig. 4.—The layer of hæmostatic sutures has been commenced at the greater curvature.

Fig. 5.—The hæmostatic layer is returning to the greater curvature where it will be tied. It is a simple over and over suture locked at every fourth stitch.

Food by mouth is given in accordance with the following scheme :—

- 1st day .. If the patient is very thirsty, one ounce of hot glucose water is given occasionally throughout the day in addition to the above.
- 2nd day .. One ounce glucose water by mouth every two hours. Continuous drip rectal saline is continued throughout the day.

Fig. 6.—The anterior seromuscular layer of sutures (M') is nearing completion and the spur is being oversewn and buried in jejunal wall. The suture on completion is tied at the lesser curvature. In practice the stomach is not released from the clamp (not shown in the diagram) until the layer of sutures is nearing its completion.

- 3rd day .. Albumin water sweetened with glucose is given, two ounces every three hours. Rectal saline is occasionally continued as on first and second days.
- 4th day .. Whey and albumin water sweetened with glucose, two ounces every two hours.
- 5th day .. Citrated milk diluted with equal parts of water, four ounces every three hours.
- 6th day .. Whole citrated milk, four ounces every four hours. Strained orange juice.
- 7th day .. Milk (with coffee to flavour), six ounces every four hours. Strained orange juice if desired.
- 8th day .. Whole milk, six ounces every four hours, with egg-flips. Strained orange juice if desired.
- 9th day .. As above, plus two biscuits and three ounces of bread.
- 10th day .. Add eight biscuits.
- 11th day .. Eight ounces of bread given.
- 12th to 14th day. Convalescent milk and bread diet plus extras such as ten ounces of mutton broth, six ounces of rice in buttermilk, two eggs, cod-liver oil twice or thrice daily.
- 15th to 17th day. Rice eight ounces, and vegetable curry four ounces for the day. Patient is allowed out of bed on the 15th day.
- 18th and 19th day. Ordinary Indian diet.
- 20th day .. Patient discharged from hospital.

The pulse rate is closely watched throughout the first 48 hours and any sudden increase of 10 beats or more per minute, especially if accompanied by profuse sweating, is taken as an indication for the immediate passage of a duodenal tube (Ryle's, Jutte's or Wagensteen's). This is only occasionally necessary and the tube is not passed as a routine. Once passed, however, it is left in for 48 hours and connected to a Cathcart drip apparatus. Reference has previously been made to the state of the mouths of these patients, and to overcome the very real danger of post-operative parotitis a slice of lime is given to the patient to suck every 3 hours, and both parotid glands are gently massaged by the nurse in charge every 4 hours. Frequent mouth washes of dilute potassium permanganate solution are given throughout the convalescence. Since adopting this regime acute post-operative parotitis has not occurred. Each patient wears a pneumonia jacket and is turned frequently from side to side throughout the first few days of the convalescence. If broncho-pneumonia develops, an expectorant mixture containing ammonium carbonate is

Fig. 7.—The operation has been completed. The stomach when released from the clamp passes high up and to the left under the costal margin. The proximal jejunal loop is diagrammatic in all the drawings. In practice it is shorter and passes more directly upwards and to the left.

given every 4 hours, and at the same time injections of vitamin C are given in large doses twice daily. This has proved a particularly valuable remedy in the treatment of post-operative pneumonia.

# RESULTS.

*Immediate results.*—170 cases of duodenal ulcer have been subjected to this operation. There have been 10 deaths giving a mortality rate of 5.9 per cent.

Causation of death	Number of cases
Hyperpyrexia .. .. .	3
Spinal anaesthesia .. .. .	1
Post-operative tetanus .. .. .	1
Hæmatemesis .. .. .	1
Broncho-pneumonia .. .. .	4

Hyperpyrexia occurred in 3 cases operated on during very hot weather, and is to be avoided by refraining from the performance of such operations during the period of the year when the temperature is highest.

The death which we attribute to the spinal anaesthetic followed a comparatively easy operation. The pulse rate on return to the ward was 80 per minute and of good volume. After an hour it began to rise steadily and continued increasing until the evening, when death occurred. The patient was quiet, was not sweating and remained conscious until the end. There were none of the usual signs of shock or internal hæmorrhage. It was not possible to examine the heart and lungs after death, but the abdomen was opened and the field of operation was found to be normal. This death is attributed to the anaesthetic in the absence of any other obvious reason, because an exactly similar death had occurred after another operation, and because several cases during the same period had developed similar symptoms but had fortunately recovered.

The death due to post-operative tetanus occurred in a patient operated on 16 days before, whose convalescence had otherwise been quiet and uneventful. Extensive investigation failed to reveal the source of infection.

The mortality rate of 5.9 per cent in this series of cases is admittedly high, but causes of death such as hyperpyrexia, anaesthesia and tetanus might be regarded as regrettable accidents and to be avoided in a further series.

The convalescence is usually uneventful, and not only has there been an actual gain in weight but the anaemia also has improved in all the cases operated on. It is this improvement in anaemia that leads me to believe that the anaemia, from which the patients nearly always suffer on admission, is nutritional and the result of long-standing gastritis. The operation is tolerated well by patients of all ages, the oldest in the series being just under 80 years of age and the youngest 18 years.

*Late results.*—It is not easy to determine with accuracy the later results. All cases are invited to return to hospital for re-examination after 3 months and at later intervals. Many avail themselves of this invitation and have appeared well, with a few rare exceptions. We have not been able to see all the cases operated on but have sometimes been able to trace patients by adopting the practice of questioning every new patient admitted to hospital for chronic peptic ulcer, as to whether there are any other cases in his village treated by us for a similar complaint. It is surprising how much we are able to learn in this fashion about our old cases. One case has returned with gastro-jejunal ulceration and three cases, all of whom were found to be suffering from heavy hook-worm infection, have returned on account of severe secondary anaemia. We are satisfied

## REPORT OF PNEUMONIA ENQUIRY AT THE MAYO HOSPITAL, LAHORE, DURING THE YEARS 1938, 1939 AND 1940

By GEOFFREY F. TAYLOR, M.A., M.R.C.P. (Lond.)  
MAJOR, I.M.S.

Professor of Clinical Medicine, King Edward Medical College, Lahore

and

NAND LAL CHITKARA, M.B., B.S.

IN 1938, the Punjab Government gave a grant for the investigation of pneumonia in the Mayo Hospital, Lahore. The grant was exhausted by the end of March 1940, and this report gives the results obtained.

Earlier reports of results at the Mayo Hospital by Chand *et al.* (1939) and Taylor and Chitkara (1939) have been published and a further paper on 'Pneumococcal Lung Abscess' has been submitted recently to the *Lancet* for publication.

The work done includes typing of the pneumococci obtained from pneumonia cases, clinical investigation, treatment by new drugs, particularly M. & B. '693' ('Dagenan') and Felton's concentrated anti-pneumococcal sera, and investigation of other pneumococcal infections associated with pneumonia, particularly pneumococcal meningitis, empyema, lung abscess and pericarditis.

The cases recorded are the usual type of admissions to the Mayo Hospital, Lahore, mainly Indian, Punjabi Muslims, Hindus and

(Continued from previous column)

that in Indian patients at any rate, the operation is not productive of a high rate of gastro-jejunal ulceration and that it is preferable to a gastro-enterostomy, in the absence of stenosis. We have observed also that the operation in no way lessens the ability of the patient to earn his living by hard manual labour if necessary and that it permits him to enjoy his usual diet in comfort.

My thanks are due to my assistant Dr. C. S. S. Sarma for the very great help he has given me in the preparation of this paper, and to Miss Patricia Cornwell for her excellent semi-diagrammatic drawings. I have also to thank Major-General N. M. Wilson, C.I.E., O.B.E., K.H.S., I.M.S., Surgeon-General with the Government of Madras, for permission to publish the paper.

Sikhs, with a few Europeans and Anglo-Indians. They are mainly of the poorer classes admitted to the general wards of the hospital.

Seventeen cases were admitted to the hospital in a moribund condition during the period and died within twenty-four hours from the time of admission, usually within a few hours. These cases are not included in this report.

### I. Typing of pneumococci

Two methods were used, Neufeld's 'Quellung' method and agglutination by type sera. The typing sera used for Neufeld's methods were obtained from Parke, Davis & Co., using

thirty different type sera and six mixtures. The technique employed was that described in Parke Davis's pamphlet with a slight modification which will be reported later. Thirty different types of sera for the agglutination method were kindly sent to us by the Public Health Department of New York, free of charge. As far as possible both methods were used in each case.

A full report of the work done on typing is being prepared and will be published later.

The following is a summary of the results of typing pneumococci from pneumonia cases :—

Total cases typed—196.

TABLE I

Type																Mixed	Mixed	Mixed	Indeterminate type

1937 ..	25	16	8	13	12	17	8	7	10	16	30	32
1938 ..	29	20	22	16	30	10	14	6	8	12	33	44
1939 ..	40	38	13	17	23	22	12	3	3	11	12	30

It is seen that type 1 pneumococci are responsible for 37.7 per cent of the total cases.

*Note.*—(1) In the cases shown as 'mixed type', pneumococci of two different types were obtained from a single case indicating infection with two different types of pneumococci.

(2) In the 'indeterminate types' no definite agglutination was found using the sera and no 'Quellung Reaction' occurred. The inability to type about 20 per cent of pneumococci from pneumonia cases by Neufeld's method has been noted by other workers elsewhere. In this work at Lahore it was found also that approximately 20 per cent of cases could not be typed by the agglutination method.

(3) Twenty cases showed positive agglutination results with type sera, but showed no 'Quellung Reaction' using Neufeld's method.

No typing was done during the months of November and December 1938, as the necessary sera were not available.

The small number of cases of type 1 pneumococci in January and February 1940 is striking when compared with the same months of 1939.

Further work is needed for a number of years to determine the changes in the types of pneumococci occurring during different years and different months of the same year. Unfortunately no funds are now available to do this.

## II. Some details of interest noted in the clinical manifestations of the cases during this period

Out of 305 cases of pneumonia admitted during the period 1938-40, only nine cases showed an insidious onset. The remainder had an acute onset.

The diagnosis of pneumonia was made either by the physical signs of frank consolidation, or when the physical signs were not definite, by x-ray confirmation of consolidation. Mild cases of 'pneumonitis' were excluded from this series.

The highest incidence of pneumonia is thus between eleven and thirty years of age, between which ages 65 per cent of the cases occurred.

The high incidence during the winter months of November to February is probably due to the low temperature which often touches freezing

point. The cause of the rise of the incidence in May and June is not so obvious as these are the hot dry months with the maximum temperature up to about 110°F.

Twenty-one of the 305 cases which form the material for this report had broncho-pneumonia, the remaining cases being of the lobar type.

TABLE V  
*The lobes involved and their number*

Mono-lobular	Poly-lobular	LEFT LUNG		RIGHT LUNG		
		L. L. lobe	L. U. lobe	R. L. lobe	R. M. lobe	R. U. lobe
139	145	159	53	167	67	51

The lower lobes were more commonly involved, the right lower lobe slightly more frequently than the left.

TABLE VI  
*The leucocyte count on admission, and details of the differential count*

	0-5,000	5-10,000	10-20,000	20-30,000	30-40,000
Number of cases.	11	66	148	54	5

Polymorphonuclear count

	0-60%	61-70%	71-80%	81-90%	91-100%
Number of cases.	7	16	70	130	45

The majority of the cases showed a leucocyte count between 10,000 to 12,000 per c.mm.

Enough data are not available to come to any definite conclusion, but as far as they go the types of pneumococci appear to bear no relation to the age of the patient.

There appears to be no relationship between the type of pneumococci and the site or extent of the pneumonia.

TABLE VII

Number of cases of each type of pneumococci isolated from different age groups

Age in years	Type												Mixed	Mixed	Indeterminate group
	1	2	3	6	7	8	10	11	12	13	15	20	1 and 2	7 and 9

TABLE X

Types of pneumococci and percentage of polymorphonuclears in the blood count

Percentage of polymorph.	Type												Mixed	Mixed	Indeterminate group
	1	2	3	6	7	8	10	11	12	13	15	20	1 and 2	7 and 9	
0-60	..	..	..	..	..	..	..	..	1	..	..	..	1	..	..
61-70	1	..	..	..	..	..	..	..	..	..	..	..	..	..	2
71-80	28	2	1	..	4	2	..	..	1	1	1	1	..	..	11
81-90	38	8	2	1	5	3	1	..	1	..	..	..	1	1	21
91-100	6	1	1	..	..	2	..	1	..	1	..	..	1	..	4

TABLE XI

*The types of pneumococci isolated and naked-eye appearances of sputum of the cases*

Character of sputum	Type												Mixed	Mixed	Indeterminate group
	1	2	3	6	7	8	10	11	12	13	15	20	1 and 2	7 and 9	
Rusty ..	42	6	2	2	7	5	..	1	2	1	1	..	3	..	10
Tenacious	18	3	1	..	2	1	..	..	..	1	..	..	..	..	18
Mucoid ..	13	4	1	..	3	..	..	..	..	..	..	..	..	1	17
Viscid .	15	..	2	1	6	..	..	..	1	..	..	..	3	1	6
Frank blood	1	1	..	..	..	1	1	..	1	..	..	1	..	..	..
Frothy ..	2	..	..	..	..	..	..	..	..	..	..	..	..	..	..

Again the above two tables do not show any obvious relationship of the type of pneumococci to the height of the leucocyte count or to the extent of polymorphonuclear leucocytosis.

Rusty sputum is most commonly found in type 1, but other than this, there appears to be no relation between the type of pneumococci isolated and the character of the sputum.

It appears from the above data that the type of pneumococci isolated from a case of pneumonia bears no relation to the age of the patient, to the number of lobes involved or character of the sputum.

The data shown in the following tables were collected from cases dying of pneumonia :—

TABLE XII

*Leucocyte counts on admission to hospital*

	0-5,000	5-10,000	10-20,000	20-30,000	30-40,000
Number of cases.	1	7	11	5	2

TABLE XIII

*Polymorphonuclear percentage in differential count on admission*

	61-70	71-80	81-90	91-100
Number of cases.	3	10	7	6

From the figures given above, it is concluded that leucopænia and a low percentage of polymorphonuclear leucocytes did not occur commonly in cases of pneumonia which died. Text-books state that a low white cell count is of bad prognosis. Our figures do not bear this out, as they do not differ markedly from those obtained in cases which lived.

It was noted that thirty-seven cases admitted for pneumonia had had a previous attack of pneumonia.

### III. Methods of treatment of pneumonia cases

During this period 305 cases of pneumonia were admitted into the Mayo Hospital, Lahore. The first 100 cases admitted during the autumn and winter of 1938-39 were treated alternately by the older methods, for control purposes, and by M. & B. '693'. The results were reported by Chand *et al.* (1939). By the time these first hundred cases had been treated it was obvious from reports from all parts of the world, and from our own results, that M. & B. '693' greatly reduced the mortality of pneumonia. It was thus decided to treat all cases of pneumonia in the hospital by this drug. Parke, Davis & Co. kindly supplied us with Felton's concentrated serum at half the usual price in order to enable us to treat some cases with M. & B. '693' combined with Felton's serum.

TABLE XV

The mortality of cases treated in the three ways

	Number of cases	Mortality
(1) Control cases treated by older methods other than M. & B. '693' and Felton's serum.	76	14 or 17.4 per cent
(2) Cases treated by M. & B. '693'.	200	12 or 6 "
(3) Cases treated by M. & B. '693' combined with Felton's concentrated anti-pneumococcal serum.	29	Nil

The cases treated by M. & B. '693' and Felton's serum were twenty-seven of type 1 pneumococci and two of type 2.

The dose of M. & B. '693' used was that described by Gainsford and Evans which is four tablets (2 gm.) on admission, four tablets after four hours and then two tablets four hourly for thirty-six hours, followed by one tablet four hourly for a further thirty-six hours. After treating the first fifty cases we decided that the treatment for the first thirty-six hours was sufficient and we stopped giving the one tablet four hourly for the second thirty-six hours. The concentration of M. & B. '693' in the blood after 24 hours' administration of the drug was 2.5 to 6 mgm. per 100 c.c. of blood.

#### Cases treated by M. & B. '693' alone

The temperature fell to normal within twenty-four hours in 140 cases, and within forty-eight

hours in twenty-seven cases. The consolidation remained for several days after the fall of temperature and resolved only slightly more rapidly than cases not treated by the drug. Many cases continued to cough up blood-stained sputum for several days after the fall of temperature. These aspects of the results of M. & B. '693' treatment are now well recognized and described in the literature on the subject.

The average stay in hospital of M. & B. '693' treated cases was three to four days shorter than the cases treated by older methods.

*Note.*—One hundred and six cases treated by M. & B. '693' were not typed, as the necessary sera were not available during part of the time.

TABLE XVII

The age of cases treated by M. & B. '693' and the mortality in each age group

Age	Total cases	Mortality
0-5	19	..
6-10	9	..
11-20	56	1
21-30	70	4
31-40	29	6
41-50	12	1
51-60	4	..
61-70	1	..
TOTAL ..	200	12

The dose given up to one year of age was one-fourth of the adult dose, namely, one tablet on admission, one tablet after four hours and thereafter half a tablet four hourly for thirty-six hours.

TABLE XVI

The number of each type treated by M. & B. '693' and the mortality in each type

Type	Total number of cases	Mortality	Age groups					
			0-10	11-20	21-30	31-40	41-50	51-60

Indeterminate	35	2	2	17	9	6	1	..
TOTAL ..	94	4	2	33	35	15	6	3

The dose over one year of age up to ten years of age was usually half the adult dosage.

Children tolerated M. & B. '693' well and vomiting occurred in only one case in the age group 0-10, in which twenty-eight children were treated.

It is also remarkable that no death occurred in children up to the age of ten who have been treated by M. & B. '693' during the period of this investigation. Twelve of these children had broncho-pneumonia and the remaining eighteen had lobar pneumonia. Mortality figures of pneumonia in children of the Punjab are not available, but in our experience it was high before the introduction of this new drug.

#### IV. *Complication in cases treated by M. & B. '693'*

The following complications were noted in the M. & B. '693' treated cases :—

1. *Vomiting*.—This occurred in fifty-two cases of the two hundred treated by M. & B. '693'. The drug had to be discontinued because of vomiting in nine cases. In the remaining cases the drug was continued in spite of the vomiting. We tried giving sodium bicarbonate, bismuth carbonate, luminal, and glucose with the M. & B. '693' when vomiting occurred, but these drugs appeared to have no influence on the vomiting and no influence on the pneumonia. In most of the cases, vomiting passed off after the first few doses had been given and it appears that the vomiting will stop in most cases, if the drug is continued.

It has been stated that vomiting resulting from M. & B. '693' is due to the action of the drug on the central nervous system. We found that the vomiting stopped when we substituted injections for oral M. & B. '693', and we consider, therefore, that it is due to the local action of M. & B. '693' on the gastro-intestinal tract. Although the vomiting is extremely unpleasant for the patient it seems to have no deleterious influence on the course of the disease.

2. *Leucopenia*.—White cell counts were done in all cases at frequent intervals. In three cases of pneumonia treated by M. & B. '693', a sharp fall in the leucocytes developed but there were no adverse clinical signs. The patients made uninterrupted recoveries. The original counts were 25,000, 25,000, 20,625 and they fell to 6,000, 6,875, and 6,240. Severe agranulocytosis developed in one case of empyema treated with M. & B. '693'.

3. *Unresolved pneumonia*.—This occurred in four of the M. & B. '693' treated cases, which is not higher than its incidence in cases treated by the other methods.

4. *Empyema*.—This occurred in four of our M. & B. '693' treated cases. This incidence of 2 per cent is not higher than the normal incidence of empyema in cases treated in other ways. When M. & B. '693' was first introduced Gainsford and Evans thought that empyema

developed more frequently in cases treated by M. & B. '693' but after treating a larger number they and others have concluded that the incidence of empyema is not increased in pneumonias treated by M. & B. '693'.

5. *Meningitis*.—Pneumococcal meningitis developed in three of our two hundred treated cases.

6. *Hæmaturia*.—Hæmaturia developed in four cases. Hæmaturia and stone formation have been reported from America as a result of M. & B. '693' treatment. Two cases in American literature showed actual stone formation in the kidney, the stone consisting of M. & B. '693'. In three of our cases there was severe hæmaturia. The fourth case showed red blood cells on microscopic examination. The hæmaturia stopped two or three days after stopping the drug. In one of the cases after a rest of one week, as the temperature was maintained, a second course of M. & B. '693' was given, and it again resulted in a severe hæmaturia. Two of the cases were examined radiologically but showed no signs of stone in the kidney. The American report says that M. & B. '693' stones are not opaque to x-ray. As a result of this experience, it is a safe rule to make that the urine should be examined microscopically daily for red blood cells.

7. *Malaria*.—The spleen was enlarged and hard in eighteen cases, probably from chronic malaria. Two of these cases failed to respond in the ordinary way, the temperature remaining high for two or three days longer than the ordinary period of twenty-four or forty-eight hours. Quinine by the mouth and by injections intramuscularly was given with M. & B. '693'. There appears to be no contra-indication to giving quinine and M. & B. '693' together, when indicated.

8. *Epistaxis*.—Epistaxis was noted in two cases. In one case the epistaxis stopped when the drug was stopped and began again when the drug was given again.

9. *Cyanosis*.—Cyanosis developed in two cases.

#### V. *Cases not responding in the ordinary way to M. & B. '693'*

In addition to the twelve deaths in our M. & B. '693' group, a further twenty-one cases did not respond in the usual way by a fall of the temperature in twenty-four or forty-eight hours. We have also tried to analyse the cause of the deaths but there appears to be no obvious common factor. Nineteen of the twenty-one cases which did not respond to the treatment, completely recovered in the hospital, while two were discharged at their own request with signs of unresolved pneumonia and a continuous high temperature. No tubercle bacilli were discovered in the sputum of these cases although we suspected that one, or possibly two cases, were suffering from active tuberculosis. Two

further cases showed signs of unresolved pneumonia and two others a 'creeping type of pneumonia'. The spleen was enlarged in three of these cases. Acute pericarditis, acute toxic delusional insanity and hæmaturia were noted in other cases of this group. Poverty and anæmia were not marked factors in causing a lack of response to treatment.

Of these twenty-one cases sixteen began treatment five or more days after the pneumonia had developed, when complications were possibly beginning. It appears that treatment of pneumonia with full doses of M. & B. '693' in the first two or three days of the disease is important.

In a further twenty-five cases there was a secondary rise in temperature occurring a few days after it had fallen to normal as a result of the first treatment. This secondary rise was treated by a further course of M. & B. '693' which led to a rapid fall of the temperature to normal in all but five cases. In five cases, vomiting prevented full doses of the drug being given. Two of these cases had an anæmia due to ankylostomiasis. The blood counts were 3,500,000 and 3,000,000 and hæmoglobin 60 per cent and 55 per cent (Sahli). One case developed severe bilateral parotitis but eventually recovered. Four cases had enlarged spleens due to chronic malaria.

#### VI. Cases treated by M. & B. '693' combined with Felton's serum

There is experimental evidence in animals that M. & B. '693' combined with anti-pneumococcal concentrated serum is superior to M. & B. '693' alone in the treatment of experimental pneumococcal infections, if the serum is given early in the disease.

In the Mayo Hospital in 1939 and 1940, twenty-nine cases of type 1 and type 2 pneumonia have been treated with combined M. & B. '693' and Felton's concentrated anti-pneumococcal serum. All twenty-nine cases recovered with no severe complications. Twenty-seven cases belong to type 1, and two cases to type 2.

The dosage of M. & B. '693' was the routine one. On admission the pneumococci were typed by Neufeld's method and as soon as either type 1 or 2 were found, the case was tested for sensitivity to the serum by the skin reaction described in Parke Davis's pamphlet consisting of the injection intradermally of 1/10 c.cm., of anti-pneumococci serum which had been diluted 1 in 10 with distilled water. If the sensitivity test was negative, as it was in twenty-four cases, 40,000 units of Felton's concentrated serum were given intravenously at once, the dose being repeated after four hours and a final 20,000 units being given after a further four hours.

Five cases were sensitive to Felton's serum, as shown by a weal and erythema developing at the site of the intradermal injection. These cases were desensitized by giving 1/10 c.cm. Felton's serum, intramuscularly as the initial

dose, and then at intervals of two minutes doses equal to double the preceding dose until the total initial dose of 40,000 units of serum had been given.

Four cases which were not sensitive to the skin serum test developed anaphylactic shock almost immediately after giving the serum, as shown by respiratory embarrassment and erythematous and urticarial skin rashes. Adrenalin was immediately given in these cases and the reaction subsided within one-half to two hours, without any serious consequences.

One case, which had been found to be sensitive to the skin test, was desensitized but developed severe anaphylactic symptoms when he was given the second dose of 40,000 units intravenously four hours after the first dose. He responded quickly to adrenalin.

Obviously, enough cases have not been treated by this method to give evidence of statistical significance, but twenty-nine cases of pneumonia treated with no deaths indicate that this method deserves further trial.

The difficulties in treating cases by this method are that the pneumococci must be typed as early in the disease as possible, and serum given before the fourth or fifth day of the disease. Given later, it is probably of little use. Also the serum is expensive.

Five cases treated with one batch of serum developed marked restlessness, sweating and a slight rise of temperature a few minutes after the first injection was given, this subsided in about half an hour. These symptoms were not noted in the other cases. They appear to have been due to some special effect of that batch of serum. It has been noted by many workers with other sera that different batches give different reactions.

Clinically these twenty-nine cases treated by the combined serum and M. & B. '693' did not differ from cases treated by M. & B. '693' alone, in the rapid fall of the temperature, or in any other features, except for the anaphylactic phenomena noted above.

#### VII. Other pneumococcal infections

1. *Pneumococcal empyema*.—During this period ten cases of pneumococcal empyema were treated in the medical wards. Early in 1939, treatment by M. & B. '693' combined with repeated aspiration of pus from the empyema cavity was tried in an effort to avoid rib resection. Three cases of early pneumococcal empyema were cured in this way. The pus in two of them was not thick and only semi-purulent. Aspiration was needed only once and twice respectively. The third case had thick pus in the chest and aspiration was done fifteen times. A total dose of 85.5 gm. of M. & B. '693' in thirty days was given. Skiagrams of the chest on discharge from the hospital showed a little thickening of the pleura but otherwise normal. We tried this treatment on five other cases in which the pus was already thick, and

continued it for a period up to five weeks. They did not respond so that rib resection was eventually done. In one of these cases agranulocytosis and exfoliative dermatitis developed and the patient died. Fuller details of these cases are given by Taylor and Chitkara (1939).

The conclusion drawn from this limited experience is that when the pus is thin, aspiration combined with treatment by M. & B. '693' is indicated, but when the pus is thick and loculated, prolonged treatment with M. & B. '693' combined with aspiration does not clear the empyema. Operation should be done as soon as the pus is thick and loculated.

There are reports of several cases of severe agranulocytosis in the literature, but this case of exfoliative dermatitis as the result of M. & B. '693' appears to be the second recorded. The first case was reported by Taylor and Chitkara (1939).

2. *Pneumococcal meningitis*.—During this period nineteen cases of pneumococcal meningitis were treated in the medical wards by M. & B. '693' and daily lumbar punctures. Fuller details of seventeen of these cases have been given by the same authors. There are now many reports of recovery from pneumococcal meningitis by this treatment. The mortality in the whole group of cases is thus approximately 85 per cent. Before M. & B. '693' was introduced, these cases invariably ended fatally.

In three cases in whom type 1 pneumococci were isolated from the cerebro-spinal fluid, Felton's concentrated serum was given in addition to the above treatment, but all three cases died.

3. *Lung abscess*.—During this period seven cases of lung abscess were treated by M. & B. '693'. Fuller details of these will be published later. Three of these cases improved dramatically with M. & B. '693' treatment and completely recovered. Two of the cases died and the two remaining cases could not tolerate the drug by the mouth and left the hospital unrelieved of the symptoms and with the signs of lung abscess persisting. Two of the cases which recovered were given M. & B. '693' injections as they could not tolerate the drug by the mouth.

4. *Pneumococcal pericarditis*.—Three cases have been treated. Two of them had large pneumococcal pericardial effusions and one was a case of dry pericarditis. The two cases of effusion are at present in the wards being treated by aspiration of the pericardial sac and short courses of M. & B. '693', repeated at fairly short intervals. The case of dry pericarditis recovered completely and the other two cases are recovering with treatment.

We wish to thank Lieut.-Colonel Amir Chand, I.M.S., Professor of Medicine, Rai Bahadur Dr. Jivan Lal, Professor of Pathology, and Dr. Mohammad Yusuf of the Medical College, Lahore, for their help. Also Parke, Davis & Co.

(Continued at foot of next column)

## A NEW METHOD FOR THE RELIEF OF PARALYSIS OF THE OPPONENS POLICIS

By MAX SCHECK, M.D. (Austria)  
Resident Surgeon, P. B. M. M. Hospital, Bikaner

ANALYSING the movements of the fingers which make the hand the useful instrument it is, one comes to the conclusion that holding of tools, instruments, etc., is possible by bending the four fingers around the tool, whereas the grasp between the thumb and the fingers is used for all more subtle movements. These finger movements make the hand more valuable and in many cases are the means by which one earns one's livelihood (violinist, artist, skilled workman). The importance laid on the thumb and its opposing power can be estimated from the social laws of countries with workers' compensation. Whereas the loss of one of the fingers counted as below the compensation rate (I refer to the old Austrian law) the loss of the thumb or its opposing function counted as a loss of 20 per cent of earning capacities. This refers to the skilled workmen. It means much more to the musician, the surgeon or the painter.

To make it possible for the disabled hand to return to the usual functions, surgical methods have been devised. All of them have as underlying principle some sort of tendon

(Continued from previous column)

for giving Felton's anti-pneumococcal serum at half the usual price, May & Baker's representatives for giving some of the M. & B. '693' free and Mrs. Bharucha for buying some of the M. & B. '693' used.

### Summary

(1) Results of typing of pneumococci from pneumonia cases at the Mayo Hospital, Lahore, from 1938 to 1940 are given.

(2) Some details of interest in the clinical findings of the cases, particularly in relation to types, are given.

(3) Results are given of treating 200 cases with M. & B. '693'; some combined with Felton's concentrated anti-pneumococcal serum, with no deaths.

(4) Twenty-eight children with pneumonia were treated and all recovered.

(5) Complications of the treatment are discussed.

(6) Results of treatment of cases of pneumococcal empyema, meningitis, lung abscess and pericarditis are given.

transplantation. Before doing such an operation two questions have to be answered—

(1) Which muscles and tendons of this region are still working?

(2) Will the elimination of the transplanted tendon not lead to disturbance of the functional equilibrium?

The extent to which muscles and tendons are paralysed depends upon the nature and localization of the original disease. Isolated paralysis of the opponens muscle occurs when the small branch coming from the median nerve and emerging from under the volar ligament of the carpus is cut. This may happen when opening a radial bursa for pyogenic infection.

Extensive paralysis of a group of muscles, including the opponens muscle, will be found in lesions to the median nerve. The muscles innervated by the median nerve are divided in two groups, the proximal and the distal group. According to the level where the nerve has been affected, both the groups are involved or only the distal group. The proximal group comprises pronator radii teres, flexor sublimis digitorum, flexor carpi radialis, palmaris longus, flexor profundus digitorum (the radial half), flexor longus pollicis and pronator quadratus muscles. The distal group comprises the abductor pollicis longus, the opponens pollicis, the two outer lumbricales, and flexor pollicis brevis muscle.

Injuries to the nerve in the region of the elbow (fractures, stab wounds, shots) will involve both groups of muscles. In this case only tendons of muscles innervated by the ulnar nerve can be used for transplantation. A modification of Ney's method is to connect the tendon of the extensor pollicis brevis with one part of the split flexor carpi ulnaris tendon. Lexer proposed to use the abductor of the little finger. After separation from the first phalanx of the little finger the tendon is drawn through a subcutaneous canal in the palm and connected with the opponens pollicis.

If an injury to the nerve occurs distal to the departure of the branches for the proximal group only the muscles of the distal group will be paralysed. In this case muscles and tendons can be used belonging to the proximal group. Ney divides the tendon of the extensor pollicis brevis at the level of the wrist joint after exposure by a dorso-lateral incision extending from the wrist joint to the insertion on the first phalanx of the thumb. A second incision is made on the anterior aspect of the wrist and the tendon of the palmaris longus muscle is exposed. The distal ends of both incisions are then connected by a subcutaneous canal. Through this the tendon of the extensor pollicis brevis is drawn and connected with the palmaris longus tendon. Baeyer fixed the tendon of the flexor longus pollicis muscle to the dorsal side of the thumb after having made an S-shaped incision. The tendon is not divided at the place of insertion.

In these cases of injury to the nerve with a well-defined clinical symptomatology and definite loss of function the task of finding a functional substitute is less difficult than in cases where not only a partial or total paralysis of the nerve is encountered but where also the muscles are directly affected and the ulnar nerve is involved. Such conditions are frequently seen in Volkmann's ischæmic contracture, in cases of extensive burns with scar formation or after cellulitis of the forearm. Here a large number of muscles have lost their function and the difficult task of finding a functioning tendon for transplantation, which in the new function will be of more value than in the old one, is put before the surgeon. It is the object of this paper to describe a new method which was used in a case.

In October 1938 a boy was admitted to the P. B. M. M. Hospital, Bikaner. He gave the history of having had a fall from a tree about ten months back. This resulted in a compound fracture of the humerus above the elbow-joint which was reduced and treated by a layman. The wound discharged pus for a long time and ultimately healed. He could not use his hand and came to this hospital. He was operated upon, but since there was no improvement, he was admitted again. On examination an extensive scar in the region of the right elbow was found, also a linear scar in the course of the musculospiral nerve, from the above-mentioned operation. (An end to end suture of the radial nerve was attempted for radial palsy.)

There was considerable wasting of muscles of the forearm. The wrist joint was in a flexed position which could be increased actively and passively. Extension of the wrist and fingers was actively impossible. Flexion of the fingers could be slightly increased by his own muscular action. He could flex the second phalanx of the thumb but it was impossible to oppose it. There was sensory loss typical of paralysis of the median nerve.

*Diagnosis.*—Radial palsy, with paralysis of the distal group of muscles innervated by the median nerve.

The radial palsy was most probably a direct consequence of the injury whereas the lesion of the distal part of the median nerve originated in the resulting suppurative and scar formation. An operation on the radial nerve did not seem worth while, as the suture of it had proved unsuccessful. An exploration of the median nerve was not considered advisable since it is very rare for an operation on the nerve in the region of the forearm to give a good result. Our plan was to reconstruct the opponens function and then to use the flexor carpi ulnaris and radialis muscles for transplantation to the fingers and the thumb respectively. To use the flexor longus pollicis muscle was the idea of the first part of the operation.

On 13th October, 1938, the operation was done under general anaesthesia. Through a vertical incision in the middle of the volar aspect of the thumb extending from the metacarpo-phalangeal joint to the base of the second phalanx the flexor longus pollicis tendon was exposed. It was then divided at its insertion on the second phalanx. The base of the first phalanx was exposed subperiosteally and a hole drilled through it in a dorso-volar direction. The tendon was threaded through and the end stitched to the proximal part by means of silk sutures, after having brought the thumb into the opposed position. A supporting plaster splint was kept on for two weeks. The wound healed by first intention.

Two weeks after operation the boy was encouraged to active movements. Within a week he could bring the tips of thumb, index and middle fingers together. In March 1939 he was re-examined. He could oppose the thumb to the fingers. There was considerable

## AUTOMATIC FLYPROOF LATRINE SEAT

By B. S. DHONDY

LIEUTENANT-COLONEL, I.M.S.

*Indian Military Hospital, Lucknow*

BEFORE I come to the actual description of the automatic flyproof latrine seat, a few points about fly-breeding will not be out of place. These points actually drew my attention to the necessity for an automatic device which I think is essential in dealing with the problem. There is a general belief that fly-breeding occurs mainly in manure and rubbish heaps, and consequently efforts are made to stop breeding in such materials rather than in human excreta, which, I consider, is a profuse breeder. This, I have repeatedly demonstrated as follows:—

I take three ordinary jam jars, and fill them up one-third with loose earth. On top of the earth is spread a layer about half an inch thick of human excreta in the first, animal droppings in the second and rubbish in the third. One dozen flies are placed in each of the jars and covered with nettings.

Factors such as the sex of flies, their age and period of fertility were ignored.

The flies are allowed to remain in the jars for twenty-four hours.

The jars are covered again with the netting, and left until the flies have hatched out. The time taken in hatching will depend upon temperature, humidity, etc. It is always observed that the jar containing human faeces contains innumerable flies. In the jar containing animal droppings there are fewer flies, whereas in the jar containing rubbish the number of flies can be easily counted. This experiment may be tried in different seasons but the results are invariably the same. It may be noted that maggots appear faster and in greater profusion if there is ample moisture and food for them in the medium.

The prevalent idea about fly-breeding in manure and rubbish heaps, etc., may be true in cold climates, and in countries better managed from the point of view of sanitation. In these places human excreta is seldom left lying about and, in any case, the climatic conditions are not so conducive to fly-breeding at such a rapid pace. In a tropical country like India, however, human excreta from the time it is voided to its

final disposal affords an admirable medium for fly-breeding, if left exposed.

Experience shows that once human faeces are exposed to flies, and eggs laid on them, no amount of trouble and expense at the trenching ground will prevent the eggs from hatching into flies. My experience in the Jail Department and Cantonments has convinced me of this. In the Jail Department there is no dearth of labour and material for efficient trenching, and yet in spite of all that I could do to prevent fly-breeding in the trenches, I found that a very large number of flies did hatch out. The places from which they came out in large numbers were in between two adjoining trenches. In some places this space was altogether honeycombed. A large number of birds were usually seen in the early morning and late evening near the trenches, evidently come there to feed on the young flies freshly hatched out.

Anti-fly measures in vogue at present in many places are to let flies breed, and then concentrate on ways and means of destroying them by poison, traps, fly sprays, etc. This method of dealing with the fly nuisance is not only very expensive but also inefficient, inasmuch as the flies have done a lot of damage before they are ultimately destroyed, and they have also laid the foundation for thousands of more batches to hatch out later.

In order, therefore, to prevent fly-breeding it is not only the ultimate disposal of excreta that is important but even more so is the protection of excreta from exposure to flies. This exclusion, to be perfect, must begin where the excreta is voided and continued right through to the point of final disposal.

The excreta may be exposed to flies in the following places:—

1. Latrine receptacles.
2. Filth bins.
3. Filth carts, for removal from the bins to its final disposal in trenches or by incineration as the case may be.
4. At the place of ultimate disposal in trenching grounds or in incinerators. The stage where most of the eggs are laid is in the latrine receptacles. Efforts have of late been made in certain places to flyproof group latrines but this is worse than useless for the following reasons:—

(i) The building is provided with a single door, which enables flies to enter and makes their exit difficult, so that in the case of such a flyproof building, the arrangement acts as a trap and the result is worse than if the building had been left freely open.

(ii) As it is a shady place, flies are tempted to get into the building during the heat of the day.

(iii) The wire gauze doors and windows are often damaged and remain unrepaired, and give flies ample opportunities to shelter in the shade inside.

*(Continued from previous page)*

strength in the grasp and he could hold various objects. The strength of the grasp could be increased by dorsiflexion of the wrist. A third operation the aim of which would have been to relieve the drop wrist by tendon transplantation was refused by the boy. A splint was given for the extension of the wrist joint.

#### Conclusions

(1) A new method is described for the relief of paralysis of the opponens pollicis. The flexor longus pollicis tendon is used for the transplantation.

(2) The result has been satisfactory.

(iv) It is an expensive method because of the upkeep of wire gauze which is often broken by misuse.

I have had opportunities of observing this type of latrine in controlled population day after day and as a rule I found them harbouring more flies than open latrines.

The pan or receptacle into which excreta is passed is the part of the latrine which attracts flies. It contains the 'bait' and it is the fly-proofing of this receptacle which is the important point to aim at. In order to be thoroughly effective and to comply with caste prejudices of Indians the flyproofing of the seat must be automatic in action. It should be so arranged that, without touching it with the hands, it shall open just previous to the act of defæcation and automatically close immediately afterwards. With the object of effecting this, the latrine described below has been devised.

Efforts have been made to devise latrines of the squatting type for Indians where the pan remains closed when not in use and opens up automatically when it is in use. The working parts in some of them are complicated and require constant attention to keep them in good condition. In other cases the latrine seats require some manipulation on the part of the user which may be against caste prejudices, or again this manipulation may be difficult for children, and a nuisance when an individual is in a hurry to use the latrine. In order, therefore, to obviate the above disadvantages, the following latrine has been designed after years of practical experience, use, and repeated experiments. The principal object of the device is to provide a pan which, when not in use, will remain covered. A further object is that the lids of the pan should automatically open when the user occupies the platform and close when the platform is vacated. A third object is to construct a sanitary latrine that can be easily made, cheap in cost, sturdy and simple in design and construction, with a mechanism requiring the minimum amount of care either on the part of the user or the sweeper.

#### *Description of the latrine*

Figures 1 and 3 give the front and side views of the latrine when not in use.

Figures 2 and 4 give the front and side views of the latrine when in use.

In all the figures—

1. The platform supported on legs.
2. The opening in the platform through which excreta and urine drop into the pan when it is uncovered and ready for use.

3. The mobile foot rests, to the undersurface of which are fixed three vertical rods—the central being the working rod, and the two side ones guide rods.

4. The central working rod.

5. The guides.

6. Vertically rotating pulley fixed to the lower end of the working rod. This works on

7. Lever fixed at an angle on the upper surface of

8. The lids.

9. The pan that receives the excreta. This slides in and out for emptying and cleaning purposes. Note that there is no space left between pan and lids and that the pan when being replaced after cleaning cannot be pushed either beyond or on either side of the lids, so that it always remains completely covered.

10. The handle provided for pulling out the pan and pushing it back into place.

11. The pivot on which the lids open and close. The device does away with hinges which are apt to rust. When the seat is not in use as

Fig. 1.

Fig. 2.

in figures 1 and 3 the lids cover the pan so that it is impossible for flies to get in. A point in the construction worth noticing is that the lids do not hermetically seal the pan but loosely cover it, allowing passage for foul air from the pan to the outside air and vice versa. This prevents the stench which is noticed with a commode when once used. A number of persons can thus use this seat one after another, and frequent cleaning of the pan by the sweeper is not necessary. When it is desired to use the seat the user puts his feet on the mobile foot rests which are thus pressed down. Nine pounds of weight is all that is required for this purpose, and therefore a small child can use the seat, if once shown how to do so.

The working rods with the pulley at their lower ends, on being pushed down with the foot rests, act on the levers attached to the lids, and raise them as shown in figures 2 and 4. The pan is thus uncovered and ready for use. The lids when opened are totally covered by the

## THE INTRADERMAL TEST AS AN INDEX OF VITAMIN-C NUTRITION

### PART II

By SACHCHIDANANDA BANERJEE, M.B., M.Sc.

and

B. C. GUHA, Ph.D., D.Sc.

(From the University College of Science, Calcutta)

IN a previous communication (Banerjee and Guha, 1939) we have attempted to find how far the intradermal test could serve as an index for assessing the vitamin-C status of the body. It was found in controlled experiments with guinea-pigs kept on a scorbutic diet that the time of decolorization increased approximately at the same rate as the body-weight diminished. When a normal diet of ascorbic acid was given

platform (figure 2) and hence cannot be soiled by the user. The lids when fully opened stand at about eighty degrees from the horizontal, and consequently fall down of their own weight and cover the pan as soon as the weight of the feet on the rests is removed. As soon as the user vacates the seat, the foot rests return to their normal position.

It is claimed that :—

1. It is a great improvement on any other latrine of the squatting type.

2. It is sanitary, hygienic, and clean.

3. The excreta in it remains always covered (except when it is actually in use) consequently there is no offensive smell nor has it the unpleasant appearance of an open Indian latrine.

4. As the excreta is covered flies cannot lay their eggs on it.

5. As flies cannot get access to the night-soil, direct infection of food and drink with germs of cholera, typhoid, dysentery, and other fly-borne diseases is not possible.

6. The mechanism is simple in construction, fool-proof and automatic. The hand is not needed for its working and consequently it does not offend caste prejudices.

7. Its cost is low.

8. The only attention that is needed on the part of the sweeper to keep it in working order is the weekly cleaning and oiling of the rods and pulleys under the foot rests. No mechanical device can go on working indefinitely unless some care is paid regularly to its working parts and this seat is no exception to the rule.

to these scorbutic guinea-pigs, the decolorization time gradually diminished and the body-weights rose at fairly equal rates. If the ascorbic acid supplement was withdrawn the weight curve and the decolorization time curve again followed each other approximately. These results received general confirmation also in experiments in which graded doses of ascorbic acid were administered, but the correlation was not quite quantitative.

With human subjects we found that administration of massive doses of ascorbic acid was followed by a peak in the urinary excretion of ascorbic acid; but there was also a reduction of the decolorization time in the skin test. This should not happen if the body were really saturated, as indicated by the peak in the urinary excretion of ascorbic acid. Further work is desirable to explore the relation between the skin test and the saturation test.

As a preliminary, it is necessary to know what the minimum decolorization time would be if a subject is fed with excessive doses of vitamin C, which may presumably correspond to the saturation point. In the present investigation attempts have been made to obtain information on this question by using guinea-pigs under strictly controlled conditions, and normal human subjects.

### Experimental

Three groups of adult male guinea-pigs of weights varying from 400 to 450 gm. were fed on an ordinary diet consisting of green grass and germinated gram supplemented with 2 mg., 4 mg., and 15 mg. of ascorbic acid respectively. The decolorization time was noted. Animals of

the group receiving the daily supplement of 15 mg. ascorbic acid for a period of 14 days were given 40 mg. on the 15th and 16th days and 100 mg. on the 17th, 18th and 19th days in order to find if the decolorization time might be further reduced. The results are given in table I.

It will be observed that, with guinea-pigs receiving the daily supplement of 15 mg. ascorbic acid, the decolorization time is gradually reduced to 1 minute and 30 seconds, which is apparently the minimum time. This is reached within 15 days and the decolorization time cannot be further decreased by the administration of even excessively high doses of vitamin C.

In order to investigate if the feeding of the guinea-pigs with smaller doses of ascorbic acid would prolong the period in which the minimum decolorization time is reached, two groups of guinea-pigs were fed with daily supplements of 2 mg. and 4 mg., respectively. With these two groups the minimum decolorization time was reached after an interval of four weeks. Here also the minimum time was of the order of 1 minute and 20 to 30 seconds. The results are given in tables II and III.

In order to determine if a minimum decolorization time may be obtained with human beings, six healthy adult students of this laboratory were subjected to the intradermal test on one day, and then on the following four days the same test was carried out after the ingestion of 700 mg. of crystalline ascorbic acid on each day. The three hours' urinary test was also studied according to the method of Harris and Abbasy (1937) along with the intradermal test. The results are given in table IV.

TABLE I

*Decolorization time in minutes and seconds in intradermal test on guinea-pigs receiving 15 mg. ascorbic acid supplement daily. The animals were fed 40 mg. ascorbic acid on the 15th and 16th days and 100 mg. on the 17th, 18th and 19th days*

From the peak in the urinary excretion of ascorbic acid 24 hours after the ingestion of 700 mg. of ascorbic acid, we find that the individuals were saturated according to the standard of Harris *et al.* (*loc. cit.*). The minimum time of 1 minute 30 seconds, however, was reached on the fifth day of the experiment and not on the third day, which should have taken place if the individuals were really saturated. As the dose of ascorbic acid administered was very high (2.8 gm. per head) and as there was no further reduction of the decolorization time beyond 1 minute 30 seconds, we may

consider that this represented the minimum decolorization time. The value was practically the same as was obtained in experiments with the guinea-pigs.

A statistical analysis on the results obtained, kindly carried out by Mr. K. C. Basak, is appended.

#### Discussion

It has to be observed that the minimum decolorization time in the skin test obtained after heavy dosage with vitamin C was approximately the same (1 minute 20 to 30 seconds) for

both guinea-pigs and human subjects. Further, this minimum decolorization time is reached in human subjects definitely after a peak in the urinary excretion of ascorbic acid has been produced by the administration of massive doses of vitamin C. The question arises as to which method would indicate the saturation of the body with regard to vitamin C. It is clear that even when saturation is indicated by a peak in the urinary saturation test, the skin is still unsaturated as shown by the intradermal test, in which the minimum decolorization time is not yet reached. It is only when this minimum time is reached that the skin may be considered to be saturated with vitamin C. Ascorbic acid being a normal urinary constituent, its increased excretion in urine may not necessarily mean that the individual is saturated. Certain individuals may have a low renal threshold for vitamin C. Further, as the vitamin C in the blood rises, it may be excreted by the kidney, vitamin C having a diuretic effect, and the body-tissues may not have time to become saturated with the vitamin. For this reason it is possible that in many cases no correlation between blood ascorbic acid level and intradermal test-time may be obtained. The skin being a part of the body-tissues its vitamin C, as estimated by the intradermal test *in situ*, might perhaps give a truer picture of the vitamin-C status of the body. Although some workers (Poncher *et al.*, 1938; Goldsmith *et al.*, 1939; Poulsen *et al.*, 1939; Bakhsh *et al.*, 1940) have not observed a correlation between the intradermal test and the blood ascorbic acid level, Suzuki (1939) has observed that the intradermal decolorization time is inversely proportional to the ascorbic-acid content of blood serum, both in normal healthy human subjects and in pathological cases. Beck *et al.* (1939) also consider the intradermal test for determining the vitamin-C supply to be adequate for all practical purposes. As we have, however, pointed out above, absence of correlation, where observed, does not necessarily invalidate the skin test and may readily be explained.

Rotter (1937) has suggested that a decolorization time of the order of 5 minutes indicates that the individual is saturated with vitamin C. From the present investigation this does not seem to be correct. Such individuals may be getting a fair amount of vitamin C but they are not saturated with vitamin C. If the skin test provides a more accurate picture of the vitamin-C status of the body, it is clear that none of the students, on whom tests were carried out in the previous communication (Banerjee and Guha, *loc. cit.*), were saturated. In fact, according to the same standard, vast numbers of people on whom tests have been carried out in other countries, would not seem to be saturated with vitamin C. Thus the whole question of the optimum requirement of vitamin C by human beings appears to require revision.

### Summary

The same minimum decolorization time in the intradermal test is obtained after the administration of massive doses of vitamin C in guinea-pigs and in human beings. This minimum time is 1 minute 20 to 30 seconds. The relation of the skin test to the urinary test is discussed and it is suggested that the minimum decolorization time may perhaps give a truer picture of the vitamin-C status of the body than the urine (saturation) test.

### STATISTICAL NOTE

By K. C. BASAK

THE two main points to be examined from the observed data of the experiments are:—

- (1) Whether the decolorization time decreases with increased administration of vitamin C.
- (2) Whether the decolorization time reaches a minimum level indicating the saturation point.

### Experiments on guinea-pigs

The decolorization times on the first day, that is before the ingestion of vitamin C supplement, have been taken as the control figures and their differences from the corresponding observations on successive administrations have been tested for significance. The following table is derived from table I and gives the mean difference, the standard error of difference and the value of *t* at each stage, beginning from the 4th day.

All the values of *t* excepting the first one are significant at the 5 per cent level. The values of the mean difference and standard error appear to be stable from the 14th day, which indicate that on an average the minimum decolorization time was reached on the 14th day. Taking the mean of all the observations from the 14th to the 20th days the minimum time works out as 1 minute 30 seconds.

		Days						
		(1-4)	(1-6)	(1-8)	(1-9)	(1-14)	(1-17)	(1-20)
Mean difference	(in seconds).	30.71	37.14	53.57	45.71	63.71	67.85	67.14
Standard error	..	13.99	10.90	20.23	10.72	15.95	15.42	16.03
t	..	2.19	3.41	2.65	4.26	3.99	4.40	4.19

Similar analyses of tables II and III are rendered difficult by the fact that the number of animals taken for each set of experiments is too small for a reliable estimate of the individual variations of the animals. In table II, however, the mean differences of the observations on the first day with those of the 28th and 29th days are significant. The minimum time, again, is 1 minute and 30 seconds.

In table III the mean difference is not significant at any stage. This is perhaps due to the high variability of the animals before the investigation of vitamin C. An alternative analysis has been attempted to see if the mean decolorization time declined gradually to a level where it remained more or less stable.

An exponential curve  $Y = A + e^{a-bx}$  . . . . (I) is fitted to the mean value of the decolorization time, where Y = decolorization time

and  $x = 0, 1, . . . . .$ , (II) beginning from the first day.

A is tentatively taken as 1 minute 20 seconds. The values of the other two constants, calculated by the method of Least Squares, are

$$\begin{aligned} a &= 4.78 \\ b &= 0.26 \end{aligned}$$

In order to test the goodness of fit, equation (1) is transformed into a straight line equation as follows:—

$$\log_{10} (Y-A) = (a-bx) \times \log_{10} e \dots\dots (2)$$

The observed and calculated values of y are given in the following table:—

Y in seconds			
Serial number	Observed	Calculated	Difference
1	185	200	— 15
2	160	173	— 13
3	125	152	— 27
4	133	135	— 2
5	130	123	7
6	135	113	22
7	112	106	6
8	107	100	7
9	105	95	10
10	93	92	1
11	85	89	— 4
12	85	87	— 2

The regression of the line represented by (2) =  $b \times \log_{10} e = 0.1113$ , and the standard error = 0.0137 therefore  $t = 8.12$  which is highly significant with 10 degrees of freedom.

OBSERVATIONS ON THE OUTBREAK OF  
EPIDEMIC CEREBRO-SPINAL MENINGITIS  
IN BURMA WITH A SPECIAL  
NOTE ON ITS BACTERIOLOGY AND  
ON PROGRESS OF THE EPIDEMIC

By G. C. MAITRA

LIEUTENANT-COLONEL, I.M.S.

*Director, Pasteur Institute, Rangoon*  
and

P. N. SEN GUPTA, M.Sc.

*Bacteriological Assistant*

CASES of cerebro-spinal meningitis occur annually in Burma in sporadic form and the disease has not been known to take on epidemic proportions for a considerable time past. Therefore when a warning was sounded by the Public Health Commissioner for India in March 1935 forecasting possible epidemics of this disease in Burma 'particularly in a number of urban centres in coming months', the medical and public health authorities had to seek advice from the laboratory workers in regard to specific measures to be adopted in case the epidemic materialized. In offering such advice the main difficulty lay in the lack of knowledge about the type or types of organisms responsible for the past attacks and hence those which would probably give rise to the predicted epidemics. Notwithstanding this handicap group I anti-meningococcus serum raised against Indian strains and the newly prepared

*(Continued from previous page)*

Thus the decolorization time follows a decreasing exponential law approaching a minimum value of 1 minute 20 seconds.

The following diagram shows the closeness of the calculated values to the observed values as the saturation level is approached.

*Experiments on human subjects*

The decolorization times given in table IV have been analysed by the method applied to table I. These figures yield the following table:—

	Days				
	(1-2)	(1-3)	(1-4)	(1-5)	(1-6)
Mean difference in seconds.	6.67	16.67	37.50	42.50	40.00
Standard error.	5.42	6.54	7.90	6.02	6.71
<i>t</i>	1.23	2.55	4.75	7.06	5.96

From the values of *t* it appears that the mean difference is significant at the 1 per cent level from the fourth day. The results of the last two days show a fair degree of stability. It may, therefore, be assumed that on an average the minimum time was reached on the fifth day. The minimum decolorization time may be estimated from the average of all the observations on the fifth and sixth days, which works out as 1 minute 29 seconds.

meningococcus vaccine issued by the Central Research Institute, Kasauli, were considered likely to be useful in an emergency.

At the same time an analysis of the public health records for epidemic diseases in Burma revealed that Rangoon town had annually shown an average of four cases from 1931 to 1934 and that since then there had been a tendency for the figures to go up. Though India had recorded several severe outbreaks in Calcutta, Ahmedabad and Delhi during 1933, 1934 and 1935, here in Burma, in spite of free communication with India, there was no significant variation in incidence of the disease during those years.

From the beginning of 1937, however, definitely increasing numbers of meningitis cases were being admitted into the contagious diseases hospital in Rangoon. This opportunity was utilized to recover cultures of meningococcus from the cerebro-spinal fluid of cases and to study them in details. The work has now been carried on for more than two and a half years consecutively and the results are recorded in the following pages.

At first some difficulty was experienced in getting growths of meningococci in primary cultures on rabbit blood agar medium. But this difficulty disappeared on incubating the cultures under reduced oxygen tension by introduction of carbon dioxide gas, as described by Maitra (1919). Once recovered the cultures were maintained on Dorsett egg medium and when opportunity occurred they were studied morphologically, biochemically and serologically with specific sera obtained from the Standard Laboratory, Oxford. In some cases high titre sera raised at this institute against strains isolated locally were used for cross agglutination tests against type strains obtained from the National Collection of Type Cultures. In this way it has been possible to study 99 strains up to the end of the year 1939. All these strains were recovered from cases occurring within the municipal limits of Rangoon city except one which was recovered from a sample of cerebro-spinal fluid sent from Bhamo in Upper Burma. The organism in the last case survived in the cerebro-spinal fluid the period of transit, which occupied at least four days, without any precautions for regulating the temperature. The case occurred in the month of July when the temperature in Upper Burma is likely to be higher than that in Rangoon.

*Morphological characters of the organisms recovered.*—The growth in primary cultures about 18 hours old on blood agar showed Gram-negative bean-shaped diplococci often exhibiting signs of extensive autolysis. In a stained film many areas could be seen to contain nothing but homogeneous material of cellular debris with occasional diplococci of very swollen appearance. A subculture taken from such a growth and incubated at 37°C. for 12 hours yielded well-formed diplococci in stained films

The signs of lysis were more marked in cultures incubated under a partial carbon dioxide atmosphere.

*Cultural characters.*—As noted before, some difficulty was experienced in obtaining primary cultures at the beginning. But they disappeared subsequently as experience was gained and the technique improved. Papaya-digest agar of pH 7.4 with 10 per cent fresh rabbit blood was used throughout, for cultural work from the cerebro-spinal fluid. Samples of fluid showing very few organisms in film preparations were always incubated for 24 to 72 hours and repeated cultures taken every day. In this way many samples of fluid, which showed no growth at the beginning, subsequently gave positive results. After isolation the cultures were maintained on Dorsett egg medium, as it was found to keep the organisms alive for about three weeks at room temperature, thus obviating the necessity of frequent transfers for maintenance.

*Biochemical reactions.*—These were studied on three sugars, viz, glucose, maltose and saccharose. To sugar solutions in 1 per cent peptone (Witte) water, clear and sterile rabbit serum was added to promote growth of meningococci. After inoculating each strain into a series of the three sugars the cultures were incubated and observed for a week, after which the results were recorded. All the strains studied here fermented glucose and maltose with the formation of acid only. The saccharose remained untouched.

*Reductase reaction.*—We had to modify the method given in Topley and Wilson's book on the principles of bacteriology and immunity in order to get a quick and clear-cut reaction. The broth culture recommended there, in our experience, did not give enough growth to release sufficient enzyme necessary for the test. The organisms were at first grown on blood agar slopes for 18 to 20 hours. The growths thus obtained were scraped off and emulsified in ordinary broth to which one drop of 1 per cent aqueous methylene blue solution was added. The mixture was then incubated at 37°C. for half an hour in a water-bath. Complete decolorization occurred in 10 to 25 minutes, and all the strains, tested, behaved in the same manner.

*Catalase reaction.*—The cultures of meningococci were grown for 24 hours at 37°C. on blood agar slopes. To the tubes set in an inclined position one c.cm. of hydrogen peroxide was poured over the growth. This resulted in an ample production of gas bubbles. All the strains tested reacted similarly.

*Serological reactions.*—So far we have been able to test 99 strains, all collected in Burma including one which was recovered from a sample of cerebro-spinal fluid sent from Bhamo in Upper Burma. The strains were first tested against group agglutinating sera obtained from

Standards Laboratory, Oxford, and the results are summarized below :—

Total number tested	Reacting with group I serum	Reacting with group II serum
99	98	1

The 98 strains belonging to group I were further subdivided into types I and III by testing each of them with a high titre diagnostic serum raised against a known type I strain brought out from the National Collection of Type Cultures. Such strains as agglutinated almost to full titre of the diagnostic serum were classified as the type I strains and those showing only slight or no agglutination with the above serum were classified as type III. Members of type III were further confirmed by their inability to remove agglutinins from type I high titre serum by absorption test. Quite a number of strains reacted almost equally against type I and type III diagnostic sera and they were classified as amphoteric. In this way it became possible to classify 98 strains at our disposal into three main categories as shown below :—

Type I	Type III	Amphoteric (types I and III)
25	61	12

The only strain that reacted against group II serum was subsequently tested against type II serum raised in this laboratory from a known type II culture. As the test culture failed to react it was classified as type IV strain.

It is significant to note here that strains recovered in Indian epidemics of 1934 belonged to group I (Ahuja and Naranjan Singh, 1935) in the same way as the meningococci recovered in Burma, and the association of this group with epidemics in Burma has been constantly maintained for the last three years, during which time the observations recorded in these pages have been carried out. The experience in South Africa where similar observations have been made, however, showed that the type distribution of meningococci recovered from cases of meningitis varied from year to year as would appear from the following table (Ordman, 1939) :—

	1934	1935	1936	1937	1938
Group I ..	24%	9%	60%	57%	64%
Group II ..	76%	91%	40%	43%	36%

*Trend of the epidemic.*—The behaviour of the epidemic was especially studied in Rangoon, a city of about 400,000 population with a substantial number of labouring class people, who

mostly live in small tenement holdings often badly overcrowded. In spite of these conditions multiple cases in the same house were not recorded. In addition to the more or less permanent element there is throughout the year a floating population of immigrant labourers, who pass through the city in search of employment in Burma. Most of these men come from India where epidemic cerebro-spinal meningitis was raging in 1934-35. In spite of this fact no explosive outbreak occurred in the city during those years, as would appear from the statement given below :—

Cases of meningitis in Rangoon

Year		Attacks		Deaths
1934	..	..	4	4
1935	..	..	8	6
1936	..	..	7	5
1937	..	..	27	20
1938	..	..	57	39
1939	..	..	36	16

Though incidence and death increased slowly from 1934 onwards no serious menace occurred like those experienced in Calcutta, Delhi and Ahmedabad between 1934-35. The highest number of seizures recorded in Rangoon city was in 1938 when 57 attacks with 39 deaths occurred, while the corresponding figures in three important cities in India in 1934-35 were as follows (Russell, 1936) :—

		1934		1935	
		Cases	Deaths	Cases	Deaths
Calcutta	..	..	..	814	539
Delhi	..	..	..	508	198
Ahmedabad	..	738	344	..	..

The only instance of a suspected epidemic of fulminating character was reported from some

remote villages in Haka subdivision, Chin Hills District, towards the first quarter, in the Report on the State of Public Health in Burma, for 1937. In four village tracts affected 103 deaths were recorded in course of three and a half months. These villages are inhabited by people of primitive type who reported the deaths many days after they had actually occurred. The public health authorities experienced great difficulty in getting accurate information and the inference of cerebro-spinal meningitis being the cause was drawn mainly from hearsay symptoms. No pathological material could be procured for examination and no record is available as to any of the cases being examined by a qualified doctor.

Summary

1. Epidemics of cerebro-spinal meningitis in Burma were forecast in 1935 but did not materialize till 1937.
2. The epidemic went on smouldering for three successive years in Rangoon and is probably continuing even now. In no instance were multiple cases reported from the same house, though considerable overcrowding and unsatisfactory sanitary conditions were associated with many holdings which returned meningitis cases.
3. Group I meningococci were responsible for this disease in almost all cases which came under observation, and this relationship has been maintained for three successive years 1937-39.
4. A single strain of group II meningococcus was recovered from a solitary case at Bhamo in Upper Burma.

A Mirror of Hospital Practice

A CASE OF PERITONITIS FOLLOWING ABORTION TREATED WITH SULPHONAMIDE

By D. A. ANDERSEN, F.R.C.S. (Eng.), M.B., B.S. (Lond.)  
Medical Officer in charge, Evangline Booth Hospital,  
Ahmednagar, B. P.

I AM prompted to put this case on record because of the patient's surprising recovery from a rapidly spreading peritonitis following on abortion.

The patient was a multipara aged about 35. She had had 11 previous pregnancies all of them going on to full term, but seven children had died under the age

of two years. (Kahn test later showed + + +.) The recent history was that she was five months' pregnant. After three or four days of considerable bleeding, the fœtus and placenta were expelled entire. The next day there was stated to be fever and lower abdominal pain, which increased for two days, when she was brought to the hospital. She had been attended by a village dai with some hospital training. Interference was not admitted.

On admission. 17th March, 1940 (9-30 a.m.).—Temperature 103.4°F. Pulse—104 per minute. Respiration—28 per minute. General condition, poor, dehydrated. The patient complained of severe hypogastric pain. Very slight and not offensive blood-stained vaginal discharge was present. Vaginal examination was not done.

Abdomen: Rigidity and tenderness below umbilicus more marked on right side. The fundus uteri could

not be felt on account of resistance. Upper abdomen not rigid or tender and moving slightly on respiration. The patient had not vomited and was taking fluids by mouth.

Blood count: Hæmoglobin—38 per cent; red blood corpuscles—2,600,000 per c.mm.; colour index—0.7; white blood corpuscles—12,000 per c.mm.; polymorphonuclears—80 per cent.

#### Treatment

17th March, 1940.—Fowler's position. Intravenous soluseptasine 5.0 c.cm. 5 per cent; 1,000 c.cm. saline subcutaneously. Glucose water allowed by mouth 2 to 3 ounces hourly.

Sulphonamide P (B. D. H.), 4 tablets, 11-30 a.m. (Sulphanilamide)

2	"	4-30 p.m.
2	"	6-30 p.m.
2	"	10-30 p.m.
2	"	2-30 p.m.
2	"	6-30 p.m.

Total 7 gm. plus 1/2 gm. intravenously.

Enema given with good result in the afternoon.

Morphia gr. 1/6 at night. Local heat to abdomen.

18th March.—The tenderness had increased in extent to well above the umbilicus and was obviously a spreading peritonitis. There was slight general distension.

All fluid by mouth was stopped and a duodenal tube passed by the nose before there was any vomiting, though the patient complained of nausea, and distension, and inability to pass flatus. Fluid aspirated half hourly was at first bilious and later in the day definitely faeculent in smell and appearance. The patient tolerated the tube well as she stated it relieved the sense of fullness. Subcutaneous saline 1,000 to 1,500 c.cm. was given twice in the day into the submammary and thigh regions. Soluseptasine 5.0 c.cm. was given four hourly by day intramuscularly and four tablets by mouth which were probably not absorbed.

In the afternoon there was almost a classical Hippocratic facies with diffuse tenderness and moderate distension of the whole abdomen and the case was regarded as hopeless. In the evening however the condition appeared to be stationary and it was noted that the fluid aspirated was less in amount and less brown in colour. The temperature remained at 102°F. and the pulse 120 per minute. Morphia was repeated at night.

Blood count: White blood corpuscles 10,600 per c.mm., and the polymorphonuclears were 84 per cent.

19th March.—General condition stationary.

Aspirated fluid less in quantity and gradually clearer and non-faeculent. Three further injections of soluseptasine were given intramuscularly and pituitrin 1/2 c.cm. hourly followed by a flatus tube. On one occasion flatus was passed.

Less distension and tenderness. Tenderness localized again mainly to the right iliac region.

Temperature between 100° to 102°F. Pulse 120 to 130 per minute.

20th March.—Definite improvement. Less distension and tenderness. Duodenal tube removed. Subcutaneous saline continued. A teaspoonful of fluid allowed by mouth, at first two hourly and then hourly. Watery motion passed after pituitrin 1.0 c.cm. Temperature—99° to 101°F. Pulse 100 to 130 per minute. Blood count—white blood corpuscles 6,000 per c.mm. Polymorphonuclears 72 per cent. No sulphanilamide given.

21st March.—Improvement continued. Abdominal signs less. Patient asked for pituitrin again. Injection repeated with passage of flatus and watery motion. Temperature—98° to 99°F. Blood count—white blood corpuscles 4,400 per c.mm. Polymorphonuclears 74 per cent.

22nd March.—Afebrile. Taking moderate amount of fluids by mouth. Blood count: Red blood corpuscles—1,900,000. Hæmoglobin—30 per cent. White blood corpuscles—3,200 per c.mm. Polymorphonuclears—

70 per cent. Concern was felt about the fall of leucocyte count and, acting on a verbal report of its value in such cases, Campolon was given daily in 5.0 c.cm. doses for three days and on alternate days in the next week.

23rd March.—Steady improvement. Light diet begun gradually.

27th March.—General condition fair. Fundus could now be felt about half-way between umbilicus and pubis. White blood corpuscles 5,000 per c.mm. Polymorphonuclears 63 per cent. Kahn test + + +. Further progress uneventful.

#### Comment

The conclusions that can be drawn from a single case of this kind are limited. A. J. Cokkinis writing on 'Sulphonamides in Surgical Infections' in the *British Medical Journal* of 29th October, 1938, states: 'My experience with sulphonamide compounds in acute peritonitis suggests that when used correctly chemotherapy may prove of life-saving value, but also that when used indiscriminately it may prove the reverse. The deciding factor again appears to be the immunity response of the patient. Although the cases treated have been comparatively few, they show quite decisively that sulphonamide compounds should not be used as a prophylactic measure against peritonitis in such lesions as perforated ulcer and intestinal strangulation or after operations such as colectomy. They also suggest that it is unsafe to employ chemotherapy in the very early stage of actual peritonitis, that is, while the effusion is still serous and the immunity presumably unawakened. On the other hand, when the more powerful sulphonamide compounds have been administered to cases of fully developed coliform or streptococcal peritonitis with either a profuse purulent effusion or extensive peritoneal oedema the result has usually been a dramatic and lasting improvement. Once started the chemotherapy should be continued for at least ten days but it should never be begun until any removable and unlocalized source of infection has been dealt with by operation'.

The above quotation has been given in full as it acts as a corrective to the impression that might be conveyed by a single successful case. The case reported does, however, confirm that sulphonamide can in certain cases of peritonitis have dramatic effects. The case was the more

surprising, as there was what amounted to faecal vomiting though the fluid was actually drawn off by a duodenal tube as a therapeutic measure.

Other features of interest are—

1. That the chemotherapy was begun late, that is 48 hours after the onset of definite symptoms of infection which is interesting in view of Cokkinis' recommendation that it should be delayed till immunity has been awakened.

2. That the chemotherapy was only continued for three days, a large dose being given by mouth during the first day of treatment, and moderate doses parenterally the next two. The administration was stopped because of the marked clinical improvement associated with a rapid fall in the leucocyte count. In view of the continued clinical improvement and also the progressive further fall of the leucocyte counts, this proved to be justified. A fairly rapid recovery towards the normal occurred when the drug had time to be excreted, but it seems that if the administration had been continued for a week or ten days as is more usual, a grave and probably fatal condition due to the drug would have resulted. This therefore stresses the advisability of very frequent blood, and particularly white cell counts, whenever large or moderate doses of sulphonamide are employed.

3. No information was obtained as to the nature of the infecting organism, but in view of the favourable response to treatment it can be presumed to be one or several of the group known definitely to be inhibited by sulphanilamide, viz, hæmolytic streptococci, certain of the non-hæmolytic streptococci, as *S. faecalis*, *B. coli*, certain pneumococci, gonococci, and possibly certain anærobes as *B. welchii*.

## A CASE OF ANEURYSM OF ASCENDING AORTA

By S. L. BHATIA

LIEUTENANT-COLONEL, I.M.S.

Superintendent, J. J. Group of Hospitals, Bombay

V. A., male, aged 30, was admitted to the J. J. Hospital with a history of syphilis for which he had had treatment with Bismuthiodol and potassium iodide. He complained of pain in the chest for four months and slight breathlessness on exertion. The pain was in the right side of the chest in front. Occasionally, he said, he also felt it in the inter-scapular region at the back on the right side.

On examination it was found that the veins on the right side of the neck were congested. There was a diffuse swelling (3 inches by 3 inches) with pulsation of the chest wall on the right of the sternum in the 3rd and 4th intercostal spaces extending from the right sternal border almost to the right nipple. This area was dull on percussion. Over it there was an expansile impulse, systolic thrill and bruit. The apex beat was in the 6th intercostal space in the left nipple line. There was a loud ringing aortic second sound. The pulse was collapsing, rapid and regular at both the wrists. The blood pressure was unequal on the two

sides, being 138/68 mm. Hg. in the right arm and 129/76 mm. Hg. in the left arm. The pupils were unequal, the left being larger than the right. The Wassermann and Kahn tests were positive.

Electrocardiographic examination showed left axis deviation. On x-ray examination an aneurysm of the

Fig. 1.—Showing aneurysm of ascending aorta (antero-posterior view).

Fig. 2.—Showing aneurysm of ascending aorta (lateral view).

ascending aorta was seen. Photographs of the antero-posterior and lateral views are given here. They show saccular aneurysmal dilatation of the convex border of the ascending portion of the aortic arch, extending to the right side and in front.

With rest, milk diet and iodides, the patient improved. The pain which was the main symptom was considerably relieved.

The case is of special interest on account of the peculiar shape and position of the aneurysmal sac.

## LINGUATULID INFECTION IN MAN

By D. N. ROY, M.D., D.T.M.

and

S. K. GANGULY, M.B., D.T.M.

Department of Medical Entomology, School of Tropical Medicine, Calcutta

THE only feature of interest in this report is the evacuation by coughing and sneezing of small white 'worms' from the respiratory tract of a female patient whose chief complaints were pain over the region of the frontal sinuses for some time. The specimens were identified as immature stages or nymphs of *Linguatula serrata* Frölich.

The Linguatulids have close affinity with ticks, mites and scorpions, although in their external appearance they resemble segmented worms. The body is vermiform and is markedly annulated. The rings are, however, merely superficial and no trace of any segmentation is present. They therefore are considered as degenerated forms of the Class *Arachnida* and have been included under a distinct Order, *Pentastomida*, which includes among others the family *Linguatulidae*. The life-history of this arthropod includes two hosts, one carnivorous and the other herbivorous. *L. serrata* is found in domestic animals of cosmopolitan distribution and the nymphal form has been reported from cattle, rodents and ungulates.

In *Linguatula serrata*, the eggs are passed in the discharge from the mouth and nostrils; they

also occur in the faeces; when swallowed by the intermediate host the egg-shell is dissolved and the larva is liberated; the larva then bores its way to the liver, spleen, etc., and after a series of moults it encysts, grows and becomes a nymph. When this nymph is swallowed by the final host it makes its way from the gut to the lungs or the nasal cavities where it becomes adult; the nymph, when fully developed, is said to be able to leave the cyst and to migrate to the bronchi or to the intestine of the intermediate host, from which positions it is passed to the exterior. It reaches its final host by being sniffed up by the dog and becomes adult in the nasal cavities (Southwell, 1924).

The nymph has also been frequently recorded from man at autopsy and usually in the liver (Darling and Clark, 1912; Sambon, 1922). In man Landon (Darling and Clark, 1912) reported a case of infection in a blacksmith, producing symptoms pointing to the invasion of the liver by larvae and later an unpleasant sensation of pressure in the left nasal cavity was followed by expulsion of a *Linguatula* with a violent attack of sneezing, thereby relieving all the symptoms of the patient.

The adult is also known as a human parasite but this condition is very rarely met with and appears to be due to embryos wandering into the nose and developing directly.

Among the domestic animals the dog is most frequently attacked and it acts as a definitive host; the adult is lodged in the nasal and ethmoidal sinuses and also in the maxillary antrum.

In view of the fact that there is a history in this case of close association with dogs, it is probable that the infection was acquired from them.

Altogether five 'worms' were collected by the patient in a living state, and they measured on an average 4.8 mm. in length and 1.18 mm. in breadth at its widest part. The rows of spines were 91 in number.

The antrum on illumination did not present any abnormal picture, and the frontal sinuses too looked normal. The cause of pain over the frontal sinuses could not be reasonably explained.

So far we know this is the first record of Linguatulid infection in man in the East.

We are grateful to Dr. S. Roy, M.B., M.Sc., F.R.C.S., D.L.O., Surgeon, Ear, Nose and Throat Department, Medical College, Calcutta, for making the necessary examinations of the nose and the antrum.

# A Triumph of Emulsification

THE OILY RING AROUND  
THIS DROP TELLS THE STORY

The ring around the drop tells the story. A drop of Agarol on blotting paper holds firmly together. Try this with a poor emulsion and you will soon see the mineral oil being taken up by the blotting paper, forming a greasy ring around the drop. For dependable efficacy in the treatment of constipation and allied disorders Agarol — mineral oil, agar-agar and

phenolphthalein emulsion — has attained a reputation all its own.

Only the finest and purest ingredients are used in Agarol. Its exceptional palatability, secured without artificial flavouring, renders it acceptable to both children and adults. Agarol contains no alcohol and no alkali and, being devoid of sugar, is particularly suited to diabetic cases.

### OF OUTSTANDING VALUE

#### ANACARDONE

An efficacious cardiac and respiratory stimulant with low toxicity. It is of value in all cases of cardiac and respiratory embarrassment, particularly during and following severe illness.

#### OESTROFORM

The natural oestrogenic hormone. Issued for the treatment of menopausal symptoms, delayed puberty, oligomenorrhœa, amenorrhœa, sterility and dysmenorrhœa due to uterine hypoplasia.

#### MERSALYL

The officially-recognized mercurial diuretic (Mersalyl B. P.). Mersalyl is particularly valuable as a diuretic in resistant cases with cardiac involvement. Mersalyl is issued for parenteral, rectal and oral administration.

#### IODATOL

For use as a contrast medium in radiography, particularly for the visualization of the bronchial tree, the uterus, the spinal column, the paranasal sinuses and the Fallopian tubes.

#### PROGESTIN

The natural luteal hormone. Issued for the treatment of menorrhagia, threatened abortion, dysmenorrhœa, pregnancy toxæmias, metrorrhagia and tonic uterine contraction.

#### DEHYDROCHOLIC ACID

A powerful stimulator of bile secretion. Dehydrocholic Acid also stimulates pancreatic secretion and assists the absorption of fats; it is of value, therefore, in the treatment of constipation and liver disorders.

## AVIATION MEDICINE

A LITTLE over one hundred and fifty years ago man began his first serious attempts to leave the earth and travel through the air, in other words he began the investigation of what is known to-day as aviation. For over one hundred years after his beginning, little progress was made, for during the whole of that time he only had the balloon in which he was unable to direct his journeys but had to rely on the natural air currents, so that the practical value of the air as a means of travel was still negligible. Nevertheless, although the mechanics of air travel were for so long at a standstill, the ill effects on man of a rapid ascent to high altitudes was appreciated in the very early days of aviation, as demonstrated by the ascent of Glaisher and Coxwell in 1862 and the tragic consequences of the historic ascent of Tissandier, Crocé and Sevel in 1875. These unfortunate accidents did not check the progress of man's conquest of the air, but they stimulated the study of the reasons for these ill effects. Paul Bert the French physiologist, who was the pioneer in the study of the effects of alteration of barometric pressure, proved that the principal influence of high altitude was due to the lowered partial pressure of oxygen, and he carried out investigations on questions of respiration and blood gases under decreased atmospheric pressure. 'As a result of Bert's work, which was done directly in connection with these problems of aviation medicine, we cannot help but confer upon him the honour of being the father, or at least the grandfather, of aviation medicine as well as being the first flight surgeon' (Armstrong, 1939).

In the first decade of the present century a beginning was made with mechanically propelled aircraft, and since then the progress in respect of speed, altitude and range of operation of these machines has steadily and rapidly advanced. These mechanical improvements have brought in their train many new complications in the added effects they have on human beings, the study of which is now regarded as a highly specialized branch of medicine. Aviation medicine, however, does not seem to have made much progress during the period prior to the beginning of the last Great War. The Germans alone had been quietly studying the special qualifications required for airmen, and had drawn up minimum standards for military pilots. The English, French and other nations started special medical services for aviators, only towards the close of the war.

During the last Great War it was found that men of physical fitness of the army standard were not necessarily suitable for the air force. In fifty per cent of cases the candidates suffered from neurosis during their training, and accidents were found to be due to the defects in the pilots themselves in 90 per cent of cases. It was thus realized that the selection and medical care of the airmen was a special problem. By the end of 1917 all of the Allies and Germany had medical departments which were integral parts of their air services, and in each were included the leading specialists of the respective countries. The subject of modern aviation medicine has been built up on the work of these pioneers and on that of their successors, all over the world, in the post-war period.

The subject of aviation medicine now includes at least three problems, namely, selection of the pilot, care of the flier, and investigation, prevention and treatment of the diseases that are peculiar to modern aviation, besides research into the newer problems that continue to arise as a result of advancement in design, manoeuvrability and mechanical complications of aircraft, from year to year. The importance of every branch of this subject can hardly be over-emphasized, for the efficiency of a modern air force is almost entirely dependent on it. There is probably no other specialty in medicine at the present time which has so much to offer to the properly qualified physician. No other branch of medicine offers a more fascinating or broader field for research, for no longer is aviation medicine restricted to the selection of candidates for flying training or to the re-examination of qualified pilots, but it includes the study of hygiene, sanitation, epidemiology, aerobiology, physiology, psychology, cardiology, ophthalmology, otology, in so far as these sciences apply to flight. Nor must we think only of the pilot but in addition must consider other members of the crew who are required on large modern aircraft, and of the comfort, health and safety of the travelling public, thousands of whom are in the air every hour of the day and night and whose welfare is a responsibility of aviation medicine.

To India at the present time the subject of aviation medicine is of special interest, in view of the recent decision to build up a large air force. The standards of fitness of fliers, that have been arrived at by experience in other countries, will undoubtedly be of help in the selection of India's aviators, but these standards may not be entirely suitable for this country. The normal physical standards of Indians, regarding height, weight, chest measurements, ocular conditions, power of endurance, etc., are generally different from those of western countries. It is quite probable that the standards for western countries may not prove suitable for this country, and slightly different standards will have to be adopted for the selection of India's pilots. The tropical climate with its

high temperature and humidity, excessive rainfall in some parts and desert conditions in others, will undoubtedly add to the problems of aviation medicine in India. Flight surgeons will have to be trained in India for Indian conditions, and research on the different branches of aviation medicine will have to be carried out locally.

Workers in the aviation industry, who are exposed to noxious fluids and gases and who are liable to serious diseases on this account, will have to be protected from these deleterious substances.

For the solution of the various problems that are likely to arise in the course of development of military aviation in India, the establishment in this country of a school of aviation medicine with aeronautical research laboratories, is a necessity. There is no dearth in India of

specialists in the different branches of medical and physical science that constitute aviation medicine. Every country that has made any progress in aviation, civil or military, has its own school of aviation medicine, where it trains up its flight surgeons. Developments of the present war have brought home to the authorities the necessity of building up an air force for India. If it is to be of any use, the air force will have to aim at superiority over other eastern countries and a huge personnel will have to be trained and equipped. This makes the establishment of a school of aviation medicine in India all the more important and urgent.

### HÆMATOLOGICAL TECHNIQUE

#### PART V

By L. EVERARD NAPIER, F.R.C.P. (Lond.)

and

C. R. DAS GUPTA, M.B. (Cal.), D.T.M.

(From the Calcutta School of Tropical Medicine)

#### *Hyperbilirubinæmia and van den Bergh's test*

BILIRUBIN is normally present in small quantities in blood plasma and blood serum, and their yellow colour is in part due to this substance.

Ehrlich observed that when sulphanilic acid and sodium nitrite were added to a solution of bilirubin, a bluish-violet substance, azo-bilirubin, was formed. The reaction is specific and will show bilirubin in a dilution of 1 in 1,500,000.

Van den Bergh made use of these observations, not only to test for the presence of an excess of bilirubin, but to draw certain conclusions from the nature of the result. His original claims are now questioned, but his general conclusions hold good and form the basis of the test which we are describing.

Bilirubin is a by-product of hæmolysis. It is normally present in the blood in a dilution of about 1 in 400,000 or 0.25 mg. in 100 c.cm. of blood. It is excreted *via* the bile ducts after passage through the parenchyma cells of the liver; during its passage through the liver cells the blood bilirubin loses its protein molecule. If the passage of the bile is obstructed (obstructive jaundice), the bilirubin from the bile is reabsorbed into the blood stream; this bilirubin, stripped of its protein molecule, reacts readily with the diazo reagent and gives what is known as a direct reaction.

In conditions of excessive hæmolysis and/or liver dysfunction, the amount of bilirubin present in the blood naturally increases; the

diazo reagent does not react with this blood bilirubin immediately but only after it has been in contact with it for some time (this is sometimes known as a *delayed direct reaction*, but this reaction is not usually taken into consideration as it has no special significance beyond that covered by the indirect reaction which is clearer and susceptible to quantitative appraisal *v. i.*). However, if the serum has been treated first with alcohol and the protein precipitated, an immediate reaction occurs; this is known as the *indirect reaction*.

A third type of reaction is that in which there is an immediate faint colour which steadily increases, indicating that both forms of bilirubin are present; this is known as the *biphasic reaction*.

The technical details of the test have been modified many times and it is done in a number of ways in different laboratories. Godfried (1935) recommends the method described by Thannhauser and Andersen (1921) as the most suitable for clinical purposes; this is the method that we follow in our laboratory.

#### *Apparatus required*

Graduated pipettes, 1 c.cm., 2 c.cm., 5 c.cm., and 25 c.cm.

Small test-tubes, 4 inches by  $\frac{1}{2}$  inch.

Centrifuge tubes.

Small glass beakers or flasks.

Capillary pipettes with rubber teats.

Centrifuge machine.

Sealed cobalt sulphate standard tubes.

\* Lovibond comparator with the coloured discs for bilirubin.

#### *Reagent*

Alcohol—absolute and 90 per cent.

Saturated solution of ammonium sulphate; this is prepared by dissolving an excess of ammonium sulphate

\* The comparator may be obtained from Tintometer Ltd., Milford, Salisbury (U. S. A.), or from the British Drug Houses Ltd., London.

in hot water (so that some undissolved salt is left at the bottom).

Normal saline.

*Diazo reagent*

- (A) Sulphanilic acid—1 gramme.  
Concentrated hydrochloric acid—15 c.cm.  
Distilled water 1,000 c.cm.
- (B) Sodium nitrite—0.5 gm.  
Distilled water 100 c.cm.

Stock solutions of (A) and (B) are made. They keep well for a long time.

The test can be done either with the serum or plasma. When the cell volume is also being estimated, the supernatant plasma in the cell-volume tubes, after the packing of the red cells, is quite sufficient for the test. When the test is done by itself, three cubic centimetres of blood is drawn in a dry test-tube or an oxalated tube.

The blood is collected in the usual way, and even the slightest hæmolysis must be avoided (part I). Preferably, the blood should be collected in the fasting state as it is claimed that food intake, especially a big meal of carbohydrate and fat, affects the level of serum bilirubin. The specimen must always be examined within two hours, as otherwise paradoxical results may be obtained.

*Technique.*—Prepare the diazo reagent by mixing 10 c.cm. of A and 0.3 c.cm. of B in a small flask or beaker.

This mixture must be prepared just before use and must never be used later than one hour after it is made.

Pipette off the clear supernatant plasma from the cell-volume tubes.

*Direct reaction.*—Take exactly 1 c.cm. of plasma in a centrifuge tube.

Add exactly 0.5 c.cm. of diazo reagent, and mix well.

One of the following things may happen :—

(i) Direct reaction—The mixture becomes bluish-violet within 30 seconds.

(ii) Bi-phasic reaction—The mixture becomes slightly reddish at once and the colour gradually increases in intensity and becomes bluish-violet.

(iii) Negative result—No change of colour occurs within 10 minutes.

*Indirect reaction.*—If no change occurs (iii), add to the mixture of plasma and diazo reagent 2.5 c.cm. of alcohol (absolute or 96 per cent), and 1.0 c.cm. of saturated solution of ammonium sulphate.

Mix well by inverting the tube, and allow it to stand for about two minutes, and centrifuge for 5 to 10 minutes.

A positive indirect reaction is indicated by the supernatant fluid becoming coloured a distinct bluish-violet, the intensity depending on the amount of bilirubin present. As bilirubin is present in normal blood, a faint violet colour nearly always appears and obviously has no pathological significance.

*Quantitative indirect reaction.*—It will be clear that some form of quantitative estimation is essential. Many elaborate methods which require special apparatus have been devised, but a fairly accurate estimation of the bilirubin content can be obtained by carrying out the test in the way described above and comparing the supernatant fluid with a prepared standard or with a permanent colour standard.

(i) Comparing the supernatant coloured fluid with the cobalt sulphate standard (2.161 per cent) has given the most satisfactory colour matching in our hands.

*Preparation of the cobalt standard solution.*—Dissolve 2.161 grammes of anhydrous cobaltous sulphate in distilled water. The colour of this solution corresponds to that of 1 in 200,000 bilirubin or 0.5 mg. of bilirubin per 100 c.cm. Solutions equivalent to 0.4, 0.3, 0.2, 0.1 and 0.05 mg. per 100 c.cm. are made by diluting the original solution.

About 2 c.cm. of each of these solutions is put into tubes made of hard glass. The tubes are then sealed, numbered, and kept in the dark, and are brought out only when required. Properly stored, the solutions retain their colour for a fairly long time. In our laboratory, we did not find any difference in colour in solutions which were in daily use for over six months, when these were compared with freshly-prepared solutions.

*Technique for the use of cobalt standard solution.*—Take about 2 c.cm. of the coloured supernatant fluid in a tube having identically the same bore as the standard tubes, and compare its colour in a comparator with the cobalt standard tubes. The figure on the tube giving the correct matching with the supernatant fluid multiplied by four gives the bilirubin value of the undiluted serum, for the dilution of the serum in the supernatant fluid containing azo-bilirubin is 1 in 4 and not 1 in 5, because the saturated ammonium sulphate remains as a separate layer and does not contain azo-bilirubin.

If the supernatant fluid is of a deeper colour than the cobalt standard tube marked 0.5, dilute the supernatant solution with normal saline (dilution with 67 per cent alcohol which is recommended makes the solution hazy and difficult to match) until it matches one of the cobalt standard tubes. Note the dilution required to match and calculate the amount of bilirubin in the specimen.

*Example.*—One cubic centimetre of supernatant fluid was taken to which was added 1 cubic centimetre of normal saline to match the tube marked 0.4.

First dilution of serum in the supernatant fluid is 1 in 4.

Second dilution to match the colour is 1 in 2.

Therefore, total dilution is  $\frac{1}{4} \times \frac{1}{2} = \frac{1}{8}$ .

Then the original plasma contained  $0.4 \times 8 = 3.2$  mgm. of bilirubin per 100 c.cm.

(ii) *Lovibond comparator*.—Quantitative estimation of the indirect van den Bergh reaction can be simplified by the use of a bilirubin disc in the Lovibond comparator. The disc contains coloured glass standards marked 0.2, 0.4, 0.6, 0.8, 1.0, 1.25, 1.50, 1.75 and 2.0 mg. which are calibrated in such a way that, when the test is done in the way described above, the matching with any of the discs gives directly the result for the undiluted serum (figure).

*Technique for the use of the comparator*.—Fit in the disc marked 'bilirubin' in the Lovibond comparator. Transfer the coloured supernatant fluid to the right hand tube of the comparator. A tube of distilled water should be put behind the hole showing the coloured glass. Hold the comparator against a source of light (daylight is much better than any artificial light). Rotate the disc till a correct colour

### Normal bilirubin

Fig.

Bilirubin disc for the Lovibond comparator.

match is obtained, the number in the disc indicates the bilirubin value in mgm. per 100 c.cm. of undiluted serum or plasma.

When the colour of the supernatant fluid appears to be between two consecutive coloured discs and does not exactly match either of them an intermediate value is recorded.

If the bilirubin value exceeds 2 mgm. per 100 c.cm., dilute the supernatant fluid with normal saline until a correct match is obtained with one of the coloured glasses. Calculate the bilirubin value by multiplying the number on the disc by the dilution factor.

### Icterus index

Like the van den Bergh reaction, the icterus index is a measure of the bilirubin content of the blood. Though the test is simple to carry out, it does not give all the information which is obtained by the van den Bergh test.

*Principle of the test*.—The colour of the serum or plasma is compared with a standard solution of 1 in 10,000 potassium bichromate, which is taken as the unit.

### Apparatus required

Test-tubes in a rack.  
Capillary pipettes with rubber teats.

Potassium bichromate solution 1 in 10,000.  
(To be stored in the dark).

Colorimeter of the Dubosq or Klett type.

*Technique.*—Pipette off the supernatant plasma from the cell-volume tube after complete packing of the cells.

Dilute the plasma with an equal part, or with twice the amount of normal saline (more in cases of jaundice); dilution diminishes the cloudiness of the plasma and gives a better matching.

*Matching in the colorimeter.*—The following adjustments of the scales and of the illumination must always be made each time before the use of a colorimeter.

(i) Adjustment of the scales. Gently raise the cups until the bottoms are in contact with the plungers. The readings should be exactly at 0 on both sides. If they are not, they must be brought to 0 by adjustment.

(ii) Adjustment for uniform illumination. Half fill both the cups with the standard 1:10,000 potassium bichromate solution. Gently raise the cups until the bottoms touch the plungers—this will drive out any air bubbles that may be in the fluid.

Now slowly bring down the cups and set them at an equal depth, say 15 millimetres. Adjust the reflector in such a way that the same amount of light is reflected up through each cup.

Slight adjustment of the eyepiece may be necessary, if both halves of the field do not match exactly.

*Taking a reading.*—Keep the cup on the left side at a depth of 15 millimetres.

Take out the cup from the right side, throw out the potassium bichromate solution, wash the cup thoroughly in water, dry it well with soft linen. Put the diluted plasma into the cup and replace it on the right side of the colorimeter. Gently raise the cup until its bottom touches the plunger. Now move this cup containing the plasma up and down until a perfect match is obtained; take a reading. Move the cup up or down and again adjust it to match; take another reading.

Take the mean of three independent readings.

### Calculation

Icterus index =

$$\frac{\text{Reading of standard bichromate sol.}}{\text{Reading of diluted plasma solution}} \times \text{dilution factor.}$$

*Example.*—One part of plasma is diluted with two parts of normal saline.

The cup containing the standard solution is at 15 mm.

The cup containing the unknown plasma matches the standard at 5 mm.

Icterus index— $\frac{1}{2} \times 3 = 9$ .

B. *Matching in tubes.*—In the absence of a colorimeter, results sufficiently satisfactory for clinical purposes may be obtained by matching the plasma or serum diluted with normal saline

against the standard 1:10,000 potassium bichromate solution.

Take two test-tubes of equal height and calibre. Into one put about 5–10 c.cm. of standard potassium bichromate solution. Into the other put 1 c.cm. of plasma and add measured amounts of normal saline from a graduated pipette until the colour matches the standard.

*Calculation.*—The dilution of the plasma required to match the standard potassium bichromate solution gives the icterus index.

*Example.*—To 1 c.cm. of plasma was added 7 c.cm. of normal saline to match the standard. Dilution of the plasma is 1 in 8. Therefore, icterus index = 8.

Normal icterus index, 4 to 7.

*Discussion.*—The significance of the van den Bergh test in hæmatological investigation is that it gives a *broad* indication as to whether the anæmia is due to excessive blood destruction or deficient blood formation.

In the true hæmolytic anæmias the test always gives a high reading, 2.0 milligrammes or more, in iron-deficiency anæmias it is within normal limits, and in aplastic anæmias it may be completely 'negative' (in the normal individual there is usually a faint violet coloration of the serum).

In pernicious anæmia a reading well above the normal range is usual, for, though it is not a true hæmolytic anæmia, the deficiency of 'hæmopoietin' leads to the formation of abnormal cells which are very susceptible to destruction by the normal hæmolytic tissues.

In tropical macrocytic anæmias, in a large number of cases, especially in those with enlarged spleens, the test is much above the normal range and in a small number of cases the test is well within the normal range.

It is not, however, an absolute indication, either of excessive blood destruction or of deficient blood formation as, for example, in an acute malarial attack, when there may be enough red cells destroyed to lower the red cell count a million or more cells per c.mm., the van den Bergh often remains within normal limits, for the liver cells are able to excrete this temporary excess of bilirubin in the blood, but if the red cell destruction is continued the bilirubinæmia will inevitably rise above the normal range and a 'positive' van den Bergh reaction will result.

On the other hand, in liver dysfunction, not necessarily accompanied by anæmia, a positive van den Bergh may be found, for the liver cells are unable to utilize the products of normal hæmolysis.

## 'DOPING' IN ATHLETIC CONTESTS

By E. S. PHIPSON, C.I.E., D.S.O., V.H.S., M.D., F.R.C.P.  
COLONEL, I.M.S.

ONE of the most remarkable developments in the field of athletics in recent years has been the growth and popularity of the international athletic contests on a grandiose scale which are known as the Olympic games.

For many years past these contests have been staged and produced on an ever-increasing scale of lavishness, and though the healthy spirit of emulation engendered by the aggregation of the world's finest athletes is sometimes clouded by jealousy, recrimination and even international 'incidents', there can be few who would not agree that, in theory at least, such contests are the expression of a worthy and even a noble ideal, even if, in practice, they do not always attain to the lofty standard which, we presume, characterized the Olympic contests in the golden days of ancient Greece.

These contests, however, have more than one disadvantage; not the least of these is the almost morbid craze for record-breaking to which they have given rise, and which has brought in its train an eager search for means, some rational and harmless, others dubious or indefensible, to raise the level of athletic performance to a standard otherwise unattainable. These means are collectively known as 'doping'.

The subject of 'doping' has recently been examined in the Laboratory of Theoretical Studies on Physical Training in the University of Copenhagen, and the present communication is based on Dr. Ove Bøje's examination (1939) of the very considerable literature, mostly German, on this little-known subject, published by the Health Organization of the League of Nations.

Resort to means to enhance the powers of endurance is no new device. Everyone has heard of the use of opium for this purpose in India, and of coca-leaves by the Indians of South America. In bygone times the Samoyeds and the Berserkers are said to have consumed a muscarin-containing mushroom to rouse themselves to the required degree of combativeness before going into battle. The word 'doping' is now used in a general sense to denote any method of temporarily improving athletic performance and includes not only the use of powerful drugs but also dietetic preparations, non-toxic salts, oxygen and ultra-violet radiation, and it might even be said to include massage and the purely psychological means

of encouragement shouted to competitors during the actual course of a contest.

It is evident that there is a wide difference between 'doping' a competitor with, for example, a feed of glucose and with highly active and toxic drugs such as cocaine or cardiazol. The extent to which it is permissible on ethical grounds, that is from the standpoint of 'sportsmanship', to use such means to improve the athletic performance of a team or of an individual is a matter which must be left to the leaders of athletic associations to decide, or ultimately, perhaps, to public opinion, though the lengths to which certain trainers and athletes will go in pursuit of a coveted record can hardly be in the ancient Greek tradition. From the purely medical standpoint, however, the strange aspect of 'doping' is, on the one hand, the variety of drugs and other means employed, and, on the other, the resilience of the human organism to maltreatment of this nature, for in many cases it is little less, and these present a curious sidelight on pharmacology. The writer believes it will be of interest to summarize the various means employed and the effects they are believed, or have been found, to produce on athletic performance.

1. *Food-preparations and non-toxic salts.*—Since prolonged muscular work leads to a fall in blood-sugar, and if pushed to extremes, to an acute hypo-glycæmia, the administration, during the course of an experiment, of *carbohydrates*, in the form of glucose, or even cane-sugar, will defer exhaustion-point by as much as a full hour in some cases, but there is nothing to show that the ingestion of glucose in considerable quantities before the experiment or contest will have the same effect. *Lecithin*, in the form of egg-yolk, or in the form extracted from soya-beans, has been largely used but on experimental evidence its value is doubtful. *Vitamin B<sub>1</sub>*, in the form of yeast, since it plays a part in carbohydrate metabolism, and if taken with glucose assists in the accumulation of glycogen reserves in the liver, might be expected to favour prolonged muscular effort, but there is no proof that, although a sufficiency of B<sub>1</sub> is, of course, necessary for health, an excess of it will raise functional capacity.

The preliminary ingestion of *phosphates* has apparently been proved in many experiments to increase substantially the output of work, in some cases by as much as 20 per cent, particularly if it is taken in the form of the widely-advertised German preparation 'Reeresal' in which the intrinsic effects are no doubt increased by the psychological effects of intensive advertising. The conclusion appears to be that phosphates, taken in excess of dietetic requirements, actually increase muscular output, and are harmless unless taken in massive doses.

Heavy physical effort in great heat entails a loss of salts, particularly of *sodium chloride*, and replacement is known to be essential in conditions such as heat-cramp, but in athletics

(Continued from previous page)

signs of salt deficiency are likely to become apparent only in long contests, carried out in warm weather. Ingestion of salt would correct this, but its value would have to be balanced against its thirst-producing tendency. The salt-content of a highly trained athlete's diet is usually cut down on this account. *Alkalis* have frequently been used and the experimental evidence on the whole indicates that an artificially-induced alkalosis, in some cases at least, increases physical efficiency and output, presumably by neutralizing excess of lactic acid produced by muscular action.

*Ammonium chloride*, though not hitherto used in athletic contests, is of established value in resisting the effects of high altitudes in aviation and in mountaineering, and in moderate doses appears to be quite harmless. Haldane's explanation of the beneficial effect of ammonium chloride is interesting: the low oxygen pressure resulting from high altitudes causes increased respiration and this causes the amount of carbonic acid expelled by the lungs to rise; the consequent alkalosis then inhibits any further increase of pulmonary ventilation. The administration of ammonium chloride retards the development of this alkalosis; the degree of ventilation can therefore rise further and the alveolar oxygen pressure can increase.

2. *Administration of oxygen*.—A considerable amount of experimental work has been carried out on the value or otherwise of oxygen in athletic contests. At the last Olympic games the Japanese swimmers were said to have been 'pumped full of oxygen' in their dressing-rooms immediately before the races started, and this led to discussions in the press on the value and on the propriety of 'oxygen-priming' as it is called. Different investigators have recorded widely different conclusions on this subject, and in general it may be stated that it is highly questionable whether 'oxygen-priming', under the conditions which must obtain in actual practice, is of any value in sports events, except, possibly, under-water swimming. All observers seem to be agreed that it is at least harmless.

3. *Artificial sunlight*.—Experimental investigation shows that exposure to ultra-violet radiation endows the organism with an increased capacity for work, and if administered in suitable doses and kept within moderate limits it should not present any dangers. Signs of marked fatigue may follow the first sittings; only after some time will an improved zest for exertion and an increased sense of well-being make their appearance.

4. *Administration of pharmaceutical substances*.—This group comprises many drugs which are very poisonous, the use of which represents at present the extreme limits of 'doping'.

*Alcohol* has a very limited range of utility as its toxic effects overshadow the part it plays as a source of energy, and it has been conclusively

shown that every type of physical work associated with mental effort or requiring delicate muscular co-ordination, is unfavourably affected by alcohol. The best that can be said of alcohol is that, as regards purely muscular effort, it may cause a transitory increase in output, followed later by an inevitable lowering of efficiency, and these characteristics of alcohol are generally recognized in the world of athletics. *Ammonia* in the form of smelling-salts is a well-known and harmless stimulant of the central nervous system acting through the nasal mucous membrane; it is widely used by boxers between the rounds of a contest. *Cocaine* is one of the oldest and most dangerous forms of 'dope'. Like opium in India, cocaine is used in South America by miners and others performing heavy physical labour under particularly arduous conditions. It has also, it appears, been largely used by athletes in contests demanding extreme powers of endurance, such as six-day cycle races. Its effect on metabolism is uncertain and probably unimportant; it is mainly effective by removing the sensations of fatigue and hunger, so that heavy work can be performed for very long periods. The dangers to the individual of the abolition of nature's safety-valve, fatigue, to say nothing of the great risk of addiction, are so manifest that the use of cocaine in connection with athletics ought to be prohibited. No Olympic laurels could be weighed in the balance against the tragedy of even one case of cocaine addiction.

*Caffeine* and other purin-derivatives are, of course, commonly used in the form of tea, coffee, cola and chocolate as well as in the pure state as stimulants in connection with physical and mental effort, and there is ample experimental evidence that drugs of the caffeine group actually increase the capacity for sustained effort and defer the exhaustion-point. It is questionable, however, whether drugs of this group can be administered in their pure state without risk to health, though there is no reason to avoid them in the form of tea, coffee and chocolate. *Benzedrine* is capable, even more than caffeine, of eliminating the sensation of fatigue, particularly in tests involving intellectual work, but its effects on muscular work have not so far been fully studied, and there is no evidence that performance is improved. The secondary effects which so often accompany its administration, such as tachycardia, vertigo, restlessness and insomnia, are of such a character that, apart from the risk of eliminating fatigue-sensation, the drug is not suitable for use in connection with athletics.

Since the circulatory system often sets a limit to athletic performance efforts have been made to increase the range of circulatory efficiency by the use of drugs acting on the circulation. *Digitalis* has been tried but, as might be expected, appears to have no action on a healthy heart subjected to abnormal exertion, and its

use, perhaps fortunately, seems to have been abandoned, as it cannot be considered an innocuous drug. *Nitroglycerine* is sometimes used in sprint cycle races and is said to relieve shortness of breath after violent efforts of short duration, but its secondary effects, such as vertigo, vomiting, hypotonia and even circulatory collapse, are so formidable that few athletes are likely to take it more than once, except in minimal doses. *Coramine* and *Cardiazol* have been extensively used by athletes in recent years for their stimulating influence on the circulation and central nervous system, and for the subjective feeling of freshness which they induce in the tired organism, and there is some evidence that there is an actual and objective increase in the capacity for prolonged effort. The use of drugs of this character cannot be considered harmless; they are known to possess convulsive properties apart from the risks of the attenuation of the normal regulative action of fatigue, which is the main purpose for which they are used.

*Hormone* treatment for healthy athletes has been employed. The British Press not long ago announced that the remarkable performances of the Wolverhampton Wanderers football team were due to 'gland extract' treatment provided by their enterprising manager, and the Portsmouth team decided to follow their example. The nature of the extract used was not stated, but it was understood to be a testicular extract, and if so, their improved performance might well have been due to the purely psychological effect of such treatment. The administration of oestrus-producing substances to women athletes is on a rather different footing. It is used to alter the time of onset of menstruation if this should coincide with the date of the contest, and it appears to be effective. It is doubtful, however, whether even that degree of interference with natural processes can be undertaken without risk to health.

To sum up, there are a considerable number of substances which athletes actually use or are urged on them by their trainers; in some cases their use does not endanger health, in many other cases they are known or believed to be injurious. The principle should evidently be to avoid the use of any stimulants whose action is directly associated with risks of toxic effects and indirectly with the danger of 'whipping up' the organism to extreme exertion. The least objectionable group would seem to be the nutrient preparations, non-toxic salts and oxygen.

The ethical considerations of 'sportsmanship' involved in the use of these or other means of artificially raising the level of athletic performance can be left to public opinion and it is to be hoped that if 'doping' is carried to further extremes public opinion can be trusted to rebel.

## MEDICAL NOTES FROM THE DIARIES OF THE THREE SURGEONS OF PATNA—1763

By D. V. S. REDDY  
*Vizagapatam*

THE diaries of Anderson, Campbell and Fullerton commence from the last week of June 1763, when matters were rapidly coming to a crisis between the English and the Nabob of Bengal. These journals faithfully record the eventful days of the massacre of Patna . . . and the other associated disasters, till the arrival of the victorious English Regiment under the command of Major Adams.

The diaries start from 23rd June, 1763, the anniversary of the battle of Plassey. Certain feverish activities in the English camp and the anxious look of the important actors in the drama, betrayed that the English colony at Patna were apprehending some immediate danger.

Next day Patna was attacked by the English. Fullerton wrote on this day as follows:—'About 10 o'clock at night on the 24th Mr. Ellis sent for me from the *Hospital* and ordered that the sick might be embarked in boats and carried over to the sand opposite to the city and from thence tracked up and crossed over to the factory'. Fullerton was to embark at 2 a.m. just the hour fixed for attacking the city. This plan was accordingly executed. The sick consisting of 23 Europeans reached the factory at 9 a.m. the same day (25th). Campbell also made the following entry:—'Numbers of *wounded men* were coming out of the city which employed Fullerton and Anderson and myself for the day'. Fullerton graphically describes the wretched condition of the English factory after the failure of the attempt to gain control of the City of Patna. Some Europeans and 100 sepoys were wounded. 'The confusion of such a number of troops (nearly 2,000) with the sick and wounded in so small a place as the factory, must be easily imagined'.

On the 26th, they got as many boats as they could and embarked at night with the sick Europeans and the factory treasure of one lakh. Dr. Campbell who was marching with the army also writes under 27th June:—'Most of the boats proceeded up the river with the *wounded Europeans* (looked after by) Drs. Fullerton and Anderson'. Anderson's diary also has a note dated 27th, 'Accordingly the sick, the treasure and the howitz with part of the ammunition, were to go by water, for want of coolies while the army marched by land. On account of the sick, I went by water'. Dr. Anderson was much disappointed that evening. 'For, the boat with my clothes *instruments, medicines* and servants did not arrive so that I imagine this must have been stopped'.

On 1st July, Captain Carstairs was injured by a shot (*Jinjal* ball). He was one of the

English heroes of the siege of Calcutta and the battle of Plassey. Anderson thus writes on this topic : 'An unlucky shot hit Captain Carstairs as he was sitting down. It entered the inside of his thigh and passed out at his loins (groins). From the nature of it, it must be mortal'. Campbell also notes under date 1st July :—'About 11, we had the disagreeable news of poor Carstairs being *mortally wounded*. He was soon after brought over and *upon dressing him I found the wound to be mortal*. He was brought aboard Captain Wilson's *budgero* and *begged of me that I would not leave him*'.

Later in the day, when the enemy began a severe fire and vigorous onslaught, the boat which carried Captain Carstairs, Dr. Campbell and Anderson pushed off to a distance and tried to run up to Patna. The boat ran aground on the way; they were wavering to go ashore or not. 'But could not think of leaving Carstairs who though mortally wounded was perfectly sensible. It must have added to his uneasiness to have his friends leave him helpless in such distress'. Next morning, the boat was hailed by a party of the enemy and after some consultation, the boat proceeded further down the river and arrived at Hadgipore, where they were kindly received by *Phousudar's son*. Campbell wrote the following note on the same day : 'Carstairs continues to grow worse every hour'. Fullerton was sent to Patna where he was received kindly by the Nabob. It was from Patna, where he was kept a prisoner in the *killa*, that Fullerton wrote a note to the English party at Hadgipore to come down to Patna, lest the country people might treat them harshly. They came and among them were Anderson, Surgeon and Peter Campbell. Anderson and Campbell, who were with Carstairs till his death on 3rd July, add further details. Anderson wrote :—'Poor Carstairs died *on shore at a small house* that had been provided for him. We had a coffin made and had him buried as decently as circumstances would allow. The same day had chit from Dr. Fullerton, who desired us to come over to Patna'. Campbell supplies some additional details, 'The Phousudar sent a *standing cot* for Captain Carstairs and appointed a house for his being ashore *as his wounds began to mortify and very offensive to us in the boat*. Prevailed upon him to go shore at 12; at 3, he died'. Fullerton also noted in his diary that the party which came from Hadgipore had lost Carstairs, who died of his wounds.

Fullerton met at Patna, Anderson and Campbell on 5th July, explained the position and asked them to go to Monghyr. For nearly a week, the diaries are silent with regard to anything connected with medical matters. Then on 12th July, Campbell wrote of his pain (gout). 'Upon getting up this morning, I was greatly alarmed with a violent pain in the instep of my foot; could attribute no cause for it, unless it was Dr. Anderson's head who lay just by my

feet; as it is pretty heavy it was generally believed to be the cause by lying on it . . . Later, in the day, he added 'The pain of my instep increased to a violent degree and before evening was fully satisfied that it was not owing to Dr. Anderson's head but rather appeared to be a touch of *gout* which I am very sorry for'.

On the 16th, Fullerton was sent to Monghyr. Anderson and Campbell arrived at Jaffar Khan's Garden and suffered from and wrote bitterly of, the extreme heat and the infestation by bugs and flies. On the 22nd, they were moved to a special building for state prisoners, where they had to live on restricted diet and drink. After a few days of waiting for supplies from the Governor, they sent Nicolo, their servant, to the Durbar to the Governor, on 30th July, with the following request :—'We should be glad he would order us an allowance in money for victualising ourselves. Likewise we demanded leave for some liquor'. Anderson queerly adds :—'To-day we sent to the Nabob to request that we might be allowed to send to the Dutch for a little liquor daily as the *custom has rendered it necessary for our healths*'. Both requests were granted; sanction was given for four rupees per day for victuals and two or three bottles of liquor per day. Next day, 31st July, Anderson noted with pleasure that they got a case of gin from the *Dutch Doctor* for 50 rupees. Campbell refers to the same event in a very sarcastic passage :—'Don Nicolo purchased a case of gin from *Dutch Snout's Scraper* for Rs. 50'. The Dutch doctor was a Jew. Anderson noted again on the 2nd August :—'Brought to-day six bottles of very good Madeira for three rupees per bottle'. Campbell's diary for the 3rd and 4th August, throws a sidelight on Anderson's moods and eccentric character. 'Anderson was a little out of humour this day and did not eat his dinner as usual, owing to a mistake made in describing a house that he and some gentlemen built at Neg . . . Nothing material to-day except that Anderson was highly offended with me at dinner for wanting to drink out of the cup before what he calls his allowance of gin'. Anderson has no entries on both these points. About 10th August, Fullerton was allowed to see Mr. Ellis's party, who were confined at Monghyr. He notes that he was allowed to see Mr. Ellis and party, as *Mr. Turner was ill*. Later, Turner died of *dysentery*.

It is in the entry for 11th in Anderson's diary that the details of the attack and ghastly murder of Amyatt are given. After the middle of August the diaries of Campbell and Fullerton are blank. Anderson makes an entry dated 23rd August :—'Fair and clear weather to-day which gives us great joy as the rain for these four days past has occasioned such a damp, as affects our health, *Campbell being sick*'. On the 31st again, he noted receiving some intimation from Fullerton. On 19th September, Dr. Fullerton was sent from Monghyr to Patna and

confined alone in the *killa*. He records the details of the tragedy on the 5th October, the Patna massacre, 'an outrage against humanity'. Anderson made the following poignant and prophetic entry on the 6th morning :—'Heard this morning that Mr. Ellis and 47 other gentlemen were cut off last night, so that, doubtless, our fate must be in 24 hours for which God prepare us all'. Campbell is believed to have been murdered at Chalisatoun, along with Captain Wilson and some six or seven other Englishmen.

Anderson was killed at Patna. Only Dr. Fullerton, a favourite of the Nabob, with great influence at court and powerful friends was spared. On the 7th, he had an interview with the Nabob which is described by him in the diary: Fullerton was finally permitted to stay at the Dutch factory at Patna. A week later, on the 15th, Dr. Fullerton made his escape from the Dutch factory to the camp of the English Army, which had successfully routed the native forces and arrived on the other bank of the river.

### THE SCHEME FOR THE CONTROL OF TUBERCULOSIS BY ORGANIZED HOME TREATMENT

It is only possible to give a brief outline of the Scheme for 'The Control of Tuberculosis by Organized Home Treatment' with an explanation of its necessity, its principles and its essential activities. This scheme was approved at a meeting of the Central Committee of the Tuberculosis Association held in New Delhi on 27th March, 1940.

#### THE NECESSITY FOR THE CAMPAIGN

Again and again it has been argued that a tuberculosis campaign in India will be useless until the hygienic and economic and social conditions have so improved that a higher standard of living becomes possible. Then it is said that tuberculosis will fade away by itself and therefore all previous efforts to prevent and treat the disease will only be waste of money and energy. But in no country in the world has tuberculosis disappeared with the raising of the standard of living. Only where there has been a vigorous attack on the disease itself by various anti-tuberculosis activities has the prevalence of the disease been reduced.

Without in any way minimizing the support the tuberculosis campaign derives from a raised standard of living it must be emphasized that a direct attack on the sources of infection is absolutely necessary to bring the disease under control. In a country like India, where a raising of the general standard of living is likely to take generations, and where tuberculosis is on the increase, it would be disastrous not to organize a campaign which would strike at the real cause of the spread of tuberculosis, the centres of infection.

#### The principles of the campaign

The principle, therefore, behind the whole campaign in India must be to search out the tuberculous patients in order to fight the disease where it exists and is spreading. But if the many and costly anti-tuberculosis measures found necessary in the West for such a campaign be compared with the meagre resources of money and personnel in India, who can wonder if administrators and others have despaired of even beginning a tuberculosis campaign in India. It is, however, a serious mistake to think that no effective campaign could be carried out in this country without transferring wholesale all the Western anti-tuberculosis measures, some of which are quite unsuitable to present Indian conditions. We can begin with those which have already proved of value in India and those which can easily be adopted and developed.

By beginning in this way it will be possible to fight tuberculosis in India by a campaign based on the right principles and to build up a balanced scheme with power enough to break the present almost unopposed onslaught of the disease. In a few years it should be possible to reach hundreds of thousands of the most

dangerous sources of infection and by helping them in their own homes prevent their spreading the disease to others.

Such a scheme of control of tuberculosis by organized home treatment is not the ideal one, but it is the only one which from a practical point of view has any prospect of success under existing conditions and for a long time to come. It is true, as has been clearly demonstrated in the West, that institutional treatment and isolation of tuberculous patients bring far better results than any home treatment, but while such measures to any great extent are for the present impossible in India, all efforts should be concentrated on a scheme which will be immensely more effective than what is at present being done. In time this will naturally be improved and developed along lines known to be the best.

Moreover, the scheme does not consist merely of ordinary treatment in the home but of prevention and 'organized' home treatment. The word 'organized' implies the application, as much as possible, of the modern specialized treatment and prevention to thousands of homes where at present patients are often left alone without any treatment whatever and without any preventive measures.

#### The essential activities

The scheme needs five main activities for its successful working, namely:—

- (a) The tuberculosis clinic.
- (b) Institutional treatment for a certain number of selected patients.
- (c) Close co-operation between the clinic and the private practitioners.
- (d) Care and after-care committees to work in connection with the clinics and other tuberculosis institutions.
- (e) Colonies or settlements for tuberculous ex-patients.

The particular importance of each of these activities in the campaign in India needs perhaps a brief explanation.

#### (a) The tuberculosis clinic

The tuberculosis clinic must have as its object prevention and, to a certain extent, treatment.

It is not necessary to go into detail about the various measures of prevention, which the clinic should introduce in the homes of patients under the supervision of the doctors treating the patients, but two measures of prevention need to be mentioned.

One is the tuberculosis survey to be conducted by the clinic. Only by this is it possible to detect many persons carrying on their work and having tubercle bacilli in their sputum; they may not know that they are sick or that they are suffering from tuberculosis. Such 'carriers' are very dangerous sources of infection to any who are in close contact with them in their offices, work-rooms, and homes. The discovery of such carriers and the diagnosis of tuberculosis is a preventive

measure of the greatest importance. In every large city in India there should be a tuberculosis clinic equipped with all modern facilities for diagnosis, and which could be a consulting institution also for the doctors in the city.

The other measure of prevention needing mention is treatment which a clinic in India must give under the present circumstances. Artificial pneumothorax may be given as an example. By introducing this treatment, and in co-operation with the private practitioners controlling its effect, a great number of patients will be helped to get better in their homes, and approximately half of them will cease to have tubercle bacilli in their sputum and so cease to be sources of infection to others.

#### (b) *Hospital wards and sanatoria*

It is now possible by certain chest operations to cure many advanced patients in whom all other treatment has failed. These operations cannot be performed in a clinic but only in a fully equipped tuberculosis hospital or sanatorium. In the scheme of control of tuberculosis by organized home treatment these institutions therefore have their place.

In or near every large city there should be such a tuberculosis institution with 100 to 200 beds, but these beds should be reserved only for patients in need of the special treatment which cannot be given in their homes or in the clinics, and after the special treatment the patients should return home for further treatment by practitioners in consultation with the clinic doctor. In this way a small number of beds can become of the greatest value and play an indispensable part in the campaign.

These tuberculosis wards and sanatoria are also of great importance for the teaching and training of doctors. Without them the doctors in the city or province would have no opportunity of learning the modern methods of treatment and prevention for application in their practice. Teaching should, therefore, be given through post-graduate courses in these institutions and in the clinics.

For the training of tuberculosis specialists each province or larger state should have a well-equipped central sanatorium with at least 200 beds. Patients should be admitted to these institutions for their whole period of treatment and not just for the time of special treatment. Apart from the value to the patients themselves it is necessary that the doctors under training should follow the treatment from beginning to end.

Only doctors who have had long training and experience in such central institutions should be placed in charge of tuberculosis wards or sanatoria. These teaching sanatoria are best situated away from large cities in good climatic conditions.

#### (c) *Co-operation between clinic doctors and private practitioners*

No anti-tuberculosis campaign anywhere in the world has succeeded without close co-operation between the clinic and the private practitioners. The private practitioner must come to understand that the clinic is his best help and if this is to be so all competition between the two must be avoided. The clinic doctor should not be allowed private practice but should be compensated in this respect. Close co-operation with the clinic will increase the reputation of the private practitioner as the public will soon discover that his patients receive better and more specialized treatment.

Special arrangements will need to be made for poor patients who cannot afford to pay any fee to the private practitioners. Unless these patients also are reached the campaign cannot succeed. The doctors who visit these patients, of whom there will be many, should have some remuneration. This should be done through a care and after-care committee in connection with the clinic. This committee should pay a small fee to the doctor who visits and treats the poor patients, but only on the recommendation of the clinic doctor. He will assure the committee that the patient is really suffering from tuberculosis, that the patient is receiving the best treatment possible under the circumstances and that

the proper preventive measures are being carried out in the home.

#### (d) *Care and after-care committees*

Besides the work of a care and after-care committee in maintaining a close connection between the clinic and the private practitioner in caring for very poor patients already mentioned, it has other important functions. Among these are helping the poor patient and his family either by food or by money, helping to isolate children from sick parents by placing them with relatives if possible or by caring for them in open-air shelters in day-time, and in finding suitable employment for patients restored sufficiently to work.

For expenditure connected with such work the committee will need a fund. When it is seen that the most effective way of distribution of help to tuberculosis patients is through such a committee working in close co-operation with the clinic and other tuberculosis institutions, it will come to be realized that the committee should receive grants from Government and local bodies as well as subscriptions from the public. Support given to such a committee is not merely a charity but is also a self-defence against the disease.

#### (e) *Colonies for tuberculosis ex-patients*

There are always a number of patients who have very little hope of being able to maintain the good results of treatment when again exposed to the strain of their old conditions. They break down and as tubercle bacilli usually reappear in their sputum, they become once more a source of danger to those among whom they live.

It is now more and more being recognized all over the world that in many patients the ultimate results of treatment depend to a great extent on the after-care, and that without this much of the expenditure of skill, time and money in treatment is wasted. In the effort to help this class of patients various after-care schemes, such as colonies for ex-patients, have been brought into being. Experience has shown that a colony for ex-patients succeeds only when linked with a sanatorium and is justified only if it develops as a part of a combined institutional scheme.

The financing of an ex-patients' colony depends, of course, on the size of the scheme, but it is not impossible to introduce such colonies in India if adapted to existing conditions. There is already evidence to show that the beginning of a colony in India can be made at a very low cost and that one may develop to be self-supporting, or nearly so, in maintenance expenditure. Such a colony should be constructed in simple village style with ordinary village houses only slightly altered to make them more open.

There are two great principles behind a colony, namely, medical help at hand for the colonists and work which gives financial security for them.

A scheme of prevention would not become fully successful without such ex-patients' colonies. They should therefore be introduced gradually in connection with each large sanatorium.

#### *Co-operation*

One of the watchwords of the whole tuberculosis campaign is education but in India it is more necessary to emphasize again and again co-operation. In the West this is a factor which now works automatically, co-operation between the tuberculosis institution and the public as well as their doctors on the one hand, and on the other between the tuberculosis institutions and Government, local bodies, and voluntary tuberculosis associations.

Co-operation is the pivot on which the whole tuberculosis campaign must turn if it is to be successful.

#### MANUFACTURE OF DRUGS IN INDIA

A list of important drugs used by the Medical Stores Department in India was prepared by the Drugs Supply Committee at its meeting in Simla. The list is to be sent to manufacturing firms in India in order that they

may investigate the possibility of manufacturing these drugs in India.

The first meeting of the Drugs Supply Committee was held to consider the question of the supply of drugs, chemicals and biological products to the Medical Stores Department. Major-General G. G. Jolly, C.B.E., K.N.R., I.M.S., Director-General of the Indian Medical Service, presided.

The Committee considered, at length, the report of a departmental committee appointed in February 1940 by the Director-General of the Indian Medical Service to investigate the sources of supply of drugs, chemical and biological products for the Medical Stores Department, the use of suitable substitutes where essential drugs were not available and measures of economy in the use of drugs during war time.

In order to assist medical officers, lists of essential drugs, chemicals and sera were drawn up giving substitutes to be used where they were not readily available. A list of British or Indian equivalents or alternatives for foreign proprietary remedies commonly used in hospitals in India was also drawn up for ready reference.

A list was also prepared of imported drugs which are expected to become progressively more expensive and difficult to obtain either through shipping difficulties, war demands or world shortage in order to warn medical officers of the necessity of restricting their use as far as possible.

### PRODUCTION OF CHEMICALS

It is expected that twelve important industrial chemicals will be in production in India by the early part of 1941. Already one plant is producing sulphuric acid from indigenous raw material; namely, Simla pyrites.

The Department of Supply have interested Indian chemical manufacturers in the production of bichromate and it is anticipated that one well-known Indian firm will be in production early next year on a scale which will enable the whole of India's normal demand to be met.

A prominent textile firm in the south of India, by far the largest individual consumer, is taking steps to instal a plant to produce its own requirements of bichromates, and it is hoped to commence production in August. A large Indian chemical firm is also importing and distributing these compounds on normal terms of business but will only sell on instructions from the Department of Supply.

This industry, which is being promoted with direct encouragement from Government, will be assured that if it is conducted on sound business lines it will be protected by Government against unfair competition from outside India.

### RECRUITS SUFFERING FROM TRACHOMA

THE increase in the percentage of rejections at recruiting centres for trachoma in the last two or three years has caused considerable concern to the Indian Soldiers' Board.

The number of rejections of candidates due to this eye disease in the Delhi area in 1937 was nine times greater than those rejected in the previous year. The figure for 1938, though less than that of 1937, was seven times the figure for 1936.

The matter was taken up with the Public Health Commissioner with the Government of India, who pointed out that the figures for the general population could not suggest any abnormal increase in the number of cases treated for trachoma in the Punjab and Delhi areas.

The increase in the number of promising young men rejected because of trachoma, however, suggests a

marked increase of the disease in the recruitable male population in the Delhi recruiting area.

The percentage of rejections at all recruiting centres in India from all causes rose from 35.73 in 1937 to 43.5 in 1939. Rejections due to trachoma made up five per cent of this total.

Next to Delhi, Jullundur recorded the largest rejections on grounds of trachoma and Ajmer and Poona the smallest.

### CHEAPER QUININE

A FIVE-YEAR programme to develop cinchona cultivation, to be taken in hand at once, has been recommended by the Advisory Board of the Imperial Council of Agricultural Research.

Rising prices and a growing scarcity of supplies, caused by the war, have made the attainment of self-sufficiency in respect of quinine a necessity for India, and to this end a plan of research has been drawn up, with the objects of increasing the output of cinchona per unit of land, and of reducing the cost to the consumer.

The plan proposes that two research stations should be set up, one in the north of India and one in the south, both to work on the same plan and not independently of each other. To each station will be attached State nurseries, and test-plots will be laid out in selected areas.

The research stations will carry out a comprehensive programme of research, involving work of a fundamental nature. The immediate object of the State nurseries will be the supply of planting material to new concerns, but ultimately it is intended to place the present empirical methods of nursery work on a scientific basis. The test-plots will be used to determine the suitability of land for growing cinchona.

It may be said that cinchona-growing in India has failed to move with the times; that it has developed as an art, rather than as a science. The early success of the grower has ultimately proved to be a misfortune, in the sense that attention was soon diverted from the more technical aspects of cultivation and utilization to the problem of large-scale production.

Mr. A. Wilson, on whose report on the prospects of cinchona-growing the proposed programme is based, suggests that India's failure to utilize modern advances in science is no doubt due to concentration on the routine of production and distribution, by an inadequate staff of workers.

This, he adds, was perhaps of no great consequence while the demand on the local industry was small, but now that the need for more adequate and cheaper supplies of cinchona alkaloids is being keenly felt an immediate change of policy is called for.

### INDIAN FISH OILS

FOLLOWING the discovery at Fanur Research Station (Madras) of four more Indian fish the oil from which has from 3 to 19 times the vitamin potency of cod-liver oil, a scheme has been prepared to popularize the manufacture of medicinal fish oil in fishing villages, as a cottage industry. The presence of vitamin A in appreciable proportions in Malabar sardine oil has been confirmed by investigations at Fanur.

Practical steps have been taken in Bombay, Madras and Bengal to develop the Indian fishing industry. In Bombay, as a result of the introduction of motor-launches to carry the catch to market, the price realized for fish has in some cases been increased from Re. 1 per thousand to Rs. 12 per thousand. There are indications that there would be considerable scope for the sale of fish if suitable marketing and transport facilities were available.

Survey work on fish marketing, under the direction of the Agricultural Marketing Adviser to the Government of India, has been started in the provinces and states.

# FOREIGN AUXILIARY TO THE NATIONAL RED CROSS SOCIETY OF CHINA

*A Survey of the West River District made by Dr. R. L. Cockfield of the United Church of Canada*

DR. COCKFIELD left Hongkong for the West River area on 27th December of last year, the purpose of his visit being:—

1. To ascertain at first hand the use to which drugs already supplied by this committee had been put.

2. To discover what further assistance is needed by the various agencies caring for refugees, sick and wounded, and in what way they could best be helped.

3. To ascertain if any large section in need of medical aid is at the present time not being served by any agency, and in what way this particular need can be met.

4. To make available such medical advice as could be given, where such was needed, and more especially where there is no doctor on the spot.

We give an account of his trip in Dr. Cockfield's own words:—

'From Macao by launch, tow-boat, sampan and walking, we reached Yan P'ing three and a half days later.

The Yan P'ing Hospital is situated on the very outskirts of the town, in buildings that were formerly used as a bus station. Very useful work has been done here in the past six months, but as Yan P'ing is now so far removed from any scene of action, and after some unfortunate experiences in removing the wounded to this hospital, the authorities finally decided that they could not send the wounded so far. It was decided to transfer part of the Yan P'ing hospital to Kung Yik. So Dr. Sporer with one nurse and four first-aid workers, are now at Kung Yik; the rest of the staff, including one Chinese doctor, are supplied by the local authorities. Dr. Sporer will return to Yan P'ing for a few days in each month to give general oversight to the work there. I called at Kung Yik on my way out and found that the hospital was already busy with both wounded civilians and soldiers.

From Yan P'ing we went to Yeung Kong, where there are two agencies for the care of the sick:—

1. The American Presbyterian Hospital, with a 50-bed capacity.

2. The American Maryknoll Mission Dispensary. Both these are doing excellent work and are quite adequate to the needs of the district.

We next retraced our steps via Yan P'ing to Sun Cheung, which is the centre of the very thickly-populated area. But there is at present no hospital or dispensary worth the name. It was decided that if he were so authorized, Dr. Sporer could fill a great need by opening and overseeing a clinic in Sun Cheung. The Foreign Auxiliary has arranged to supply the necessary drugs for this clinic at Sun Cheung.

From Sun Cheung we went to Tak Hing, on the river, three and a half days away. In Tak Hing there is a 30-bed hospital. We found a very small number of in-patients, but a rather well-attended out-patient department. Tak Hing has remained almost untouched by the war, but has many refugees, chiefly from Canton.

Next we went further up the river for about five hours to Do Sing, where we ran into a situation fortunately not frequently encountered in the West River area—a town of about 35,000 with about 10,000 refugees, where there is no organization for care of the indigent sick or wounded. Learning of a Maryknoll Mission at Wat Naam, which is about five hours inland from Do Sing, we went over for a talk with Father Rauschenbach, who is well aware of the situation at Do Sing and would be glad to furnish the necessary trained dispenser and personnel over-sight if he can get the drugs and a centrally-situated shop for dispensary. The Foreign Auxiliary has therefore granted to Father Rauschenbach the sum of N.C. \$36 per month for a minimum of six months for rent of a shop, as well as the necessary drugs for the relief of indigent sick and wounded in Do Sing.

At Wat Naam itself the Maryknoll Mission runs the only free dispensary under Dr. Rauschenbach, as well as two others in the surrounding country. Wat Naam has a population of about 20,000 and harbours a great many Canton refugees.

Our next visit was to Wuchow. This city has suffered the most from air-raids of any city which we have seen. However, in spite of the repeated bombings, the city is well populated, but has a large number of desperately poor, who require more than ever before the ministrations of the various medical agencies now at work here. The Stout Memorial Hospital, under the American Baptist Mission, has a 40-bed capacity and is fully staffed and equipped. At present it is receiving N.C. \$50 per month from the International Red Cross of Canton for the care of sick and wounded and refugees. Some quinine has also been received from them, but this is now almost used up. The Maryknoll Mission also maintains a very good dispensary here, with French Canadian sisters in charge, who are qualified in dispensing. This mission is also the centre for seven dispensaries in the district farther up the river, all in the charge of qualified dispensers. The Municipal Hospital at Wuchow we found to be the best staffed and equipped yet encountered in South China.

The Military Hospital is just outside the city and has a 2,000-bed capacity. Nearly all the cases at present are medical, chiefly malarial and dysenteric. The place is well and efficiently run, but lacks supplies of drugs. We suggested that, rather than allow the patients to suffer because of these deficiencies, the Stout Memorial Hospital should supply them with urgently needed drugs from their own stock and that this committee should make good any such contributions. The Foreign Auxiliary has agreed to supply these extra drugs.

From Wuchow we went by tow-boat down the West River to Lok To, eight hours away, and then inland to Wan Fou, where there is a small dispensary of the Maryknoll Mission, which is quite adequate to the needs of the 15,000 inhabitants.

Thence we went further inland to Sun Hing, which is a large town of 50,000 inhabitants, where there is a poorly equipped and poorly staffed Municipal Hospital, not adequate to the needs of a town which has suffered badly from bombing. A dispensary will fill a real need here, so we approached the Southern Baptist Mission with this problem and they will supply the necessary dispenser and premises for the dispensary, if the Foreign Auxiliary will supply the drugs.

As a result of my experiences I made the following observations:—

1. The drugs already supplied, chiefly quinine, have saved thousands of lives and relieved an unassessable amount of suffering. They have been dispensed with extreme caution, my only criticism being that, if anything, they were being too careful, especially with the quinine. All the dispensers are well qualified to diagnose simple ailments and supply the required drugs.

2. The diseases most commonly encountered, in order of frequency, are:—

Malaria, intestinal parasites, chiefly round-worm and hook-worm, typhoid, dysentery, mostly amoebic, skin diseases, eye troubles, mostly trachoma, chest cases, tuberculous and others, Bright's disease, massive oedema, smallpox, at present epidemic in some places, beri-beri, mostly among the soldiers, general mal-nutrition, prevalent all over the district.

3. Although one can scarcely imagine such a large area ever having a really adequate medical service even in normal times, one is impressed by the tremendous amount of really good medical work being done. Given support, the agencies already existing, with one or two additions, can and will fulfil a vital function in the provision of medical service to the sick and wounded. This support must be forthcoming if they are to continue this work, as unprecedented demands are being made on their resources, which they cannot meet without our help.

The Foreign Auxiliary has undertaken to supply drugs to the value of H.K. \$10,239.60 to the West River District, in addition to a total of 1,000,000 tablets of quinine for the next six months.

#### *Our appeal*

These drugs will help the wounded sick and civilians and refugees in the West River District to regain health and to become once more useful citizens of the New China. But the Foreign Auxiliary needs funds to renew stocks, which are becoming sadly depleted at a time when it is absolutely essential to continue supplies to every distressed area in China.

[Note.—Messrs. Thacker's Press and Directories Limited, the proprietors of the *Indian Medical Gazette*, are sending a donation to this worthy cause and will be pleased to transmit any sums sent to them by our readers, in response to this appeal.—Editor, *I. M. G.*]

### THE PHARMACEUTICAL AND ALLIED MANUFACTURERS' AND DISTRIBUTORS' ASSOCIATION, LIMITED

We have received a copy of the Memorandum of Association and Articles of Association of the Pharmaceutical and Allied Manufacturers' and Distributors' Association, Limited, recently formed in Bombay. The seven members represent some of the principal drug distributing agencies in Bombay and in our opinion this association cannot fail to be of great assistance to the drug trade in Bombay in particular and it will have a wide sphere of influence, as a properly constituted body of this nature will have much greater power in influencing Government in the interests of drug manufacture and distribution than isolated firms would have. It is a move in the right direction and a step in improving drug distribution in India and we wish it all the success it deserves.

### EMERGENCY COMMISSIONS—INDIAN MEDICAL SERVICE

In view of the many applications received for emergency commissions in the Indian Medical Service from medical men who fulfil all the conditions for the grant of such commissions except that they are over age, the Government of India have decided to grant the Selection Board powers to relax the age limit up to 40 years of age in the case of candidates suitable in all other respects.

Medical men above the former maximum age limit of 32 and up to 40 years of age will be eligible for commissions on the same terms as younger men, that is to say, on selection they will be given the pay and allowances admissible to short service commissioned officers in the regular cadre of the Indian Medical Service and on release after the war will receive a gratuity at the rate of one month's pay for every 12 months' service. They will also be eligible for disability pensions, while widows' and other dependents' allowances will be admissible under the same conditions as for permanent officers of the Service.

While during the war Government are accepting no new commitments as to the grant of permanent commissions, selection for appointment to permanent vacancies in the Service will on the conclusion of the war be made from among all officers holding emergency commissions.

Emergency commissions only are being granted during the war. Selection for commissions will be made on the recommendation of the Indian Medical Service Selection Board from amongst candidates who apply to the Director-General, Indian Medical Service, Simla, for appointment.

### INDIAN MEDICAL BIRTHDAY HONOURS, 1940

The following are the names of medical men and others associated with medical institutions in the Indian

Honours List of date 11th July, 1940. We offer them our congratulations:—

#### *C.I.E.*

Colonel (Honorary Brigadier) H. C. Dibben (Retired list), lately Director of Veterinary Services in India.

#### *Khan Bahadur*

Syed G. Hussain Sahib Bahadur, Civil Surgeon (Retired), Madras.

#### *Rai Bahadur*

Rai Sahib H. Singh, District Medical Officer of Health, Lahore, Punjab.

Rai Sahib S. Pujari, Professor of Anatomy, Prince of Wales Medical College, Patna, Bihar.

Mr. N. Ghosh, Teacher, Berry-White Medical School, Dibrugarh, Assam.

#### *Rao Bahadur*

Mr. R. A. G. Ayyar, District Medical Officer (Retired), Madras.

Mr. N. R. Summanwar, Civil Surgeon, Wardha, Central Provinces and Berar.

#### *Shifa-ul-Mulk*

Hakim M. N. Zahiri, Member, Board of Indian Medicine, Meerut, United Provinces.

Hakim M. H. Qarshi, Principal, Tibbia College, Lahore, Punjab.

#### *Khan Sahib*

Syed R. Hussain, Medical Officer in Sub-charge, Bulrampur Hospital, Lucknow, United Provinces.

Mr. C. M. Ahmad, Hospital Surgeon, Punjab Veterinary College, Lahore, Punjab.

Maulavi M. A. Hai, Lecturer in Pharmacology, Prince of Wales Medical College, Patna, Bihar.

Jemadar G. Muhammad, in charge, Swat State Hospital, North-West Frontier Province.

#### *Rai Sahib*

Mr. K. Prasad, Medical Officer in charge, Health Unit, Partabgarh, United Provinces.

Mr. D. Chand, Sub-Assistant Surgeon, Civil Hospital, Allanmyo, Burma.

Babu L. Ram, Assistant Surgeon, Sadar Hospital, Ranchi, Bihar.

Babu J. N. Sen, Assistant Surgeon, Sub-divisional Hospital, Dhanbad, Bihar.

#### *Rao Sahib*

Mr. H. N. A. C. Ayyangar, Lecturer in Anatomy, Madras Veterinary College, Madras.

Mr. A. S. Barot, Medical Practitioner, Dohad, Broach and Panch Mahals District, Bombay.

Mr. P. A. Patadia, Medical Practitioner, Wadhwan Civil Station, Western India State Agency.

## Current Topics

### The Therapy of Dropsy

By H. M. MARVIN, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CXIV, 2nd March, 1940, p. 757)

Dropsy, or œdema, is usually defined as the accumulation of serous fluid in the intercellular spaces of the subcutaneous or deeper tissues and in the serous cavities. The source of this fluid is the blood, from which it has escaped by passage through the walls of the blood vessels. Œdema is always but one manifestation—although sometimes the most dramatic and important—of some abnormality or disease process, and its removal by medical means should logically begin with treatment of the causative process. Specific

measures for its removal are necessary only if its location or extent render it harmful or uncomfortable to the patient and should ordinarily be employed only after correction or treatment of the underlying abnormality.

There are many conditions with which oedema may be associated, but only a few of these will be considered in this review, which is concerned primarily with the practical aspects of medical treatment. The conditions to which attention will be devoted comprise congestive heart failure, acute and chronic nephritis, cirrhosis of the liver, the Pick syndrome of constrictive pericarditis, vitamin deficiency and marked lowering of the protein content of the blood plasma, whether this is found in malnutrition, in chronic glomerulonephritis or in so-called lipid nephrosis.

For a clearer understanding of the discussion that follows, it is desirable to review briefly the mechanisms involved in the formation of oedema. The opinion first expressed clearly by Starling in 1896 has received the almost unanimous support of investigators in recent years; in its simplest form it may be stated as follows: The capillary wall is a membrane freely permeable to water and to most of the crystalloids of the blood, such as salt, sugar and urea, which pass from the capillary into the surrounding tissue spaces, or from these spaces into the capillary, in response to physical laws now well understood. The most important factor causing movement of fluid out of the capillary is the pressure exerted on it; in other words, the intracapillary blood pressure. If this were unopposed, most of the fluid of the blood would readily pass into the tissue spaces. But it is opposed, as Starling first showed, by a force due to presence of proteins, chiefly albumin, in the blood plasma. These protein substances cannot pass readily through the capillary wall; by remaining within the lumen they attract fluid powerfully through the process of osmosis, the force so exerted being known as the colloid osmotic pressure of the plasma. Obviously the direction and extent of movement of fluid through the capillary wall must depend on the balance of these two opposed forces; if the intracapillary pressure is higher than the colloid osmotic pressure, fluid will pass out of the blood stream and oedema will form. On the contrary, a rise in the colloid osmotic pressure above the capillary blood pressure will result in prompt withdrawal of fluid from the tissue spaces into the blood.

It is thought that both these processes are operating continuously in health and in disease. It is impossible to assign any constant value for the capillary blood pressure, since this varies in different parts of the body and in response to many influences, but in the capillaries at the base of the finger nail Landis has found that the pressure at the arterial end of the loop averages about 43.5 cm. of water, while the colloid osmotic pressure is about 34 cm. of water. The result of this difference is to force fluid from the capillary. But when the blood reaches the venous end of the loop the pressure has fallen to an average value of 16.8 cm., while the colloid osmotic pressure has risen because of increased concentration due to loss of water. At the venous end of the capillary, then, fluid will be drawn from the tissue spaces into the blood. It is therefore clear that oedema may result from either or both of two changes: an increase in the capillary pressure or a decrease in the amount of protein in the blood plasma.

This statement has been purposely simplified and abbreviated but is essentially correct. The mechanism that it describes is not the only one concerned in the formation of oedema but is generally regarded as the most important. The other primary and contributory factors have been lucidly reviewed by Landis, whose studies of the capillary circulation have added greatly to our knowledge. He regards as other primary factors injury to the capillary wall, which increases its permeability and obstruction to lymph channels. As contributory factors he mentions low tissue pressure, high salt intake, high fluid intake, a warm environment and disturbances of innervation. It is well to emphasize that the contributory factors may become of great

importance and may actually determine the occurrence or disappearance of oedema.

Thus in the capillary bed there are two important and opposed physiologic processes involved in the formation of oedema; similarly in the kidney there are two fundamental and opposed processes involved in the formation of urine. It is now believed that the renal glomerulus acts essentially as a filter; relatively enormous quantities of a protein-free ultrafiltrate normally pass through it into the tubules, where most of it is reabsorbed, leaving only a small percentage to be excreted as urine. It is apparent that the volume of urine may be increased by either or both of two processes: an increase in glomerular filtration or a decrease in tubular reabsorption.

With this brief outline of the more important mechanisms in mind, we may consider the treatment of oedema associated with various clinical conditions.

#### CONGESTIVE HEART FAILURE

Congestive heart failure is the most frequent cause of oedema sufficient to require treatment; fortunately it is also the condition in which specific treatment is most gratifying. The oedema is thought to be due to several factors, which probably vary in relative importance in different cases. The effective filtration pressure in the capillaries is increased by the rise in general venous pressure that occurs in congestive heart failure and also by the muscular inactivity that generally accompanies it. In addition there is increased permeability of the capillaries to water and crystalloids, and in some cases there is a fall in the effective colloid osmotic pressure of the plasma because some protein passes into the tissue spaces. The hypoproteinemia is probably increased at times by the loss of albumin in the urine and by the low protein diet often prescribed by the physician.

A detailed discussion of the treatment of congestive heart failure is beyond the scope of this article, but it is now generally agreed that this should include complete rest in bed, necessary sedatives, limitation of fluid and of salt intake, and full digitalization. These measures should precede the use of diuretics in most instances, since they will often result in marked diuresis and render further treatment unnecessary. But there are several important exceptions to this statement. If there is considerable fluid in one or both pleural cavities it should be withdrawn at once by means of paracentesis, for such fluid often causes great respiratory discomfort and is but slowly absorbed and excreted, even when diuretics are employed. Furthermore, if the oedema elsewhere is so extreme as to be the cause of danger or grave discomfort, the mercurial diuretics should be administered at once, without waiting for the effect of digitalis. I am in agreement with Thomson that the diuretic effect of these agents is often just as great without digitalis as with it, and the patient may be spared some days of discomfort if they are used immediately.

*Xanthines.*—Until about fifteen years ago the xanthine diuretics, sometimes known as the purine bases, were the only ones in general use. For practical clinical purposes this group may be regarded as consisting of theophylline and theobromine with their derivatives; caffeine is also a member but has little or no value as a diuretic in disease states. Theophylline may be administered in gelatin capsules containing from 3 to 5 grains (0.2 to 0.325 gm.) and may be given two or three times a day. Even in this small dosage, however, it often causes nausea and vomiting after four or five doses have been given and must then be discontinued. Because of the likelihood of vomiting, it is usually wise to give theophylline for periods of only a few days at a time, even if it is well tolerated; there is some evidence that the total diuretic effect is greater with intermittent than with continuous administration. It is the most potent of the xanthine diuretics but can seldom be given in effective dosage because of its unfortunate side actions. In recent years it has been used far more frequently in combination with other salts, the best known preparations being theophylline with sodium acetate and theophylline with

ethylenediamine (aminophylline). These are usually tolerated better than is theophylline alone and can therefore be used for longer periods, but it is well to omit them for a few days after a period of brisk diuresis. Theophylline with sodium acetate is available in tablets containing from  $2\frac{1}{2}$  to  $7\frac{1}{2}$  grains (0.16 to 0.5 gm.); those which have an enteric coating are better tolerated by most patients. The therapeutic dose should be determined in each case by actual trial, starting with small amounts in order to avoid the induction of vomiting. Total daily quantities of from 15 to 30 grains (1 to 2 gm.) can be taken by many subjects without discomfort if given in three or four doses, but amounts less than this often cause satisfactory diuresis. The other preparation, theophylline with ethylene diamine, is better known to-day because of its widespread use in recent years for its supposed effect on the coronary arteries. It is not a potent diuretic but may be of value in preventing the reaccumulation of oedema that has been successfully removed by other agents. It is marketed in tablets containing  $1\frac{1}{2}$  grains (0.1 gm.), and six or eight of these a day are required in most cases for any significant diuretic effect. Like other theophylline preparations, this also may cause nausea if given in doses sufficiently large to increase the volume of urine.

The Council on Pharmacy and Chemistry makes the following statement concerning the actions and uses of xanthine derivatives:—

*Actions and uses.*—The Council recognizes no therapeutic claim for any xanthine derivative beyond those for diuretic action and for use as a myocardial stimulant. Theobromine and theophylline surpass caffeine in their diuretic, and perhaps in cardiac and muscular actions. They are therefore generally preferred in cardiac oedemas, etc., since they are equally, or more, effective, more prompt and largely avoid the unpleasant side effects (insomnia, nervousness, gastric disturbance) which often interfere with the use of caffeine in adequate doses. This freedom from side effects holds true, particularly for theobromine. Theophylline surpasses theobromine in diuretic efficacy, but its action is probably not so lasting; it may produce gastric disturbances; renal irritation has been reported. Theobromine is therefore generally preferred, sometimes preceded for a few days by theophylline. If central stimulation is desired, caffeine must be used.

It has been the experience of almost all observers that theobromine and its compounds are less powerful diuretics than the closely related substances just named, but they are often well tolerated in effective dosage and may therefore prove to be far more satisfactory. Theobromine may be administered in capsules in doses of 5 or 10 grains (0.325 or 0.650 gm.) three times a day and continued for a number of days if nausea does not occur. One of its best known compounds is theobromine with sodium salicylate, which contains approximately 50 per cent theobromine. This is one of the mildest of all diuretics, seldom causes nausea or vomiting and must be given in doses of from 40 to 60 grains (2.6 to 4 gm.) or more a day. Another preparation is theobromine calcium salicylate, or theocalcin, which is said to contain 48 per cent theobromine, 11 per cent calcium and 38 per cent salicylic acid. Stewart's study indicated its advantages, and these have been confirmed by subsequent experience. It is a potent diuretic, often superior to theophylline in this respect, seldom causes nausea and may be continued without intermission as long as diuresis results. It is available in tablets containing  $7\frac{1}{2}$  grains (0.5 gm.), and the usual effective dose is from three to six tablets a day; larger amounts may be given if necessary.

It is the belief of many students that the xanthines cause diuresis by an action on the renal glomerulus, increasing the infiltration, but authoritative opinion is not agreed on this.

The xanthines as a group are far from negligible; in recent years they have been overshadowed and to a large extent superseded by the mercurials, but they have an important place in the treatment of patients

with slight or moderate oedema and of those patients who object seriously to intravenous injections.

*Organic mercurials.*—The mercurial diuretics are unquestionably the most effective available to-day, even though an occasional patient may exhibit a greater response to one of the xanthines. Merbaphen, the first to be introduced, has been almost completely displaced in recent years by salyrgan, which is regarded as more potent and less toxic. These are organic mercurial compounds containing about 10 per cent of mercury and are effective when administered by intravenous or intramuscular injection or in the form of rectal suppositories. Their effectiveness is greatly increased if acid-producing salts are administered by mouth for several days preceding the injection, and this preliminary medication should be a routine unless the need for the first injection is urgent. Ammonium chloride and ammonium nitrate are the salts most commonly used, but calcium chloride and calcium nitrate are also effective. It has been shown that there is a true synergism between these salts and the mercurial preparation; all four regularly cause a lowering of the carbon dioxide combining power of the plasma and increase the diuretic response. Alkalinizing salts cause a rise in the carbon dioxide combining power and a decrease in the diuretic effect, while neutral salts cause no change in either function. The statement is often made that doses of these acid-producing salts as large as from 90 to 120 grains (6 to 8 gm.) a day must be given in order to secure satisfactory results, but my experience is in accord with that of Thomson, who has found doses of from 60 to 90 grains (4 to 6 gm.) quite sufficient. Even these smaller doses will almost invariably cause nausea and vomiting unless administered in the form of enteric coated tablets, which are taken by most patients without discomfort in the doses mentioned.

The mercurials for injection are available in ampoules containing 1 and 2 c.c. It is customary to give only from 0.5 to 0.75 c.c. at the first injection, in case there should be an idiosyncrasy to mercury or some untoward reaction, both of which are rare. Subsequent doses are usually 2 c.c. If the patient requires a series of injections it is satisfactory to continue ammonium chloride without interruption and inject the mercurial every third, fourth or fifth day. The results are almost always satisfactory and sometimes astonishing; it is not unusual to secure a urinary secretion of from 6 to 10 litres in twenty-four hours, and quantities as large as 15 or 16 litres have been recorded.

A few years ago Shelling and Tarr reported that the diuretic effect of salyrgan might be increased by combining magnesium sulphate with it. They recommended the use of 15 c.c. of 50 per cent magnesium sulphate with 2 c.c. of salyrgan and 1.5 c.c. of 5 per cent procaine hydrochloride, the whole to be mixed thoroughly in a 20 c.c. syringe and injected deeply into the gluteal muscles. There can be no question that this combination is sometimes remarkably efficacious with patients who have shown little or no response to salyrgan alone. To secure such effects, however, it is not always necessary to use such large quantities of magnesium sulphate; a mixture of 2 c.c. of salyrgan, 6 or 8 c.c. of 50 per cent magnesium sulphate and 2 c.c. of 1 per cent procaine hydrochloride solution has often given excellent results. This is about half the total quantity recommended by Shelling and Tarr, and its injection into the muscles seldom causes pain at the time or later. It should be added that the anterior muscles of the thighs are more suitable for such injections than are the gluteal muscles if the patient is confined to bed.

It is generally agreed that the mercurial diuretics owe their effect largely, if not exclusively, to a direct action on the renal tubules, diminishing their power of reabsorption.

Since there was a widespread belief that the xanthines caused diuresis chiefly by increasing glomerular filtration and the mercurials by diminishing tubular reabsorption, it was but natural that attempts should be made to secure a more effective diuretic agent by combining the two substances. In Europe such a combination was introduced as early as 1929; several years

later it appeared in America under the name mercurpurin. According to the revised supplement to New and Non-official Remedies 1939, it contains 10 per cent of the mercurial component and 4.86 per cent of anhydrous theophylline; each cubic centimetre contains about 39 mg. of mercury in nonionizable form. DeGraff and his collaborators in a series of important studies have shown that the addition of theophylline to a mercurial diuretic causes much more rapid absorption from the site of intramuscular injection and also renders it far less injurious to the tissues. Comparative clinical studies have shown that the combination of the two substances is a more potent diuretic than is the mercurial alone, and this increased potency is apparently due entirely to the addition of theophylline. The advantages of combining the two have been so apparent in recent years that practically all mercurials now marketed in Europe have been modified by the addition of 5 per cent theophylline. Several years ago salyrgan was thus modified and is available under the name salyrgan-theophylline; apparently its content of mercury and of theophylline is approximately the same as that of mercurpurin. More recently there has been introduced a combination of the two under the name esidrone, which is said to contain 31.2 per cent mercury in nonionizable form and 28 per cent theophylline, which is chemically connected with the mercury molecule. The reports on its clinical use thus far available are not sufficient to determine whether the great increase in the amount of theophylline in the mixture has caused any considerable increase in its diuretic potency.

There can be no question that the combination of a mercurial with theophylline is the most powerful diuretic agent now available for most patients with congestive heart failure.

Both salyrgan and the mercurial component of mercurpurin are available in the form of rectal suppositories, each containing approximately 0.5 gm. of mercury and a small amount of local anæsthetic to prevent rectal irritation. A cleansing enema usually precedes the insertion of the suppository, and the diuretic response is often increased by the preceding administration of the acid-producing salts. Some observers have found the suppositories to be almost as effective as intravenous or intramuscular injections of the mercurials, but most regard them as about one-third to one-half as effective. (It should be noted that the suppositories of salyrgan have recently been found to result in rectal irritation or ulceration in so many cases that their acceptance has been rescinded by the Council on Pharmacy and Chemistry, and many clinicians have discontinued their use.) Similar unfortunate results have apparently not followed the use of mercurin suppositories, but any such preparation should be used with great caution and should be discontinued immediately on the appearance of signs of local irritation.

There is general agreement that the mercurials should not be used in the presence of acute nephritis or ulcerative colitis. For some years fear was expressed that they might cause serious injury to the renal tubules, and a few such instances have in fact been reported. But the accumulated experience of the past ten years justifies the statement that the mercurial diuretics, especially those combined with theophylline, are safe and highly effective and often retain their full potency after hundreds of injections over a period of many months or years. In the great majority of cases, even of chronic nephritis, there is no evidence that the kidneys have been injured by the mercury.

**Potassium salts.**—According to Keith and Binger, potassium salts were recommended for the treatment of dropsy as early as 1679. In recent years most of the studies relating to their diuretic action have been concerned with nephritic patients, but in 1932 Barker reported excellent results from the administration of potassium chloride to a group of patients whose cedema was due to congestive heart failure. He emphasized the importance of placing such patients on a full general diet with an excess of acid ash in which a low ratio of sodium to potassium is maintained. The dose of

potassium chloride found to be effective in most of his cases was 5 gm. (75 grains) a day; this amount was given to the patient each morning in a salt shaker and sprinkled on the food instead of sodium chloride. At the end of the day any salt remaining was dissolved in water and taken by mouth. Twelve of his sixteen patients obtained excellent results, and he observed, as others had done, that no ill effects followed even if very large doses were given for long periods.

In a later and more elaborate study, Keith and Binger found that potassium salts gave 'very satisfactory diuretic results' in 48 per cent of their sixty cases and fair results in another 33 per cent, but their figures do not indicate in how many of these cedema was due to heart failure. After a careful study of five potassium salts they concluded that the nitrate was preferable, since it frequently caused diuresis and seldom gave rise to untoward effects. They pointed out that any potassium salt must be given in large doses, amounting to 12.5 gm. or more of the nitrate a day, but state that smaller doses should be administered first. One of their patients took 24.5 gm. of potassium salts daily for thirteen days and 871 gm. in sixty-eight days without complaints or toxic symptoms! The salts may be administered in powder form or in solution, but the most satisfactory method is by means of enteric coated tablets containing  $7\frac{1}{2}$  grains (0.5 gm.) each. Like ammonium chloride and ammonium nitrate, the potassium salts may be used in conjunction with other diuretics to enhance the action of the latter.

A great many studies are in complete harmony in indicating that in the experimental animal, in normal human subjects and in patients with cedema due to several different causes the replacement of sodium by potassium results in increased excretion of water, while the substitution of sodium for potassium results in increased retention of water. The exact mechanism responsible for these results, however, is not entirely clear. It is known that potassium is quickly absorbed from the intestine and is promptly excreted by the kidney, which is able to concentrate it as much as fifty times; even after large doses the amount in the blood is seldom elevated appreciably and often not at all. In fact the careful measurements of Barker revealed practically no changes in the sodium, potassium, calcium, carbon dioxide combining power, pH, or cholesterol of the blood during the administration of potassium. In some cases it seems possible that the diuresis is linked with a shift in the acid-base equilibrium, but this cannot be demonstrated regularly.

**Bismuth.**—Ten years ago, Mehrtens and Hanzlik brought forward evidence indicating that certain bismuth preparations injected intramuscularly in small doses act as a diuretic and are almost devoid of toxic manifestations.

The reports on this preparation were so encouraging that it is surprising not to encounter further reports in recent medical literature. Untoward actions or toxic effects cannot explain this apparent neglect, for these are absent or negligible; in fact, Hanzlik states that the group of observers at Stanford University has used bismuth preparations in various ways in several thousand cases and in animals in the past twelve years without serious disturbances, injuries or fatalities. It seems probable that this drug, like others of undoubted merit, has failed to come into general use because the mercurial diuretics are usually more potent, even though their action is less sustained than that of bismuth.

According to Stockton, bismuth sodium tartrate probably causes diuresis by general tissue action, resulting in mobilization of chlorides and water. He explains the effect of the mercurial diuretics and of theophylline in the same way, whereas most students to-day believe that these substances act directly on the kidney. A belief in general tissue action of diuretics was widespread ten years ago but has been largely abandoned in the light of recent studies.

**Urea.**—Although urea has been recommended as a diuretic in renal disease for a long time, its use for the treatment of cardiac cedema seems to date from the report of Crawford and McIntosh in 1923. They found it to be of great value in seven of eight cases in

which œdema was due to heart failure and recommended it both for the removal of œdema and to prevent its recurrence. No toxic effects were observed. In 1932 Miller and Feldman emphasized several of the cardinal virtues of this substance, demonstrating that its diuretic potency does not diminish during months or years of practically uninterrupted use, that there are no demonstrable deleterious effects on the kidneys or other tissues and that it acts, alone or in conjunction with other agents, as an admirable prophylactic to prevent the recurrence of œdema.

Large doses are required, varying from 15 to 60 gm. or more (225 to 900 grains) a day. It is administered most satisfactorily in ice cold aqueous solution three times a day immediately after meals. Its unpleasant taste, which is practically its only disadvantage, can be mitigated for some patients by dissolving it in syrups or fruit juices. Syrup of acacia has been especially recommended as a vehicle for urea, its colloidal nature serving to mask the urea quite satisfactorily. Urea is rapidly absorbed from the intestine and is practically devoid of action in the tissues, even in large doses. After it has been taken for a few days the blood nitrogen should be determined to ascertain whether it is being properly excreted. In almost all instances of congestive heart failure, and even of nephritis and nephrosis, it is readily excreted and carries with it large quantities of water. This mechanical diuretic action is thought to be enhanced by decreased reabsorption in the renal tubules.

Urea is an extremely valuable diuretic and deserves wider popularity than it seems to enjoy at present. All available clinical reports emphasize its complete freedom from untoward actions and its extraordinary constancy of diuretic effect. While it is usually less dramatic in its immediate results than are the mercurials, it has obvious advantages and may be used to supplement the latter. There are but few patients who cannot take it for at least several weeks at a time, and many continue it for months or years without interruption.

#### NEPHROSIS

Despite the enormous literature devoted to the subject of nephrosis in the past thirty-five years, there is not yet complete agreement among authoritative observers as to the existence of 'pure' or 'lipoid' nephrosis as a separate disease entity. There is, however, general agreement that the combination of low serum proteins, profuse albuminuria, normal blood nitrogen and œdema may properly be known as the 'nephrotic syndrome' and that its treatment is the same whether it is regarded as resulting from a specific renal lesion, a nonspecific renal lesion (one stage in the development of chronic glomerulonephritis) or a general metabolic disease. The œdema is thought to be due in large measure, as Epstein first pointed out, to the marked hypoproteinemia, which results in great lowering of the colloid osmotic pressure of the blood.

The general principles of treatment include maintenance of the nutrition at the highest possible level by an adequate diet high in protein, limitation of salt and fluid intake and exercise in moderation as long as the clinical state permits. Practically all known diuretics have been tried in this condition; any of them may give satisfactory results in a given case but most of them prove quite ineffective. Thyroid has been extensively used because of the low basal rate in most patients but is seldom effective in causing diuresis, possibly because the low metabolic rate is caused in most instances by the undernutrition rather than by thyroid deficiency. The xanthine diuretics have proved useless in the hands of most observers. Encouraging results have sometimes been obtained from the use of potassium salts, as already outlined. Urea also has occasionally been effective in doses of from 15 to 50 gm. or more a day and deserves a trial if it is tolerated. But there can be little question that the mercurial diuretics are much the most effective in the majority of cases, and they may be used without fear of increasing the renal lesion. They should be preceded by one of the acid-producing salts. In many cases the mercurials also are useless.

Because of the belief that the œdema is due largely or wholly to the reduction of serum proteins, many attempts have been made to raise these to normal levels by means of diets high in protein and by the intravenous injection of such substances as whole blood, blood plasma and solutions of acacia. Leiter has stated that this form of treatment, however plausible it may seem, is inevitably doomed to failure because the amount of material injected cannot be sufficient to cause an appreciable increase in the colloid osmotic pressure of the plasma and because it will be rapidly excreted from the circulation, since the glomeruli are much more permeable to colloids than normally. However, Hartmann and his collaborators, Lepore, Landis and Shelburne have all reported excellent results from the repeated and cautious intravenous injection of acacia solutions. The strength of the solutions has usually been from 6 to 15 per cent, in water or in physiologic solution of sodium chloride, and the injections may be given daily or at intervals of from two to four days. In practically all reported cases of benefit from acacia many diuretics had been tried without success. Following the disappearance of œdema, a diet high in protein should be continued; Shelburne regards this as an essential part of the treatment.

The administration of acacia is not wholly without disadvantages, and some have stated that these are so serious as to make the use of the substance unjustified. The work of Dick is often quoted in support of this belief, but Shelburne has recently pointed out that this work is open to serious criticism and should not prevent the proper use of a valuable therapeutic agent. Immediate reactions to injections of acacia are infrequent if the solutions are freshly and carefully prepared, but serious reactions have followed the use of impure solutions. It seems clear that if acacia is to be used it should be in a hospital rather than in the patient's home. If other methods of treatment have been tried without success and the removal of œdema is highly desirable, recent experience would certainly justify the trial of acacia. If this also proves ineffective, other diuretics should be employed immediately after the acacia, as they may then prove beneficial.

#### VITAMIN DEFICIENCY

In the past several years evidence has been presented, chiefly by Weiss and his collaborators, indicating that deficiency of vitamins, especially of vitamin B<sub>1</sub>, may lead to various types of cardiovascular dysfunction, whether the heart was previously normal or diseased. The cardiovascular manifestations do not form a fixed clinical syndrome but may include the characteristic signs of congestive heart failure with marked œdema. The diagnosis of the condition may be very difficult, but the possibility of vitamin deficiency should be seriously considered when any patient with an abnormal nutritional history develops the syndrome of heart failure with œdema in the absence of convincing signs of heart disease. The presence of other signs of vitamin-B<sub>1</sub> deficiency, especially polyneuritis, glossitis and cutaneous changes suggestive of pellagra, may give an important clue. According to Strauss 'it is rare to observe "beri-beri heart" without at least minimal signs of polyneuritis'. Both Weiss and Strauss emphasize the possible importance of measurements of the circulatory velocity and the minute volume output of the heart, as these are increased in the condition now under discussion and are conspicuously slowed in heart failure due to other causes. The response to specific therapy, however, may provide the first and most convincing evidence of the nature of the condition.

General, or nonspecific, treatment consists of the application of the measures enumerated previously: rest in bed, limitation of fluids and of salt and the administration of digitalis and diuretics. Some patients respond well to such a regimen, while others show little or no improvement; indeed, some of Weiss's patients became worse when placed at rest. Specific treatment consists of the administration of vitamin B<sub>1</sub>. Preferably this should begin with the intravenous or intramuscular injection of from 20 to 50 mg. of thiamin chloride

daily, and this method should be employed as a routine in the more severe cases. After improvement has occurred, usually within two weeks, the dose may be decreased to 10 or 20 mg. daily, or the larger doses may be given by mouth. If the symptoms are not particularly severe or have been largely relieved by intensive treatment, brewers' yeast may be used instead of the crystalline form of the vitamin; doses of about 30 gm. three times a day are recommended.

The response to such treatment may be prompt and spectacular, with marked improvement in a few days and complete disappearance of symptoms and signs within two or three weeks, or improvement may be gradual over a period of six or more weeks. Rapid improvement is said to be associated with diuresis, slowing of the heart rate and rise in the arterial pressure. If there is not clear evidence of improvement after adequate dosage of vitamin B<sub>1</sub> for several weeks it is probable that the cardiovascular manifestations are not due to vitamin deficiency. Beneficial effects do not follow the administration of this vitamin to patients with other types of heart failure.

Weiss has properly emphasized that deficiencies are seldom limited to a single vitamin, and these patients often present evidences of inadequate intake of vitamin A and of ascorbic (cevitamic) acid, of anemia, of hypoproteinemia and possibly of other dietary deficiencies. These should, of course, receive appropriate treatment simultaneously.

#### MALNUTRITION

The oedema, often very extensive, associated with serious degrees of malnutrition is thought to be dependent in large part on the diminished proteins of the blood plasma and the consequent lowering of the colloid osmotic pressure. It is clear that this condition may be intimately related to and complicated by the vitamin deficiency state just discussed. Diuretics may be employed, but the logical and highly effective treatment is the correction of the nutritional state by means of a proper diet rich in proteins and in vitamins. Unless the patient is dying, the dropsy usually disappears with gratifying promptness.

#### PICK'S DISEASE

For many years the term 'Pick's disease' was used loosely and inaccurately and was applied to a number of quite different pathologic states. Now, thanks largely to the clinical reports of White and the experimental and surgical studies of Beck, it is possible to say with conviction that Pick's disease is actually chronic constrictive pericarditis. Among the more important clinical features of the condition may be mentioned gradual onset of dropsy, disproportionate enlargement of the liver and ascites, increased venous pressure, low arterial pressure and a heart that is normal in size or smaller than normal. A single cause is responsible for all these manifestations: the heart is so encased by unyielding fibrous or calcified tissue as to be unable to dilate and fill properly during diastole. In some cases there is, in addition, marked constriction of the inferior vena cava. The immediate mechanisms of oedema formation are those discussed under congestive heart failure.

The milder diuretics are of little or no value in this condition, although they may occasionally lengthen the interval between abdominal paracenteses. The mercurials, however, may prove extremely useful, as in the case reported by Noth: A man aged 53 in seven and one-half years had had forty abdominal paracenteses and 450 injections of mercurial diuretics and had taken 6 gm. (90 grains) of ammonium nitrate a day for three years. At the end of this time he presented no signs of hepatic or renal injury and had been able to continue an active life as a banker. However, if the diagnosis is reasonably certain and the patient is a good operative risk, the best treatment is surgical resection of the constricting pericardium. This often results in rapid and spectacular improvement and in restoration of the patient to normal activity, even after years of invalidism.

#### NEPHRITIS

The oedema of acute nephritis is generally believed to be due in large part to widespread injury to the capillaries, which makes them more permeable than normally. It is theoretically unwise to administer diuretic drugs which might irritate an organ already acutely inflamed, and experience has shown conclusively that they are practically always devoid of beneficial action. In most cases diuretics are clearly unnecessary; if special circumstances seem to make a trial of such drugs essential, only the very mildest, such as urea or theobromine with sodium salicylate, should be used.

In chronic nephritis also diuretics are usually unnecessary if one excludes the 'nephrotic syndrome' of chronic glomerulonephritis. But if oedema becomes a serious problem almost any of the diuretics previously discussed may be used safely. The xanthines, urea and potassium salts may prove ineffective. The mercurial diuretics, combined with ammonium chloride or nitrate, are usually very satisfactory and almost never increase the renal disease. It is unwise to use these if there is acute renal inflammation or much retention of nitrogen in the blood, but extensive oedema and nitrogen retention are seldom associated.

#### HEPATIC CIRRHOSIS

It is not often that ascites and oedema of the lower extremities resulting from portal cirrhosis of the liver can be removed satisfactorily by means of diuretic drugs. It has been the almost universal experience that the milder ones, including the xanthines, urea and bismuth, are almost devoid of beneficial action. In occasional cases the mercurials, preceded by acid-forming salts, prove to be fairly satisfactory, but in most instances all that can be expected is a prolongation of the interval between abdominal paracenteses. This, however, is distinctly worth achieving, and a trial is always justified.

#### COMMENT

Even from the foregoing survey it is clear that the occurrence and removal of dropsy may present involved and baffling problems to the physician. Proper treatment of the underlying disease may result in disappearance of the oedema, but often this must be supplemented by control of the diet, by diuretics and in some cases by surgical operation. It is highly encouraging to realize that all the specific measures discussed in this article, with the exception of the xanthines, have come into general use in this country within the past fifteen years. Our knowledge of the mechanisms involved in the formation of oedema and the occurrence of diuresis have steadily widened, and our use of specific remedies has consequently become more intelligent. It is not often that the disease responsible for dropsy can be wholly cured, as in vitamin deficiency and constrictive pericarditis, but the dropsy itself can often be controlled very satisfactorily by means of medical treatment for many months or years.

### Modern Therapeutics

#### The Use and Abuse of Aperients

By R. H. MICKS, M.D., F.R.C.P.I.

(Abstracted from *The Practitioner*, Vol. CXLIV, March 1940, p. 285)

It is proposed to begin with a few paragraphs on the misuse of aperients, putting forward some maxims and cautions which represent the teaching and practice of a large number of teachers of medicine and surgery.

#### SOME CAUTIONS AND MAXIMS

(1) It is unnecessary to begin the treatment of an acute fever, for example pneumonia or scarlatina, by administering an aperient.

(2) It is unnecessary, and probably harmful, to administer aperients during the course of a long febrile

illness. The constipation that accompanies such illnesses is harmless and, when the illness is over, a week or so later, no difficulty is found in getting the bowels to move again.

(3) No one has ever shown that a 'brisk purge' has any good effect in acute tonsillitis or any other acute inflammatory process.

(4) An initial purge is often recommended in the treatment of acute congestive heart failure, but experience has shown that it can be omitted. If it is not necessary, then it is merciful to refrain from giving it to a dyspnoic patient.

(5) The popular belief that a sick or sulky child should be 'dosed' is stupid and a little dangerous. The claim is made that the child is often a great deal better after the aperient, but this is beside the point, for the sulks and minor illnesses of childhood are usually evanescent. The danger of these nursery doses lies in the possibility that the child's indisposition may be due to an abdominal pain about which he does not complain, as bitter experience has taught him that a complaint of a 'tummy-ache' usually brings a dose.

(6) There is little need to emphasize the almost criminal folly of giving aperients to patients with undiagnosed abdominal pain or vomiting. It would be well if all medical students and nurses could be taught that aperients should be given only to those who are in good health, and never in the expectation that they will set right some malady or ailment.

(7) The pre-operative purge of former days has been abandoned in most surgical units. The routine post-operative purge given three or four days after an abdominal operation has also been abandoned by many surgeons (it is especially dangerous after gastro-enterostomies), but unfortunately they do not always succeed in controlling the meddlesome activity of their nursing staff; for, strange though it may seem, there are still clinics in existence in which ward sisters are allowed to prescribe aperients.

#### EFFECTS COMMON TO ALL APERIENTS

The classical division of aperients is into—*Laxatives*, which increase the bulk of the stools but do not alter their consistency; *purgatives*, which produce unformed motions; *hydragogues*, which are followed by watery stools; *drastic purgatives*, which excite an inflammatory reaction in the intestine. This is not a bad classification, but it should be remembered that it is a classification based on the intensity of the effect produced by the drug, which depends not merely on the choice of the aperient, but also on the dose given and the contents of the patient's colon.

*Consistency of the motion*.—Any aperient tends to produce a stool which is more watery than normal, for by shortening the time taken for the journey through the intestine it reduces the time available for the absorption of water in the colon.

*Gripping* is the sensation of pain produced by over-vigorous muscular action in the intestine. Those vegetable irritants (aloes, cascara, rhubarb, senna, colocynth, podophyllum and jalap), which act largely by direct stimulation of smooth muscle fibres, tend to gripe more severely than the aperients which increase peristaltic activity indirectly by increasing the bulk of the intestinal contents. But the latter too may gripe unpleasantly, especially if some resistance is offered to the passage of the fluid intestinal contents by an already formed faecal mass in the lower part of the large intestine.

*The time of action* depends to some extent on the contents of the intestine and the bodily exertions of the patient during the few hours after taking the aperient. The salines and castor oil act quickly, within a few hours, or sometimes within an hour; the vegetable aperients, as will be seen, are considerably slower.

#### THE CHIEF APERIENTS

The most useful classification of aperients is that which is based upon their mode of action.

(1) Aperients which increase the non-absorbable bulk of the intestinal contents, and thus indirectly excite increased peristaltic activity.

(2) Aperients which directly excite increased peristaltic activity by means of an irritative action on the intestinal wall.

#### (1) Increase bulk of contents

*Food and drink*.—The hearty eater and drinker is rarely constipated. If the lesson taught by this fact is borne in mind no attention need be paid to 'special diets for constipation', which tend to divert the patient's (and the practitioner's) attention from the important fact that quantity matters more than quality.

*The dried seaweeds*.—The most popular is agar-agar, which is sold under a number of trade-names. If swallowed dry it imbibes water like a sponge, but if already mixed with a liquid (as in some proprietary preparations) it cannot of course do so. Such dried seaweeds are satisfactory mild laxatives, and there is no objection to their use.

*Liquid paraffin*.—When the oil is taken already emulsified (as in many proprietary preparations) the stools become slightly softer and more bulky on account of their admixture with the emulsified oil. When the oil is taken neat it still exerts a mild aperient effect, though the exact mode of action is uncertain. It probably acts partly by virtue of its own mass and partly by interfering with the absorption of foodstuffs.

*The salines*.—Magnesium and sodium sulphate, potassium sodium tartrate and basic sodium phosphate are the salines most used, but it should be remembered that all the salts of magnesium exert an aperient action. The salines should be taken in watery solution on an empty stomach, for example on rising from bed, and the solution should be either hypotonic or isotonic; hypertonic solutions tend to excite pylorospasm, with the result that the draught leaves the stomach slowly and vomiting may occur.

The salines owe their action to the fact that the salts themselves are so poorly absorbed by the intestinal epithelium; absorption of their water of solution cannot take place past the point at which further absorption would leave in the intestine a solution of higher osmotic pressure than that of the solutes in the tissue of the intestinal wall. A 6.5 per cent solution of magnesium sulphate is isotonic with human tissue-fluids and so, if a draught containing two teaspoonfuls of magnesium sulphate is drunk, about four ounces of water will remain unabsorbed in the intestine to maintain the isotonicity of the magnesium sulphate solution. This unabsorbed water excites peristaltic waves which are transmitted to the colon, and thus the contents of the colon too are hurried on even before the saline draught has reached the caecum. A large fluid motion is passed, the volume of which is far greater than that of the original saline draught.

It should be noted that the aperient action of a saline amounts to this, that a certain volume of water is rendered non-absorbable by the intestinal epithelium. There is no evidence that magnesium sulphate exercises any direct action on the wall of the intestine, and it has been shown that little or no absorption of the salt occurs. It is interesting to note that when magnesium sulphate is injected directly into the circulation its effect is to produce narcosis, and in fact it has been employed for this purpose. It is a dangerous narcotic. The popular belief that the regular daily dose of a saline purgative is in some way deleterious is, of course, wrong. A daily dose of salts is an excellent way of securing a daily motion for patients who wish to aid Nature.

*The sulphates and sulphonamides*.—The notion that sulphates should not be given to patients who are being treated with drugs belonging to the sulphonamide group is almost certainly incorrect and has just as little theoretical or experimental support as the *ipse dixit* that eggs too are incompatible with drugs of this group.

*The irritants*.—The drugs so classed are reagents which, when brought into contact with an isolated strip

of intestine, excite muscular contractions. It is uncertain to what extent these irritants act directly on the smooth muscle and to what extent through reflexes evoked by stimulation of the epithelium or local nerve plexuses, for it is difficult to conduct decisive experiments to distinguish these modes of action. Senna has been shown to act directly on the isolated muscle-fibre, and probably other similar vegetable preparations do so too.

**The anthracene group.**—The chief members of the group are aloe, cascara, rhubarb, and senna. These act by virtue of several anthracene derivatives which they contain, and which are so slowly set free from their combination in larger molecules during the passage of the drug through the intestine that the irritant action of the anthracene derivative is not exerted until the colon has been reached. Thus the action of this group is a delayed action, and the members of the group are particularly suitable for use in 'dinner pills' to be taken after the evening meal in expectation of a result in the morning. In fact this group of drugs could not be used with safety if their active principles were liberated high in the small intestine, for then these would be freely absorbed into the blood stream, and unpleasant and possibly dangerous toxic effects would be produced.

**Pregnancy and the anthracene group.**—Violent purgation is probably always dangerous to some degree for the pregnant woman, but tradition has attached a special odium to the anthracene purgatives, and in particular to aloe. It is true that aloin (the active principle of aloe) when injected intravenously into laboratory animals causes violent contractions of the uterus, but it is most unlikely that the oral administration of an ordinary purgative dose can have any such effect in man.

**Castor oil** is non-irritating until it has undergone lipolytic digestion in the small intestine. Being a compound of glycerol and a fatty acid (ricinoleic acid) it undergoes emulsification with bile salts and digestion with lipase just as butter does, and the ricinoleic acid thus set free is an irritant, as so many other fatty acids are (compare the laxative effect of 'rich' dinner). Castor oil acts in a few hours, and rarely if ever produces any tendency to subsequent diarrhoea, probably because the ricinoleic acid is absorbed into the circulation. The constipating after-effect attributed to castor oil is probably due to nothing more recondite than the thoroughness of the evacuation which it brings about. Castor oil is an excellent aperient with no disadvantages except that it is unpalatable; it may excite vomiting even in those who find no difficulty in swallowing it, and is so thorough in its action that when misused (for example when administered to patients suffering from an acute appendicitis) it may do much harm.

**The drastic purgatives.**—These are vegetable products which contain reagents capable of not merely stimulating the wall of the intestine but of exciting an acute enteritis with a diarrhoea lasting for several days. The chief members of the group are colocynth, jalap, and podophyllum, the active principles of which are glucosides split off from resins in the course of digestion.

**Croton oil**, which contains a highly irritating resin, has been removed from the British Pharmacopœia, but it is still used in mental hospitals, as it has the merit of being tasteless when well mixed with food or drink. Among medical students it is the weapon chosen by the avenger who wishes to lay a trap for pilferers of his food supplies; the enteritis produced by a large dose may be severe enough to incapacitate the thief for several days.

**The mercury compounds.**—I never prescribe mercurial purgatives (calomel and mercury itself), and I am far from being alone in my dislike for them. The objection to their use is that in some cases even a small dose may have an unpleasantly powerful and prolonged effect, and in other cases a large dose may be required to produce even a mild laxative action. The assertion that calomel is 'chologogic' and 'antiseptic' is based solely on tradition and not on fact.

**Phenolphthalein.**—This drug has the advantage of being tasteless, and has for that reason been recommended as suitable for children if given in the form of medicated sweets; it is also an ingredient in several proprietary preparations of emulsified paraffin and a number of proprietary pills. There are two objections to its use: First, it may produce an ugly, blotchy red rash and, secondly, it is easily absorbed and excreted again in the bile (compare the use of the iodine compound in radiography), with the result that its purgative action may be repeated for several days. The mode of action of phenolphthalein is similar to that of the anthracene group in that it is a direct irritant of the wall of the intestine.

#### STRYCHNINE IN PURGATIVE PILLS

**Strychnine** has no aperient action whatsoever, and yet this poison is to be found in many proprietary pills and in at least three B. P. C. pills. It is not widely enough known that little children have been killed by swallowing a fistful of such pills in mistake for sweets; one American writer on therapeutics goes so far as to assert that it is the commonest mode of accidental strychnine poisoning. It is to be hoped that drug manufacturers will stop the reprehensibly ignorant practice of dispensing such a useless and dangerous poison as strychnine in conjunction with harmless vegetable aperients, and that all doctors will do their best to prevent the occurrence of tragedies by ceasing to prescribe pills which contain even a trace of this convulsant.

#### THE ENEMA

The ordinary soap and water enema is not always absolutely safe and harmless, though as a general rule it is so. When the large intestine is ulcerated and its wall thinned, an enema may be just as dangerous as a purgative in appendicitis, and indeed in any case of suspected disease of the lower bowel the enema is a therapeutic measure which should be employed with the greatest caution.

**Ulcerative colitis** is a comparatively rare disease, and so practitioners who find themselves called upon to treat a patient suffering from it naturally turn to their textbooks for help. Among the treatments mentioned in textbooks is to be found regular washing-out of the colon, but many physicians, of whom I am one, have formed the opinion that these wash-outs are useless, add to the patient's discomfort, and probably are harmful.

#### RECTAL CONSTIPATION

**Rectal constipation**, that is to say constipation in which the faecal mass reaches the rectum but is not passed through the anus, is not uncommon. The chief causes are muscular weakness and insensitiveness acquired through habit. A method of dealing with the trouble which sometimes succeeds in not merely relieving the patient temporarily, but in preventing recurrence, is the daily injection of glycerin, at first about one ounce, but less and less every day; after a short while some patients are cured or greatly improved. Digital breaking up of a rectal impaction is occasionally necessary in the old. There is no other way of dealing with a troublesome 'lodgment', and the hardened mass which obstructs the anus by acting as a ball-valve is usually surprisingly small. Enemas and aperients are worse than useless in this condition.

#### THE TREATMENT OF CONSTIPATION

(1) In *acute constipation*, that is to say in constipation of recent origin, aperients should be withheld until the physician feels absolutely certain that they will not do harm. No patient ever died for want of an aperient.

(2) In *chronic constipation* it is wise to assume that the patient who makes this his chief complaint has either got something more than mere constipation the matter with him, or else has some reason for visiting the practitioner other than the wish to have an aperient prescribed. Many patients consult a doctor about constipation because they fear that it may be a symptom of more serious trouble; many others wish

for an opinion about their heart or their blood pressure, but are too apprehensive to ask for it directly. In advising a patient found to be suffering simply from chronic constipation it is wise to begin by telling him three things:

(a) That chronic constipation does not poison the blood or lead to cancer, and is in fact a harmless inconvenience rather than a disease.

(b) That plenty of food and drink, so far from being dangerous and tending to produce obstruction, are Nature's method of ensuring regular motions.

(c) That the regular taking of aperients is harmless. The choice of the aperient and the frequency with which it is taken is a matter for the patient's own taste and convenience.

(3) Agar-agar or some similar water-imbibing substance is the best aperient for those who find its feeble action adequate. A saline draught in the morning is trustworthy and rapid. Aloes, cascara, senna pods, and rhubarb are more variable in their effect, but can be taken at night and will not act till the following morning. Castor oil is too nasty for most people, although it is trustworthy and effective; calomel is far too uncertain and, like the drastic purgatives, too liable to set up a short attack of painful diarrhoea.

## Treatment of Prostatic Inflammation

By KENNETH WALKER, O.B.E., F.R.C.S.

(From *Medical Press and Circular*, Vol. CCIII, 10th January, 1940, p. 27)

ALTHOUGH this series of articles deals only with treatment it is necessary to discuss in brief the symptomatology and pathology of prostatic conditions. Infections usually reach the prostate directly by way of the urethra, although a hæmatogenous infection sometimes occurs as a complication of parotitis, small-pox and cellulitis of the neck. Acute prostatitis may also form part of a hæmatogenous infection of the urinary tract by the bacillus coli communis.

The varieties of prostatitis are acute prostatitis, prostatic abscess and chronic prostatitis.

### ACUTE PROSTATITIS

This occurs most frequently as a complication of gonorrhoea and is particularly liable to occur when instruments have been passed or posterior irrigation has been carried out unskillfully or with antiseptics that are too strong. Other predisposing causes to the development of a prostatitis are bicycling, track racing, sexual excess and constipation. This being so, complete rest in bed, and the avoidance of all instrumentation or local treatment is the first essential in treatment.

The second most important measure is the application of heat to the inflamed tissues. In the case of a patient in his own home and without skilled help, the only method of achieving this is by means of hot baths and by the application of hot water bottles or poultices to the perineum and supra-pubic regions. If a nurse is available better results may be obtained by hot rectal irrigations, or by the insertion of a special rectal nozzle kept warm by the circulation through it of warm water. Later, when the patient can be moved, the application of a diathermy current directly to the inflamed prostate by means of rectal and supra-pubic electrodes will be found to be the most effective method of applying heat.

If rectal irrigations be employed, pain may be relieved by injecting into the rectum at the end of the irrigation a small enema made up of antipyrin (20 to 30 gr.) and tincture of opium (10 to 15 minims) in 10 ounces of warm water. If a nurse is not available relief is obtained by a morphia and belladonna suppository. Belladonna and atropine are believed by L. Harrison to reduce the likelihood of the development of an epididymitis, a common and troublesome complication to the prostatitis.

Attention to the bowels is of the utmost importance, and as a preliminary measure four grains of calomel

followed by a saline is useful. Should, however, it be decided to treat the infection by means of sulphanilamide, paraffin must be used as a means of securing a satisfactory action of the bowels.

The only other drug used with success in pre-sulphanilamide days was sandalwood oil, given either in 15 minim capsules, or as an emulsion. This was proved more useful than any other preparation in relieving the painful and frequent micturition that is usually a feature of prostatic inflammation. Nowadays, however, sulphanilamide enters so largely into the treatment of acute infections that all methods that conflict with its use must be abandoned. For the same reason the ingestion of large quantities of bland fluids (formerly a part of treatment) is no longer advisable.

Although several writers have stated that M. & B. 693 is the best form of sulphanilamide treatment in cases of gonorrhoea, I have not found that this is necessarily the case. Whatever be the sulphanilamide preparation that is selected, largish doses (4 to 6 grams) should be given for the first two to three days, and then reduced. As a rule not only does the temperature rapidly fall under this treatment, but so also do such distressing symptoms as frequency of micturition and strangury subside.

### PROSTATIC ABSCESS

Could the histology of the prostate be examined in a case of acute prostatitis small collections of pus would frequently be discovered in its parenchyma, collections that by coalescence and growth can easily become abscesses. Indeed, prostatic abscess is a fairly common sequel to an acute prostatitis.

The appearance of an abscess is marked by an increase in the temperature, pulse rate, toxicity and symptoms of the patient. The swelling of the prostate results in greater and greater difficulty of micturition, culminating in retention, and on rectal examination a soft area may often be detected in the general hardness of the swollen gland. If left to itself, in a large number of cases, the abscess will discharge itself into the urethra or rectum, with the immediate relief of all symptoms.

It is, however, a mistake to wait too long for such a happy event. Not only is there always a danger of that serious sequel to a prostatic abscess, pelvic cellulitis, but a poorly drained cavity in the prostate may be left that continues to discharge for weeks or even months after the abscess has burst.

Once a prostatic abscess has been diagnosed the correct treatment is drainage through a perineal incision. The operation is an easy one, requiring little experience in perineal surgery since the pus usually comes to meet the operator soon after he has made his incision and reached the lower border of the triangular ligament. The insertion of a blunt instrument in the direction of the posterior aspect of the prostate generally results in a gush of pus, and all that is then necessary is to widen the track according to the Hilton method, and to leave in place a drainage tube. With the patient sitting up in bed excellent drainage is obtained and convalescence rapid.

It is often possible to avoid an open operation by draining the abscess into the urethra. This can be done best under ocular control through an operating posterior urethroscope. The chief disadvantage, however, of such an operation is that it leaves a cavity in the prostate discharging into the urethra through a comparatively narrow channel. Convalescence is slow, and prolonged prostatic massage is necessary before all discharge disappears.

### CHRONIC PROSTATIS

The symptoms of a chronic infection may be divided into four categories: (1) urinary symptoms; (2) nervous symptoms; (3) sexual symptoms; (4) symptoms due to secondary infections, e.g., synovitis and arthritis, fibrositis, etc. No disease is more variable in the severity of the symptoms it produces than prostatitis, some patients being prostrated by a comparatively mild infection of their prostates whilst others are the

victims of a severe grade of trouble without complaining of any discomfort.

The main difficulty in the treatment of a chronic prostatic infection arises from the fact that the prostate is a highly composite gland and that no method of draining away inflammatory products is satisfactory except the drastic method of open incision. Reliance must therefore be placed on such make-shifts as prolonged prostatic massage and dilatation by the passage of large-sized bougies. Prostatic massage is indeed our 'sheet-anchor' in the treatment of chronic prostatic infections. The massage should be carried out at first two to three times weekly, and then weekly until a microscopic examination of the expressed prostatic fluid reveals that only five or six pus cells are visible in every field examined. Theoretically the patient cannot be regarded as cured until pus cells are altogether absent, but this is an ideal standard that can rarely be attained. It is important that the massage should be done with method and thoroughness, the massaging finger emptying every part of the prostate downwards and inwards towards the urethra.

The passage of a large bougie has a somewhat similar action to massage, since it stimulates a contraction of the muscle fibres of the prostate and an emptying of the distended acini of the glands. It is, however, a less useful method of treatment than is massage, and should not be repeated too often.

If massage is necessary for the treatment of deep-seated trouble, so also is posterior irrigation essential for the keeping down of surface infection. With a little patience the majority of patients can be taught to irrigate out their own bladders, according to the Janet method. The most useful fluids for this purpose are a one in five thousand solution of potassium permanganate or of oxycyanide of mercury.

Rectal diathermy is a useful but by no means essential adjunct to treatment. If this be used as a

preliminary to massage it will often be found that a greater quantity of infected secretion can be expressed than is otherwise possible. Diathermy is particularly useful in the case of patients who complain of nervous or of sexual symptoms. Another method of obtaining relief in nervous cases is to give a suppository containing ichthyol 3 grains, extract of belladonna  $\frac{1}{4}$  grain and iodide of potassium 5 grains.

Because sufferers from chronic prostatitis often become neurotic general tonic treatment is important. In the later stages of convalescence outdoor exercise, with the exception of horse riding and bicycling, should be encouraged. Nor is it necessary in the later stages of the trouble to forbid sexual intercourse, provided there be no risk of spreading gonococcal infection. Coitus results in a complete emptying of the prostatic glands and therefore can be regarded as acting similarly to massage. If indulged in too soon coitus may be painful, so that judgment must be exercised before it is permitted. Should any doubts concerning the bacteriology of the infection exist in the medical man's mind it should only be permitted with a rubber sheath.

The two complications most likely to arise during the treatment of a chronic prostatitis are epididymitis and the development of a sexual neurosis. Should the former arise all local treatment must be stopped until the swelling of the epididymis has subsided. Occasionally it happens that the epididymitis recurs every time that massage is resumed. In very troublesome cases of this kind vasotomy should be undertaken.

The development of a neurosis is avoided by looking after the patient's health and taking every opportunity to reassure him concerning his sexual future. Should symptoms of nerve strain develop it is better to interrupt all treatment and send the patient away for a holiday.

## Reviews

**THE PINEAL ORGAN. THE COMPARATIVE ANATOMY OF MEDIAN AND LATERAL EYES, WITH SPECIAL REFERENCE TO THE ORIGIN OF THE PINEAL BODY; AND A DESCRIPTION OF THE HUMAN PINEAL ORGAN CONSIDERED FROM THE CLINICAL AND SURGICAL STANDPOINTS.**—By R. J. Gladstone, M.D., F.R.C.S., F.R.S.E., D.P.H., and C. P. G. Wakeley, D.Sc., F.R.C.S., F.R.S.E., F.Z.S., F.A.C.S., F.R.A.C.S. Baillière, Tindall and Cox, London. Pp. xvi plus 528, with 324 illustrations. Price, 42s.

THIS interesting book is a study of the history of the pineal body and parietal sense organ from the standpoints of embryology, comparative anatomy and geology. The field covered by the book is so wide that few people could appreciate properly all the different sections, which cover the vast field of development and histogenesis of the pineal organ of vertebrates and invertebrates, the eyes of types which are intermediate between vertebrates and invertebrates, the relation of the median to the lateral eyes, the stricture of an adult organ, its function and the pathology, symptomatology, diagnosis, and the treatment of pineal tumours, including the operative technique. The manner in which the pineal body arises in man is fully described. In the concluding chapter the authors have discussed the nature and function of the pineal body of the human brain. But how this body has become associated with the development of the sexual system is still an enigma. The position of this organ as an endocrine gland is by no means secure.

This book constitutes an achievement in writing, in original observation and in scientific manner of description. It is one of the rare and comprehensive treatises in which a subject is approached from an

original point of view, is expanded and propounded and exhaustively portrayed. The authors, a surgeon and an anatomist of ability and experience, have the capacity of combining an abundant understanding of anatomy and physiology with a good sense of pathology. In addition, the symptomatology and the clinical picture are dealt with in a commonsense way and good judgment, devoid of fixed opinion, flexible and open-minded, which combined with the surgical experience make an excellent presentation of the whole subject.

This is a readable volume with unusually good illustrations and extensive references from world literature. The views expressed from the biological point of view are remarkably balanced, and controlled judgment with regard to the treatment of pineal affections makes the volume one of interest and of great value. The book is produced and printed in a manner befitting such an outstanding work, in a subject where so little real research has been undertaken hitherto.

R. N. C.

**THE MEDICAL ANNUAL: A YEAR BOOK OF TREATMENT AND PRACTITIONER'S INDEX.**—Edited by H. Lethby Tidy, M.A., M.D. (Oxon.), F.R.C.P., and A. Rendle Short, M.D., B.S., B.Sc., F.R.C.S. Fifty-eighth Year 1940. John Wright and Sons, Limited, Bristol (Stonebridge House). Pp. xiviii plus 604. Illustrated. Price, 20s.

In a changing world there are a few things that remain unchanged; of these the *Medical Annual* is one. It is still about the best investment for the medical practitioner and to the specialist it is invaluable, for it provides him with a rapid means of keeping up to date in collateral specialties. To the reviewer, however, it provides a problem, for there is so little scope for

general comment that is not mere repetition and so much scope for detailed review that he does not know where to begin. It is the policy of the publication, and an excellent one, to choose certain important subjects, on which there have been considerable advances in recent years, for a short but fairly complete summary of our present knowledge; this is well exemplified in the summary on hæmorrhagic diseases. This practice makes the *Medical Annual* a valuable book of reference for many years. The article referred to is by Drs. Stanley Davidson and H. W. Fullerton; it is an excellent summary of recent work and gives a very good idea of the present position, especially of the treatment of these troublesome conditions. Some light has been thrown on the pathogenesis of thrombocytopenic purpura by the observation that spleens from patients suffering from this condition contains a substance which depresses platelet formation in normal animals to a far greater extent than the same extract from normal or other diseased spleens. A very similar effect is produced by the injection of allyl-isopropyl-acetyl-carbamide (sedormid), a sedative medicament, and clinically many cases of severe purpura have followed its continued use, or even brief use in persons with a hæmorrhagic tendency. Good permanent results are claimed for splenectomy in thrombocytopenic purpura.

Our knowledge regarding prothrombin and vitamin K is advancing rapidly. What appears to be chemically-pure vitamin K has been prepared and the synthetic preparation is only a matter of time, if it has not been prepared already. The parenteral administration of vitamin K in all forms of jaundice where there is any hæmorrhagic tendency seems to be indicated, as bile appears to be necessary for its absorption from the intestinal tract.

There is a good discussion on the antacid drugs for administration in hyperchlorhydria. They are a difficult problem as most of them stimulate an increased acid secretion after they have left the stomach, and are also liable to give rise to an alkalosis. Colloidal aluminum hydroxide appears to be the most useful with magnesium trisilicate as an alternative, not yet fully tried.

There are some interesting figures showing the effect of severe hæmorrhage from a peptic ulcer on the blood. The immediate result is a loss of total blood volume—a blood count at this stage would not show any anæmia as the proportions are not disturbed; then within a few hours the blood plasma recovers its normal level—at this stage a blood count would show a marked anæmia; finally, after a matter of weeks the red cells are replaced and the blood picture is again normal. This emphasizes the importance of blood volume estimations, which are so seldom carried out in clinical practice.

We feel that we must add a mild criticism. The *Medical Annual* is essentially a practical publication and however interesting the subject may be to a small section of readers, we do not feel that it is justifiable to occupy over a page on a review of one paper on the blood groups of African natives; the review itself contains many irrelevancies. Nor on the opposite page is there much value to the practitioner in a diagram and an admittedly very short description of transfusion into the abdominal aorta, however thrilled the young surgeon may be by such a display of questionable surgical acrobatics.

The illustrations are, as usual, useful and of a high standard. This remark applies particularly to the coloured plates showing gastroscopic views of the intestinal mucosa in various conditions, taken from an article in the *British Journal of Surgery* by J. Howell Hughes. There is a very significant picture of the mucosa in early carcinoma, before there is any ulceration and therefore almost certainly no symptoms.

**PHYSIOLOGICAL CHEMISTRY: A TEXTBOOK FOR STUDENTS.**—By Albert P. Mathews, Ph.D. Sixth Edition. 1939. Baillière, Tindall and Cox, London. Pp. xvi plus 1488. Illustrated. Price, 44s.

WITHOUT doubt biochemistry plays a very important part in the practice of medicine, especially in helping

the diagnosis, prognosis and treatment. One would not be far wrong in saying that recent advances in biochemistry have gradually been transforming medicine into a perfect science and rapidly replacing the art of guessing and empiricism in the diagnosis and treatment of disease.

The present edition serves to show that the author had to work hard in bringing the rapidly changing subject into line with the modern advances so as to make it as much up-to-date as possible. This has necessitated a thorough revision of almost all the chapters of the book. The labour of the author in accomplishing this heavy task appears to have been highly successful. The book has been written in a clear, lucid and simple style and gives much valuable information to the general practitioner and senior medical student, so that they can understand many of the intricate physiological problems, not only in connection with the metabolism of the body but also in connection with other problems such as digestion, nutrition and growth, energy transformation, endocrinology, etc., in the light of clinical medicine.

We are of opinion that the book is a valuable contribution to our up to date knowledge of the physiological principles in medical practice and should prove to be useful to those for whom it is intended.

J. P. B.

**TOMOGRAPHY.**—By J. B. McDougall, M.D. (Glas.), F.R.C.P. (Ed.), F.R.S.E. 1940. H. K. Lewis and Co., Ltd., London. Pp. 73, with 110 illustrations. Price, 21s.

TOMOGRAPHY, which is best defined as sectional radiography, is the latest addition to radiological science. It provides us with a means whereby we can obtain diagnostic pictures of a previously selected section of a thick part of the body such as the chest. It is of course applicable to other parts as well; but, it is in chest radiology that the method is of particular use.

In his introduction the author points out that one of the main sources of difficulty in interpreting an ordinary skiagram of the chest is the superimposition of the shadows of the bony framework and blood vessels, bronchioles and alveoli. It is not generally appreciated, for instance, that the ribs cover two-thirds of the pulmonary fields. In the pathological chest pulmonary fibrosis, displacement of the mediastinum, pleural thickening and distorted rib shadows further increase the difficulty of interpretation.

At one time it was thought that stereoscopy would solve our problems in this respect; but for various reasons, more especially the personal factor, this method has never been widely adopted.

Following this general discussion the geometrical principles underlying the method are discussed and the technique of examination described. These call for no special remarks.

The rest of the book is occupied by a collection of tomograms with accompanying notes.

The volume as it stands gives a clear and concise account of a method of diagnosis which must in time become indispensable to every department dealing with diagnosis of pulmonary tuberculosis. The author and the publishers are to be congratulated for the mode of presentation of this new departure in diagnostic medicine.

J. A. S.

**REASSURANCE AND RELAXATION: A SHORT TEXTBOOK OF PRACTICAL PSYCHO-THERAPY DESCRIBING THE NATURE OF ANXIETY AND HOW TO INDUCE RELAXATION IN THE NERVOUS PATIENT.**—By T. S. Rippon, M.R.C.S., L.R.C.P., and P. Fletcher. George Routledge and Sons Limited, London (Broadway House, 68-74, Carter Lane, E.C.4). Pp. 221. Price, 6s.

THIS is a brief outline in simple language of what may be described as the elements of psycho-analysis.

It is clearly written and avoids the numerous technical terms that have grown up around the science of psycho-analysis so that it is readily comprehensible to

## KEEPS FALSE TEETH CLEAN

### Steradent

REGD. TRADE MARK

"I really think in all my experience that 'Steradent' is the finest product I have used" writes a leading dentist. It is widely acknowledged by the Dental Profession to be the most efficient preparation for cleaning and sterilising dentures. It removes mucin film, tartar, stains, tarnish and all unsanitary accumulations. It is harmless to gold, platinum, stainless steel, etc. Patients should immerse their dentures overnight in a glass of warm water in which 'Steradent' has been dissolved. Then take out and rinse.

Samples and literature will gladly be sent on application to

## CLEANS & STERILISES FALSE TEETH

the physician who has not studied this subject. It should be of great value to general practitioners as it gives him quite enough information as to how he can apply this aid to healing in those of his patients whose physical disability is aggravated by the simpler types of psychic trauma.

The book is also of use in indicating to the physician himself minor shortcomings that may be present in his own psychological make-up, the understanding of which cannot fail to make him a better doctor.

**PSYCHOLOGY AND PSYCHOTHERAPY.**—By William Brown, D.M. (Oxon.), D.Sc. (Lond.), F.R.C.P. Fourth Edition. 1940. Edward Arnold and Company, London. Pp. viii plus 260. Price, 12s. 6d.

ALTHOUGH the title of this book indicates its concern with the treatment of mental disorder, it actually deals with only a few aspects of treatment. Occupational therapy, hydrotherapy and 'shock' therapy, to mention a few well-established forms of mental therapy, are not even mentioned. On the other hand, psychoanalysis, hypnosis and so on are discussed at some length. The psychoanalytical psychology of Freud comes in for a good deal of adverse criticism, but the author overlooks entirely the one great flaw in psychoanalysis, *i.e.*, its disinclination to bring its principles into relation with the mental activities of non-human animals. The author appears to entertain the view that man is capable of attaining to almost any degree of sublimation, in spite of the existence of an immensity of proof against any such presumption. His optimism in respect of the results of the treatment of alcoholism and drug addiction will doubtless shock many workers in the same field, particularly in view of the crudity of the procedure which he advocates. Dr. Brown has a good deal to say on the psychology of peace and war, but omits any reference to the most penetrating study that exists on the subject in the English language, namely, 'Instincts of the Herd in Peace and War' by W. Trotter. In his chapter on 'Relation of Mind to Brain', the author shows himself to be under the spell of the fascinating philosophy of Bergson and so oblivious to the damaging criticisms to which its difficulties lay it open. The book is supplied with a copious bibliography and a tolerably good index.

O. B.-H.

**THE HISTAMINE AND INSULIN TREATMENT OF SCHIZOPHRENIA AND OTHER MENTAL DISEASES.**—By Horace Hill, M.R.C.P. 1940. Baillière, Tindall and Cox, London. Pp. vii plus 133. Price, 6s.

THIS is a very informative little book on the subject with which it deals. The writer points out that histamine is present in the body in any and every variety of shock and that a lot of the poisonous symptoms seen during shock therapy can be shown to be a mixture of the symptoms produced by poisonous doses of insulin and histamine. This induced the author to employ non-toxic doses of insulin and histamine. By this method the patient gets small repeated shocks and no 'fit'. This form of treatment is particularly favourable in its action on cases of long-standing. According to the author it is important to remember that histamine acts differently in different circumstances but always the same way under the same circumstances. As the dose suitable to each case varies so much, the author recommends keeping small quantities of the fluid of various strengths to be injected. The standard dose is 0.5 mgm. The indications for the correct dosage are the sensations of the patient and the extent and duration of the flush to which histamine gives rise, along with the pulse and respiration rates. The author recommends using three phials each containing one fluid ounce of mixtures of insulin and histamine. The amount of insulin used is 5 units while the amounts of histamine are 0.5 mgm., 1 mgm., and 1.5 mgm. Each dose is 5 minims. When the appropriate dose is found, it may be given daily for a week and then on alternate days. The author gives a number of case histories

in illustration of the type of cases treated and the results obtained.

O. B.-H.

**MY LIFE.**—By Havelock Ellis. 1940. William Holman, Limited, London. Pp. xviii plus 542. Price, 15s.

IN the preface to this book the author states that he began to write his biography as far back as 1899 and that he chose his 'Finest moments' in which to write it. The son of a sea captain, Havelock Ellis always entertained a strong liking for the sea and the ships upon it. When seven years old he went round the world in his father's ship and at the age of sixteen he went to Australia, once more on board his father's ship. In Australia he spent four happy years mostly as a school master and during a part of this period in a very lonely place called Sparkes Creek in New South Wales. Here he read and pondered over life as he saw it. He read enormously from early boyhood and throughout his life. He acquired a considerable knowledge of French literature and published in 1935 a study of French literature under the title *From Rousseau to Proust*. On his return to England he decided to become a doctor and joined St. Thomas' Hospital in London. In spite of his great intellectual gifts he had great difficulty in passing his examinations to qualify, so that it was not until seven years had passed that he took the Licentiate in Medicine, Surgery and Midwifery of the Society of Apothecaries. During the whole of the period of his medical education Ellis was deeply engaged in various forms of literary work. It was about this time that he became acquainted with the works of James Hinton whose doctrines made a profound impression on Ellis. In 1883 he made the acquaintance with the woman who played an immense part in his life, Olive Schreiner, the talented authoress of that remarkable novel, *The Story of an African Farm*. Ellis and Olive Schreiner became very devoted to each other and their friendship lasted long after each of them married. In 1891 Ellis married Edith Lees, a brilliant woman with much talent for public speaking and writing. Although sexually an invert, she did nevertheless make Ellis a devoted wife until her mental balance broke down never completely to be re-established. In 1898 the famous Bedborough trial was held in the London Central Criminal Court. The trial arose through a man named George Bedborough selling a copy of the first volume of Ellis' *Psychology of Sex* which dealt with sexual inversion. Bedborough pleaded guilty and after a long and wearisome trial was bound over in the sum of £100 to come up for judgment, when called upon. The proceedings were a reflection on the law of England and to some extent on the medical profession of England for no eminent English doctor had the courage to come forward and attest in court as to the scientific value of Ellis' book. *The Psychology of Sex* was doubtless Ellis' *magnum opus* but his exquisite prose is not to be found therein but in later works, notably *The Dance of Life*. Though afflicted at times with much sorrow and anxiety, Ellis testifies to much happiness in his life which ended in 1939. A few months before there died another great exponent of sexual psychology, Sigmund Freud.

O. B.-H.

**A TEXTBOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY.**—By Rai Bahadur Jaising P. Modi, L.R.C.P. & S. (Edin.), L.R.F.P.S. (Glas.). Sixth Edition. 1940. Butterworth and Company (India), Limited, Incorporated in England, Phoenix Building, Graham Road, Ballard Estate, Bombay. Pp. 820 plus clv, with 3 plates (2 coloured) and 158 illustrations in the text. Price, Rs. 15

THIS excellent book by one of the pioneers in the field of forensic medicine in India has been thoroughly revised. All points referred to in the review in this paper on the last edition have received attention.

In the description of the picture of blood groups a and b should be a and b. In the technique of grouping

blood a 2 per cent suspension of red blood cells is preferable to a 5 per cent suspension.

With the advice to the practitioner to call in a consultant 'to save his own skin', when looking after a case on whom an illegal operation to procure abortion has been performed by someone else, younger medical men will not agree. An average medical man is ethically sound and his skin safe. He is not a detective. Letting an unhappy woman keep her secret is not the same thing as letting a murderer escape. Unnecessary consultation is unnecessary publicity.

War gases have been included. Gases used in household refrigeration and slimming drugs could have been included with greater justification, and so could have been manganese poisoning, a recent addition to industrial risks.

The index perhaps could be made fuller.

The paper and printing are good. No printer's errors attract attention. To the impregnated cloth used in the binding insects are rather partial.

The book should be on the desk of all medico-legal workers in India. The price is reasonable.

**TREATMENT BY DIET.**—By Clifford J. Barborka, B.S., M.S., M.D., D.Sc., F.A.C.P. Fourth Edition. Revised. 1939. J. B. Lippincott Company, Philadelphia and London. Pp. xv plus 691. Illustrated. Price, 21s.

THE book is written with the purpose of presenting to the physicians a practical and systematic method of prescribing diets and applying treatment by diet in health and disease, and also teaching the patient to make a selection of the proper amounts and types of food prescribed for him.

The first two parts deal with the subject of diet in health, the recent knowledge regarding the vitamins, their common sources, requirements, vitamin deficiency diseases, etc., and the application of diet in therapy. Part III deals with the diets in various diseased conditions, part IV, the routine hospital diets and special methods of feeding, and part V is the appendix, which contains a large amount of useful information.

In dealing with diet in each disease the author has followed a very commendable method. He has first described briefly the 'nature of the disease', the 'object of diet' and the principles that should be followed in prescribing the diet, and then the diets that are to be advised in different stages of the disease, in full detail. Most of the important diseases have been dealt with, but the serious omissions include infant feeding, diet in diarrhoeic diseases and marasmus in children.

The book is an American production, so the detailed diet tables are necessarily more suited to American and European tastes and caloric requirements. The reviewer feels that it is a pity that there is no single book in this country that contains details of dietary in health and disease, suited to the peoples of India, with diet tables consisting of indigenous foodstuffs and recipes.

The book under review will be useful to the practitioner in India in that it contains sound principles on which he can base the diet of his patients and a practical method of prescribing suitable diets, which he can modify to suit his requirements.

P. C. S. G.

**AN INTRODUCTION TO BIOCHEMISTRY.**—By W. R. Fearson, M.A., Sc.D., M.B., F.I.C. Second Edition. 1940. William Heinemann (Medical Books) Limited, London. Pp. xii plus 475. Price, 17s. 6d.

THIS is a good book on physiological chemistry which starts with a detailed account of the elements found in the living organism and then proceeds to consider the inorganic and organic compounds associated with life. The book appears to us to be admirably suitable for students entering upon higher studies in the subject. It has been written in an excellent style and the author has dealt comprehensively with the fundamental processes going on in the human body, avoiding lengthy discussions on debated points, which are often confusing to the student.

The book is up to date, well arranged and well set up. Several chapters have been entirely re-written, especially chapter II, dealing with the classification and discussion of the biological elements, the perusal of which will give a mine of information. Among other subject-matter thoroughly revised and brought up-to-date may be mentioned chapter IV, dealing with solutions and colloidal systems, chapter XII, dealing with pigments, chapter XIX, dealing with tissue respiration and chapter XXV, dealing with blood and tissue fluids.

As an admirable summary of the recent advances in biochemistry we recommend the book not only to medical students but also to all who want to be introduced to the subject of modern biochemistry.

J. P. B.

**AIDS TO PHYSICAL CHEMISTRY.**—By R. G. Austin, B.Sc. (Lond.), A.I.C., F.R.M.S. 1940. Baillière, Tindall and Cox, London. Pp. x plus 361. Illustrated. Price, 5s.

THIS handy little volume belongs to the well-known Students' Aid Series and is designed to meet the needs of students of medicine, dental and veterinary surgery, pharmacy and also of science students preparing for university intermediate examinations. Although it does not pretend to be a complete text, it has dealt with all the important aspects of physical chemistry and can be easily followed by students who have attended lectures on general theoretical chemistry. The use of mathematics has been avoided as far as possible, but the illustrative numerical examples dealing with physico-chemical measurements will assist the student in the proper understanding of the principles. Physical chemistry finds an increasing importance in the curricula of the medical students as well as in those of students of other sciences, and this volume, written in a clear and simple style by an author who has had the experience of teaching students of medicine, science and cognate subjects over many years, should prove indispensable for those who have no time to go through the larger standard texts on the subject.

S. G.

**MINERAL METABOLISM.**—By Alfred T. Shohl, M.D. 1939. Book Department, Reinhold Publishing Corporation, 330, West Forty-second Street, New York, U. S. A. Pp. x plus 384. Illustrated. Price, 30s.

THE development of knowledge in the various branches of chemical science has been so rapid during the last two or three decades that it is almost impossible for any single individual to keep in touch with all the branches outside his own speciality. To obviate this difficulty and to facilitate the work of those engaged upon different fields of chemical and physical problems, the American Chemical Society undertook, since 1919, a systematic production and publication of scientific and technical monographs on chemical subjects. The present volume is one of these publications, the main purpose of which is to describe the rôle of minerals in the structure and function of the human body.

Within the last few years, the subject of mineral metabolism has advanced by rapid strides and many eminent authorities have increased considerably the bounds of our knowledge by their valuable contributions to the subject. We welcome the present volume because it is not only a valuable addition to the list, but it has several new and interesting features of its own. In the first place it deals with the mineral composition of the body and discusses such matters as minerals of the whole body, mineral content of the different organs, etc., it then deals with the composition of the secretions and excretions and discusses the mineral composition of secretions like saliva, gastric, pancreatic and intestinal juices, bile, etc. The mineral composition of urine, faeces and sweat are then discussed. Among other subjects dealt with in the book are the mineral composition of the internal secretions of the adrenals, pituitary, parathyroid, thyroid and other glands. The chapter on the studies of the mineral intake, balance and requirements is very interesting

## CREMAFFIN

(Cream of Magnesia with Liquid Paraffin)

A pleasantly flavoured emulsion free from any oily taste. Cremaffin is an ideal antacid and gentle laxative.

### CREAM OF MAGNESIA WAFERS

Each wafer contains the equivalent of one teaspoonful of Regesan Cream of Magnesia.

## BURNOL

A creamy emulsion containing 0.1% of the powerful non-toxic antiseptic Neutral Acriflavine presented in handy collapsible tubes ready for immediate application.

BURNOL has given excellent results in the treatment of burns and scalds, tropical sores, tinea infections, Dhobie itch, insect bites, minor injuries, ophthalmia of all types, suppurating wounds, and septic conditions generally.

# THE CALL OF PAIN

The call of pain is seldom stilled, and relief is of primary importance to the suffering patient. The paroxysmal pain of dysmenorrhœa, the persistent and intense throbbing of migraine, the shooting pains of neuralgia, the pain in affections of the bones and joints, the pain resulting from accidents — all these, and many other conditions, yield with impressive readiness to the sedative and analgesic efficacy of Veganin. With Veganin there is no systemic disturbance, no habituation. It may therefore be safely entrusted to the patient as a dependable means of relieving and preventing pain.

Prepared by WILLIAM R. WARNER & CO. LTD., LONDON, ENGLAND.

and will repay perusal. We do not hesitate to recommend the book to our readers.

J. P. B.

**AIDS TO MEDICAL DIAGNOSIS.**—By Arthur J. Whiting, M.D., M.R.C.P., and G. E. Froderick Sutton, M.C., M.D., B.S. (Lond.), M.R.C.P. Fifth Edition. 1940. Baillière, Tindall and Cox, London. Pp. vii plus 293. Illustrated. Price, 5s.

This is the fifth edition of a book that is meant to help the reader in getting a good outline of the subject of medical diagnosis.

The book contains concise descriptions of the diagnostic features and differential diagnosis of the various infectious and systemic diseases. Though the subject of diagnosis of the diseases that are common in the United Kingdom has been dealt with more or less satisfactorily, there is no mention of such important diseases as malaria, kala-azar, amoebic dysentery, etc., diseases that the practitioner in the tropics has to diagnose in his day to day practice.

The fact that little attention has been paid to the tropical diseases has lessened the value of an otherwise useful book to students and practitioners in the tropics.

P. C. S. G.

**THE AUSTRALIAN ARMY MEDICAL SERVICES IN THE WAR OF 1914-1918. VOLUME II.**—By Colonel A. G. Butler, D.S.O., V.D., B.A., M.B., Ch.B. (Camb.). 1940. Australian War Memorial, Canberra. Pp. xvi plus 1010, with 212 illustrations, maps and graphs. Price, 21s.

It was a coincidence that this volume came into the hands of the reviewer on the very day that the names Peronne, Amiens, Abbeville, etc., had again begun to figure in the war news. This indicates clearly that its appearance has been too long delayed to give it any real value as a guide to field operations in the present war.

Nevertheless it is a good outline of the activities of the Australian Army Medical Corps in the second phase of its career in the Great War, that is in France and the base depôts and hospitals in England and as such it is a useful contribution to the history of the war.

Perhaps the most valuable part of the book as a guide to future Australian medical administrators is the account of the difficulties that arose at headquarters in England by the failure of the superior authority in Australia fully to appreciate the conditions in France and England, and the necessity of complying in every detail with the orders issued by the War Office. The result of this failure to understand was that the Australian medical service was often hampered by orders from Australia which were at variance with the advice sent by those on the spot in England. The same refusal to accept advice led to many men being sent as reinforcements who were unfit for the rigorous condition of service in the European winter.

If the book prevents such things occurring again in this or in subsequent wars it will have served a useful purpose.

P. A. M.

**THE PRINCIPLES OF ANATOMY: AN INTRODUCTION TO HUMAN BIOLOGY.**—By A. A. Abbie, M.D., B.S., B.Sc. (Syd.), Ph.D. (Lond.). 1940. Angus and Robertson, Limited, Sydney. Pp. 143. Illustrated. Price, 10s. 6d.

This book is stated to have been '... particularly designed to help those who come to the study of anatomy without any biological training'. Students in this category must be few and far between because even schools now give a certain amount of instruction in biology and kindred subjects, so the number of persons who take up the study of human anatomy so ill-equipped as this must be negligible.

It is little more than an illustrated dictionary of elementary anatomical terms in which the words defined are indicated throughout the text by being printed

in heavy type. It is difficult to see in what manner this book will be of any real help in the study of anatomy.

**THE ROMANCE OF TUBERCULOSIS.**—By Amiya Jiban Mookerjee. 1939. Thacker, Spink and Company (1933), Limited, Calcutta. Pp. xlv plus 196. Price, Rs. 2-8

The problem of tuberculosis, which may be truly called 'Public Enemy No. 1', is attracting the attention of the medical world and the general public, but only very few are aware of the serious nature of the disease and little is being done in this country to control its spread. In this book the author has studied and observed the problem from his life's hard experiences, thus to save others from an untimely death. The origin, growth, development, diagnosis and treatment of the disease, and the anti-tuberculosis work in India and abroad have been described well by a sufferer himself as 'the problem is no longer a monopoly of the specialists'. Those, who are interested in this country's welfare, would do well to respond to the stirring appeal made by the author by lending their greater support and help in the struggle, to combat this serious disease. Victory is assured if each one will do his part.

**CATALOGUE OF THE GRANT MEDICAL COLLEGE LIBRARY, BOMBAY, 1939.**—Compiled by K. N. Achyut, B.A. (Bom.). Third Edition. 1940. Government Central Press, Bombay. Pp. 460. Price, Rs. 2-8 or 4s. 6d.

This is not the main catalogue of the library. The main catalogue, which is meant for the use of the readers, is maintained by means of cards and is called 'The Dictionary Card Catalogue'. The present catalogue is a printed shelf-list and is mainly intended to help the internal administration of the library such as stock taking, keeping the number of books in various classes properly balanced, preventing unnecessary duplication of copies, etc.

This shelf-list is divided into two parts. Part I contains new books which have been classified according to the Dewey System. Part II lists the old stock of books. The old accession and group numbers, as given in 1930 catalogue, are preserved in this part. This is a useful publication and will meet the requirements of those concerned.

#### OTHER BOOK RECEIVED

Shell Shock in France—1914-18. Based on a War Diary kept by Charles S. Myers, C.B.E., F.R.S. 1940. The University Press, Cambridge. Pp. xi plus 146. Price, 4s. 6d.

## Abstracts from Reports

**INDIAN CHEMICAL MANUFACTURERS' ASSOCIATION: REPORT OF THE COMMITTEE FOR THE YEAR 1938-39**

The Indian Chemical Manufacturers' Association was inaugurated on the 16th July, 1938. The rapid development of the chemical and pharmaceutical industry in India has given rise to various problems and the necessity of having an all-India organization of manufacturers of chemical, pharmaceutical and allied products in India was long felt. In order, therefore, to enable the manufacturers to combine and co-operate in solving the various problems facing this industry and to put the view-point of the industry on matters concerning it before the Government and the public, the above association was started. Acharya Sir P. C. Ray, in his message at the time of inauguration, stated:

'The import of chemical, pharmaceutical and other allied products forms a substantial part of the annual drain of our wealth to foreign countries. It is a happy augury that the chemical and pharmaceutical industry is receiving adequate attention these days from entrepreneurs and many large and good factories have been established in India. With the growth of the industry, however, a number of questions are cropping up which require concerted action on behalf of all engaged in the industry. I am, therefore, glad to learn that some manufacturers are actively considering the question of establishing an Indian Chemical Manufacturers' Association and that it will be affiliated to the Indian Chamber of Commerce, which is always active in advancing the cause of the Indians. I need hardly say that the time is ripe for the formation of such an organization and I wish them every success. I trust that the association will be able to render useful service to the chemical and pharmaceutical industry.'

The Association is an organization of manufacturers of chemical, pharmaceutical and allied products and its membership is confined to manufacturers only. Besides the chemical and pharmaceutical industry, it is intended to represent the interests of manufacturers of heavy chemicals also.

The inaugural meeting, which was attended by representatives of various chemical concerns, was held at the premises of the Indian Chamber of Commerce at 135, Canning Street, Calcutta, on Saturday, the 16th July, 1938.

[The formation of this association is an important step forward in the general tendency towards the improvement in the quality of drugs which began with the Drugs Inquiry Committee in 1930 and which since that time has made slow but steady progress in many directions.—Editor, I. M. G.]

#### THE TUBERCULOSIS ASSOCIATION OF INDIA. (INCORPORATING THE KING-EMPEROR'S ANTI-TUBERCULOSIS FUND AND THE KING GEORGE THANKSGIVING (ANTI- TUBERCULOSIS) FUND): FIRST ANNUAL REPORT 1939

FOLLOWING the general approval conveyed by the the provinces and states to the draft constitution of the Tuberculosis Association of India, the Association was registered on the 23rd February under the Societies Registration Act, XXI of 1860. The King George Thanksgiving (Anti-Tuberculosis) Fund along with the King-Emperor's Anti-Tuberculosis Fund was incorporated in the new Association.

The inaugural general meeting was held at the Viceroy's House under the presidency of Her Excellency the Marchioness of Linlithgow on the 29th March, 1939. In addition to the members of the central committee the meeting was attended by the other foundation members and by two representatives from each of the major provinces, from Baluchistan and from the following states: Bhopal, Indore, Gwalior, Hyderabad, Baroda, Travancore, Mysore, Jaipur, Jodhpur and Bikaner.

At the meeting of the 30th March, 1939, the central committee of the Tuberculosis Association of India appointed Dr. C. Frimodt-Møller, C.B.E. (Hon.), M.B., Ch.B. (Copenhagen), as medical commissioner for a period of two years.

Since his appointment on 1st May, 1939, the medical commissioner has rendered help in the development of a number of tuberculosis schemes in provinces and states advising on contemplated new projects as well as on the improvement and development of existing work.

After a careful study of the tuberculosis problems in India and after personal contact with tuberculosis workers and administrators all over the country, the medical commissioner has advocated a scheme of 'Control of Tuberculosis by Organized Home Treatment' as the chief measure to aim at in the present campaign. Such a scheme requires as its foundation

a great number of modern tuberculosis clinics and a smaller number of large central tuberculosis sanatoria and tuberculosis hospitals. Without this foundation and without the establishment of close co-operation with the medical practitioners, with care and after-care committees, ex-patients' colonies, and with the government and local bodies and private organizations the scheme can never work successfully.

In his tours the medical commissioner has visited only those places whence requests have come for his visit and advice. After his visit he has drawn up a report with detailed suggestions of improvement of existing institutions and a scheme for the most effective campaign in the provinces, states or places in question. Copies of these reports have been sent to the committees and administrators concerned.

The main objectives of the Association's educational efforts are firstly to help the public towards a practical knowledge of tuberculosis, its causes and prevention, and secondly to create a public opinion favourable to the application of the necessary public health measures. By producing educative material for distribution throughout India, the centre carried on an activity which had previously been used with good effect by the King George Thanksgiving (Anti-Tuberculosis) Fund.

Propaganda material was issued free to most of the St. John Ambulance Brigade Overseas centres which organized lectures on tuberculosis in connection with their training camps. As most of the provincial and state associations came into being in the latter half of the year under review their activities in this respect naturally did not assume large proportions.

The Association maintains a large stock of pamphlets, leaflets, charts, posters, giving in plain language suitable for laymen the important facts about tuberculosis. During the year 20,584 pamphlets and leaflets, 7,925 posters and 2,050 charts were issued from the Red Cross Depot where our material is stocked.

The following new pamphlets were issued by the Association during the year:—

1. Social Service in Tuberculosis (English).
2. Planning of Tuberculosis Institutions in India (English).

During the year it has been necessary to reprint the two pamphlets:

'What a Teacher should know about Tuberculosis' (English, Hindi and Urdu, 3,000 copies of each) and 'Social Service in Tuberculosis' (English, 10,000 copies).

Five sets of magic lantern slides were sold during the year and four sets lent for demonstrations by interested organizations.

Training of doctors in the preventive aspects of tuberculosis has been a successful activity under the King George Thanksgiving (Anti-Tuberculosis) Fund and this activity is therefore continued by the Tuberculosis Association of India. There has been a great demand for this training from all parts of India and during the year under review two post-graduate courses were organized, one in Calcutta (January-February 1939) and the other one in Madras (October, 1939). Fifty-five doctors selected from different provinces and states received training at these courses but the number of applicants far exceeded the accommodation available.

The short post-graduate courses are not intended for the training of tuberculosis specialists though they are of the utmost importance as a link in the chain of anti-tuberculosis measures and in fact indispensable in the present campaign.

The object of these courses is to supply doctors with the knowledge of the new developments of treatment and of the various problems of tuberculosis, so that they may be able to co-operate effectively with the tuberculosis specialists in charge of the institutions. Without such an understanding no effective co-operation will be possible between the doctors and the tuberculosis clinics, and without such a co-operation the scheme of 'Control of Tuberculosis by Organized Home Treatment' which is now being inaugurated all over India cannot achieve the results hoped for.

## ‘Elastoplast’ in the treatment of Varicose Ulcers

The ambulatory treatment of Varicose Ulcer of the Leg by the Dickson Wright method with Elastoplast is now standard practice.

The combination of the particular adhesive spread used in making Elastoplast, with the remarkable stretch and *regain* properties of the Elastoplast cloth, provide the precise degree of COMPRESSION and GRIP shown by clinical use to be essential to the successful practice of the bandaging technique.

# MODERN VIEWS OF INFANT FEEDING

"The best available substitute for human milk is a good variety of dried milk. Such milk is safe, in that it is free from tubercle bacilli and pathogenic organisms; its vitamin and iron content is adequate; it is quickly and easily prepared and thereby error is reduced to a minimum; and it has been made to resemble human milk to an extent that could never be achieved in the average home". —"Lancet" 3.7.37.

## Cow & Gate Milk Food

This view is now well established in Medical and Nursing Practice, as is also the view that Cow & Gate Milk Food not only ensures bacteriological purity, provides adequate vitamins and minerals, is easily digestible and is simple to prepare, but also has been amply shown to provide the Doctor and Nurse with the most responsive Milk Food for their difficult cases.

One of the essential parts in the campaign against tuberculosis is the provision of a sufficient number of doctors fully trained in the modern methods of diagnosis and treatment who can take charge of tuberculosis institutions. Unfortunately there are at present in the whole of India only a few places where doctors can be given the proper training. Therefore one of the first measures in the campaign in India is that each province and state should concentrate its efforts to establish a large tuberculosis training centre, before clinics are widely organized.

According to the scheme passed by the King George Thanksgiving (Anti-Tuberculosis) Fund Committee a course for the training of tuberculosis health visitors was organized at Delhi from the 16th January to 15th July, 1939. At the request of the Fund Committee the authorities of the Lady Reading Health School and the Delhi Municipality very kindly agreed to give all the facilities for the above course at their institutions.

At the termination of the course the candidates were examined in the following subjects:—

Home Nursing, Hygiene, Domestic Sciences and Tuberculosis.

Out of ten candidates, nine passed and one who failed to come up to the required standard was re-examined after a month's extra training and was declared successful.

The first conference of tuberculosis workers organized by the Tuberculosis Association of India was opened by Her Excellency the Marchioness of Linlithgow, the President of the Tuberculosis Association of India, in the Red Cross Conference Hall on the 20th November, 1939.

This is the third year in succession in which the editor of the *Indian Medical Gazette*, at the request of the Central Tuberculosis Organization, has issued a special tuberculosis number of the *Indian Medical Gazette*.

The special tuberculosis numbers have been very popular not only in this country but have attracted considerable attention outside India and the editor has received a number of appreciative letters from prominent tuberculosis workers in other countries.

A summary of tuberculosis news giving brief reviews of tuberculosis activities in India, has been contributed to the *Indian Medical Gazette* from time to time during the year.

The constitution of eleven provincial and of six state tuberculosis associations has during this year satisfied the conditions of affiliation as defined in the by-laws of the Central Associations and these associations have consequently been affiliated to the Tuberculosis Association of India.

Her Excellency the Marchioness of Linlithgow desired that a sum of Rs. 1 lac should be set aside for the construction of a Tuberculosis Model Clinic in Delhi and that when the clinic comes into existence the Tuberculosis Association of India should make a yearly contribution of Rs. 4,000 to this institution 'a controlling interest in the clinic in order that full use of it can be made for training and experimental purposes'. The central committee has resolved that steps should be taken to give effect to the conditions contained in Her Excellency's letter.

Dr. C. Frimodt-Møller visited the Pasteur Institute of India, Kasauli, in February 1939, with the object of reporting on the possibility of converting the Pasteur Institute into a sanatorium. After a study of the site and buildings he gave his opinion that if funds were available it would be possible to establish a sanatorium for 110 beds in the first instance with the possibility of development to 200 to 250 beds, with all modern facilities for treatment of pulmonary tuberculosis.

The Kasauli Sanatorium when established should be a centre for the training of doctors in tuberculosis for the whole of Northern India.

The Executive Sub-Committee of the Tuberculosis Association of India awarded the Hassan Masud Suhrawardy Memorial Anti-Tuberculosis Challenge

Shield to the Station Municipality, Bangalore, in recognition of a commendable effort made by a young organization in the anti-tuberculosis field.

Research on tuberculosis in India so far as it is undertaken at present is largely financed by the Indian Research Fund Association. The promotion of research in tuberculosis is also one of the activities of the Tuberculosis Association of India but as this Association is not at present in a position to support tuberculosis research on a large scale, it was decided to make a grant of Rs. 4,000 to the Indian Research Fund Association for expenditure during 1940 on research work in tuberculosis subject to the condition that the programme of work is approved by the Chairman of the Tuberculosis Association of India.

The Tuberculosis Association of India succeeded the King George Thanksgiving (Anti-Tuberculosis) Fund as the national representative of India on the International Union against Tuberculosis. The Association was represented on the Union by Major-General E. W. C. Bradfield and Dr. C. Frimodt-Møller as councillor members.

The year under review has been one of transition with the inauguration of new activities both in connection with existing institutions and schemes and in the planning and development of the campaign as a whole. Many new provincial and state tuberculosis associations have been formed and the affiliation of 17 to the Central Association has been completed.

#### ANNUAL REPORT OF THE INSTITUTE FOR MEDICAL RESEARCH, FEDERATED MALAY STATES, FOR THE YEAR 1938. BY A. NEAVE KINGSBURY, DIRECTOR

ENDEMIC areas of filariasis often have a considerable simian population. A number of monkeys (*Macaca irus*) have been trapped and examined. Three of ten were found to harbour microfilaria morphologically similar to *Mf. malayi*. It has been shown that these readily infect *M. longipalpis* and *M. uniformis* and that neither mature nor immature larvae could be distinguished from those of *Mf. malayi*. The experimental transmission of the latter to *Macaca irus* is in progress. The difficult problem of filariasis control will be still further complicated if the simian parasite proves also to be pathogenic to man. This is a matter of considerable public health interest which as yet remains an open question. The importance of *M. longipalpis* as the principal local vector of *Mf. malayi* has been demonstrated, though other species of *Mansonia*, if plentiful, may play a part.

The tuberculosis survey has been extended and the results of the Mantoux test on upwards of 3,000 Kuala Lumpur children are recorded. The parents of Tamil children in the local schools are largely of the 'clerical' class or artisans in the employ of Government: these children consequently enjoy good housing and reasonable dietary and it is noteworthy that the percentage of positive reactors is little more than half that for Chinese and Malay children. Among the latter there is a significant and sudden rise in the percentage of positives at about fourteen years of age; shortly before that age they pass from vernacular to 'English' schools where they mix freely with the more heavily-infected Chinese.

Apart from the Malays—few figures are available for the female children of that race—the rates for males and females are very similar, suggesting that the home is the main venue of infection. Chinese children appear to be the most heavily infected. Although this is probably due to crowded conditions of living with consequently massive infecting doses, racial susceptibility to allergy may perhaps be a factor contributing to these results. The general rates are high and indicate that unless there is considerable improvement in the general standard of living, no appreciable decrease in clinical tuberculosis can be expected within the next decade.

Experiments on the chemo-prophylaxis of malaria have been continued. Plasmoquine in an adult dosage

of 0.02 gm. twice weekly was given to the whole population (excepting very young children) of estate 'T' on which hyper-endemic malaria, mainly due to *P. vivax*, prevails. The numbers were large—five hundred rising to seven hundred—and the attendance at treatment musters averaged over ninety-five per cent. Gauged by malarial incidence, trophozoite and gametocyte rates, infection of new arrivals and of newly-born children, the effect was disappointing. Infected anophelines continued to be trapped at about the same rate as formerly, though from eighty *A. umbrosus* and *A. novumbrosus* dissected after feeding on *P. vivax* gametocyte carriers who had had plasmoquine within four days, oöcysts only have so far been obtained in two instances.

Trapping has been continued on this estate. In the first six months of the year the catches of *A. novumbrosus* were as numerous as those of *A. umbrosus*. Dry weather commenced in May, continuing until August and, as in 1937, *A. novumbrosus* did not, except for occasional specimens, reappear until November. In the case of *A. umbrosus*, however, there was no evidence of seasonal periodicity. Projected extensions to the estate have necessitated the felling of a large area of contiguous jungle, and probably as the result of this clearing, a few *A. maculatus* were taken during the year. It is of interest that this species had been unrepresented in the catches over the previous three years. The nearest hilly ground on which breeding is known to occur is five miles distant from the trap and three and a half miles from the new clearing: the intervening land is swampy and covered with high jungle.

On another estate the population was divided into three groups. Atebrin in a dosage of 0.3 gm. once weekly and of 0.3 gm. daily for five days every fifth week was given to two of the groups, while the third provided a 'control'. The regular weekly dosage was found to have considerably greater prophylactic value.

New anti-malarial remedies tested included 'Certuna', 'A. granulate', 'Malarin', 'Malario' and 'Sulphanilamide'. The last three will find little place in the therapeutics of malaria for all proved to be less effective in the treatment of malignant and benign tertian infections than quinine. 'Certuna', however, is of greater interest for Kikuth and Hecht have found its action on the gametocytes of *P. cathemerium* to be more potent than that of plasmoquine, while Sioli and Muhlen, and Missiroli have reported that it was less toxic. The virtue of 'Certuna' is claimed to reside in its gametocidal properties. Preliminary observations indicate that its value as a schizonticide in *P. vivax* and *P. falciparum* infections is small and that, as a gametocide, its value is similar to that of plasmoquine for *P. falciparum* but somewhat inferior to it for *P. vivax*. This drug may have been a causal factor in a case of mild acute bulbar paralysis. Another interesting new drug tested during the year was 'A. granulate', which has been developed to facilitate administration to children. In therapeutic value, however, the results, up to the present, point to a marked inferiority *vis-a-vis* atebrin, to which it is chemically allied.

The use of mosquito traps has been advocated for many years past and it is gratifying that the method is being more and more employed by health authorities. Among a batch of trapped anophelines forwarded for dissection from Bagan Datoh, one *A. sundanicus* was found with sporozoites in the glands. This was the first of that species to be found infected of over 4,000 dissected by the Entomological Division in the past five years.

Investigations of anti-larval oils have been continued and field experiments are now in progress. The effect of the addition of small quantities of pyrethrum has been tested: the rapidity of kill was often increased but the final mortality was unaltered for oils that are employed for anti-malarial purposes.

The study of local typhus fevers has been continued. The mutation of an X19 rat strain on transmission by *X. cheopsis* to the XK type has again been observed. As far as experiments have progressed, it appears that Sumatran mite fever and tsutsugamushi (Japanese

river fever) are probably one and the same disease; our Dutch colleagues, however, inclined to a different view.

Experiments relating to the preparation of a prophylactic vaccine against Japanese river fever has continued, though the protection of experimental animals has not yet been achieved.

The immunization of a horse against Japanese river fever has been continued with enormous quantities (1,000,000 guinea-pig infecting doses) of virus. After this last immunizing course two c.c.m. of the serum failed to protect guinea-pigs against ten infecting doses of virus. The serum was then concentrated (approximately 5/1), after which its effect had greater promise.

It is of interest that the demand for rice polishings extract has doubled in the past two years and quadrupled since 1933. Certain proprietary preparations have been assayed for vitamin-B<sub>1</sub> content and the time appears to be not far distant when synthetic products will provide an economic substitute for the rice polishings extract.

It is widely held that rice, parboiled in ordinary cooking utensils, retains considerable vitamin B<sub>1</sub>, irrespective of the degree of subsequent milling, if not subjected to excessive washing. But occasional commercial samples, probably through exposure to unduly high temperatures during parboiling, show marked vitamin loss. Extensive experiments are in progress with a view to defining conditions for controlled parboiling.

The report of the Division of Chemistry includes an interesting table showing the percentage of milk samples that have been found adulterated over the past ten years. This malpractice is far too common and continues practically unabated by the fines inflicted by magistrates.

Lymphogranuloma inguinale is being further investigated. Seventy-five suspected and control cases were tested with Frei antigen and also with an emulsion of Ducrey's bacilli. Positive results with the Frei antigen were obtained in fifteen cases of subacute inguinal bubo and in four cases of stricture of the rectum. Three cases reacted favourably under 'Sulphanilamide' treatment.

With a view to the further refinement of routine tests for the 'grouping' of blood stains, preliminary investigations with anti-'M' and 'N' sera have been made. Sera have been prepared and adsorbed. The results with experimental stains from 0.02 c.c.m. of blood proved inconclusive, but with double that quantity of blood the reactions were more definite. The number of exhibits of blood stains submitted by the police in the past year approached six hundred. On sixty-two of these 'A' and 'B' grouping was attempted with conclusive results in forty-nine instances.

For the routine diagnosis of early pregnancy two rabbits are utilized, one being injected with fifteen c.c.m. of urine, the other with a concentrate from fifty c.c.m. Tests on local rabbits have shown that hæmorrhagic ovarian follicles develop after the injection of about fifty rat units of gonadotropic hormone. The quantity of urine utilized in the routine test—if from cases of early pregnancy—should thus contain ample hormone to induce positive results. In tests on thirty-one of fifty-three specimens submitted from cases of doubtful pregnancy, hæmorrhagic follicles were seen, but in nine of these the 'concentration' method alone gave positive results. It appears that either the hormone content of the specimens was unduly low or a considerable loss had occurred during transit.

Experimental work on methods of rat destruction has been continued. The toxins of *B. dysenteriae* (Shiga), *S. enteritidis* 'Liverpool', and *Cl. botulinum* have proved relatively innocuous to local rats. The collection of biological data has been extended and the ratcidal value of certain commercial and other poison baits has been examined.

The work of the Lymph Station continued to be satisfactory. Following a fall in the vaccination success rate in one district, tubes of a batch of lymph were returned for re-testing. The rabbit potency had fallen to about one-seventh of its original value and the

# The Value of Dietary Supplements

*A Summary of Investigations\* published in the  
"Medical Officer," March 30 and April 6, 1935*

A NUMBER of children, all receiving their customary home diet, were given either No Supplement, Cod Liver Oil, Halibut Liver Oil (with milk to provide equal calories) or Virol. The experimental scheme provided that each child should have a period on each treatment in turn, in such a way that every possible sequence was included. Rigid statistical control was thus possible.

## Gain or Loss in Weight on Various Supplements :—

Supplement	Total gain in ozs. over all periods	Average gain per child per week in ozs. over all periods	Total loss in ozs. during summer period only	Average loss per child per week in ozs. during summer period only
No Supplement - -	88	0.3	— 103	— 1.4
Cod Liver Oil - -	287	1.0	— 77	— 1.1
Halibut Liver Oil with milk - - - -	333	1.2	— 184	— 2.6
VIROL - - - - -	762	2.6	— 7	— 0.1

Whereas earlier investigations had shown that the mere addition of vitamins had no effect on growth, these investigations have conclusively proved that Virol—a balanced food containing all the necessary vitamins—has a definite and remarkable effect in bringing the rate of growth up to the recommended standard. Virol was the only one of the supplements used that promoted this ideal rate of growth.

Virol was the one and only preparation that maintained the children's weight in the hot weather.

and at 37, Lombard Street, London, E.C.3

results of infant vaccination were also indicative of deterioration. It is believed that the vaccinator had failed to return unused tubes to cold storage after the completion of his rounds. Attention is again invited to the importance of the careful supervision of conditions of lymph storage.

[The above abstract from the general review, by the Director, indicates the valuable work being carried out by this research institute. All research workers in tropical medicine should obtain a copy of this report because they are sure to find in it something of value touching their own work. This applies particularly to workers in India where our problems are closely allied to those of the Federated Malay States.—EDITOR, I. M. G.]

# ABSTRACT OF THE ANNUAL REPORT OF THE CENTRAL NARCOTICS INTELLIGENCE BUREAU, EGYPTIAN GOVERNMENT, FOR THE YEAR 1939. BY T. W. RUSSELL, LEWA

In my annual report for 1938 I stated:—

'The official figures published in this report, while not showing any big relapse to drug addiction, do bear out the need of the warning that I expressed in my 1937 report against any self-complacency as to results obtained and against any slackening off in preventive effort.

... the slightest relaxation of police effort in Egypt or the slightest enfeeblement of anti-narcotic policy will quickly see this country drifting back to where she was ten years ago'.

In reviewing the situation for 1939 I must repeat that warning but still more emphatically.

The total of traffickers in the State prisons on 1st October has increased since that date last year by 754 and that of addicts by 52, i.e., a total increase of 806 persons imprisoned under the Narcotic Law: this means that after steadily improving up to 1937 we have now slipped back on the general total to where we were in 1934.

As regards quantities of drugs seized in the contraband trade, fewer drugs have been seized than during the previous year.

If we take it that the police effort has remained constant, a reduction in drugs seized might be considered as proof of fewer drugs coming in.

Again an increased number of traffickers arrested might be taken as showing increased energy and zeal on the part of the police: it might, on the other hand, mean a large increase in traffickers of whom the usual proportion only have been arrested.

On the whole I believe that more black drugs than formerly are getting into the country, that police energy has not actually diminished, that, on the other hand, it has not increased in proportion to the increased traffic and that addiction to hashish and opium is definitely growing greater.

It can be taken as a basic fact that the only deterrent to drugs entering the country is the energy of the preventive services; the desire for drugs remains but cannot be indulged in so long as the preventive cordon is efficient. Failure on the part of the police to keep level with the increased trafficking is largely due to the increased preoccupation of the police, especially in the provinces, with the mass of crime work which they cannot escape.

Narcotic trafficking, unlike murders and robberies, does not force itself upon a provincial police officer's attention: it has to be looked for and time and patience spent in its detection. What provincial police officer to-day has the leisure for this voluntary work?

In the cities, and especially the port cities, the Bureau still has specialized narcotic officers and agents who keep a constant eye on the traffic; they, however, are faced with an arduous and often impossible task in trying to control contraband drugs after they have entered the country.

The mass production of hashish in Syria and of the smuggling of hashish and opium through Qantara,

makes our danger front as I have so often pointed out, the Eastern Mediterranean, the Suez Canal and the Gulf of Suez.

It is here that contraband in bulk should be seized before it has had time to enter the heart of the country and be dispersed throughout the provinces.

To do this, the coastguards and the Suez police must be equipped with powerful sea-going launches to deal with off-shore shipping.

Our Eastern front remains as dangerous as ever and beyond this front are the countries of origin, Syria for hashish, Turkey for opium and the Far East for white drugs.

In my speech this year at Geneva, I paid a tribute of thanks on behalf of the Egyptian Government to the French Authorities in Syria for their continued and successful efforts to prevent the illicit cultivation of hashish in the Lebanon. The shock was, therefore, considerable when I received in the month of June a long cypher cable to the effect that vast areas of hashish cultivation had again been discovered in those districts.

The task of repressing hashish cultivation in Syria has always been an arduous and invidious one for the French authorities when the geographical features of the country, the poverty of the villagers and the high profit to be made are realized. In spite of these difficulties, however, the Sirété have been able these last few years to enforce the laws prohibiting this cultivation all over Syria, except for small areas hidden away in the mountainous regions of the Lebanon.

How came it then that suddenly the situation had changed from little or no cultivation to square miles of it?

An indication of where the answer would eventually be found was given in the first telegraphic news received that on 28th June, M. Colombani himself and a force of police and military had discovered in the neighbourhood of the village of Laboué 5 hectares (50,000 square metres) of hashish cultivation and has proved that it was the property of a member of the cabinet.

This was followed on 11th July, by the seizure of 17 sacks of hashish powder, weighing 270 kilogrammes, in the house of a near relative of the same cabinet minister.

It was soon evident that many of the governing classes of the Lebanon had defied the Mandatory Authorities and planted vast areas of hashish cultivation, with the natural result that the smaller landowners had followed their example thinking that they could do so with impunity.

For weeks after these discoveries, the Syrian press indulged in a furious battle for and against hashish cultivation and for pure cynical opportunism I cannot do better than quote the 'Saout El-Ahrar' for 18th July, which wrote:—

'I do not believe that the breaking of the regulations of the League of Nations constitutes a crime when one considers the numerous infringements by the most civilized European countries of the basic Laws of the League. So far as harm to humanity goes, I do not think that one could charge with crime a feeble and poor people who, not willing to die of starvation, allow the foreigner to die by the slow and joyful method of hashish. We have been led to this conviction after having witnessed the great evils inflicted by the civilized races on more feeble races. Killing a race is of far greater importance than the export of hashish to habitual consumers who have the money to procure it elsewhere'.

So now we know what Egypt may expect if the hashish growers of the Lebanon have their own way.

It is difficult enough, as I have said, to keep out of Egypt the not inconsiderable quantities of hashish and opium that annually escape the control of our neighbouring countries. What, then, would have been the situation this year in Egypt had sixteen hundred tons of hashish been thrown against our eastern defences?

There is only one answer which is that, owing to the weight of the attack and to the weakness of our defences, several hundred tons would have got through.

Egypt owes a deep debt of gratitude to the French Government, and to M. Colombani in particular, for averting this mass attack on the enemy.

We can only hope that by next year the energy of the French Government and the preventive measures of our own Government will have been doubled and trebled.

To conclude I will sum up my opinion on the situation as I see it to-day.

*The four great dangers:*

(1) *Desire*.—The desire for narcotic drugs in Egypt is not exorcised: it remains very much alive and will continue so for as long as the present unsatisfactory economic and physical condition of the general mass of the population is permitted to persist.

(2) *War*.—It was war which brought the white drugs to Egypt. It has taken us the best part of ten years to defeat the drug effects of that war on Egypt. You may be sure that in this new war which has hardly yet begun every drug trafficker in the world is gleefully looking forward to profits on a far vaster scale.

(3) *Far East*.—Mass production of white drugs in the Far East is undoubtedly continuing unchecked and is likely to grow in volume if and when the big nations start mutual massacre on a large scale. This is where the drug traffickers will concentrate for their deadly munitions of war.

(4) *Syria and Lebanon*.—The danger last year of Egypt's being flooded with Lebanese hashish was imminent.

## ANNUAL REPORT ON THE HEALTH OF THE ARMY IN INDIA FOR THE YEAR 1938. VOLUME I. BY THE DIRECTOR OF MEDICAL SERVICES IN INDIA

A RECORD low figure for pulmonary tuberculosis for British troops over the last twelve years in the Northern Command, remarkably small admission rates among Indian troops in Waziristan and persistently low admission rates for malaria and sandfly fever, are some of the features of this report issued for the first time as a separate volume. Previously the report was issued as volume II of the Annual Report of the Public Health Commissioner with the Government of India.

Over the five-year periods since 1918 admission rates among British troops have shown a tendency to become stabilized at a figure approaching pre-war (1914-18) rates, while the rate for officers is distinctly lower. But invaliding shows no sign of reduction.

Admission rates generally rose by 36 per 1,000. Actual admissions however showed a drop of nearly 900. The principal causes of admission, with the admission rates per 1,000, were: malaria (50.4), cellulitis (45.2), tonsillitis (33.7), dysentery (26.8), and sandfly fever (24.8).

Death rates also went up slightly, but invaliding rates dropped by 1.6 per 1,000. The chief causes of death were infectious diseases and pulmonary tuberculosis, while those of invaliding were mental diseases.

The number of working days lost owing to disease was 822,195 compared with 878,997 days lost in 1937.

The incidence of malaria among British troops was higher than in 1937 but otherwise lower than any other year and was half the figure recorded in 1919. Among Indian troops the figures for 1938 were only higher than that for 1937 and half the 1933 figure. The return of troops infected in Waziristan led to an increase in relapse cases in other areas, but cases in the Western Independent District showed a big drop.

Lahore Cantonment, the dreaded Mian Mir, shows what anti-malarial measures can achieve. Cases among British troops which stood at 617.70 per 1,000 in 1924 dropped to 19.67 in 1938.

Sandfly fever among the British troops remained at the same level, reductions in admissions elsewhere being offset by an increase in the Western Independent District. Figures for the Northern Command and Landikotal, a hotbed of sandfly fever, showed a considerable fall.

The incidence of dengue fever fell considerably in 1938, both for British and Indian troops, figures in both cases being a fraction of those for 1937 and lower than those of the five preceding years given.

The incidence of enteric among both British and Indian troops was below one per 1,000. On the other hand dysentery and diarrhoea showed an increase both among British and Indian troops. The proximity of insanitary hazaar areas is one factor in the spread of these fly-borne diseases.

In spite of widespread epidemics of cholera there were only 42 cases among Indian troops, 41 of them in a Gurkha battalion on its arrival at Razani in Waziristan.

There were only 11 cases of smallpox among British troops and their families, while respiratory diseases showed a slight increase.

Admission rates among women and children have decreased over the past three years. The dysentery-diarrhoea group accounted for 21 per cent of the total admissions, tonsillitis and bronchitis together for about 16 per cent.

In the Indian Army, admissions among officers showed a continued increase, digestive diseases, local injuries and malaria being the principal causes. Among the soldiers the fall in admissions recorded over ten years continued. The rate for 1938 was 421.8 per 1,000 and the average for 1935-38 was less than the average for the five-year period 1930-34 by 37.6. The death rate showed an increase over the 1937 figure, while invaliding was practically stationary.

Tuberculosis accounted for about one-third of the invaliding. Cases of oriental sore were numerous in Quetta and a special grant was made by Government to control the infection. Admissions for heat stroke were the highest for several years.

Among followers the admission rate of 272.0 per 1,000 was lower than for any of the preceding five years. Special attention has been paid to the conditions of work of welders and painters in arsenals.

The percentage of rejections at recruiting centres rose from 35.73 in 1937 to 43.5 in 1938. The growing incidence of trachoma among promising candidates in the Delhi recruiting area has caused a considerable concern to the Indian Soldiers' Board.

A steady increase in the welfare work among the families of Indian soldiers was noted in 1938. The movement, run with grants, donations and annual allotments from public and semi-public funds, is also largely supported by officers and their wives and by the men of the regiments themselves both financially and with their services. There is a constant cry for more funds owing to the increasing demand.

Altogether during the year 84,677 women and 100,367 children were treated.

## Service Notes

### APPOINTMENTS AND TRANSFERS

COLONEL A. C. MUNRO, K.H.P., to be Officiating Deputy Director of Medical Services, Northern Command. Dated 6th May, 1940.

Colonel D. F. Murphy, M.C., V.H.S., to be Officiating Assistant Director of Medical Services, Western (Independent) District. Dated 13th May, 1940.

Colonel A. C. Macrae to be Officiating Assistant Director of Medical Services, Peshawar District. Dated 30th May, 1940.

Lieutenant-Colonel M. P. Atkinson, an Agency Surgeon, is appointed as Medical Officer in charge of the Crown Representative's Police Force Hospital, Neemuch, with effect from the forenoon of the 22nd May, 1940.

Lieutenant-Colonel S. M. A. Faruki, to be Officiating Officer Commanding, Indian Military Hospital, Rawalpindi. Dated 26th May, 1940.

# 'OVALTINE'

## *For Restful Sleep*

THE control of insomnia presents a problem that often cannot be effectively or safely solved by recourse to the use of hypnotic drugs. 'Ovaltine' provides a safe and natural means of inducing sleep in many cases, especially where the basis of the insomnia is digestive unrest, nocturnal hunger or nervous instability. Taken before retiring, it promotes quiet and restful sleep, by reason of its gentle sedative effect on the nervous system and its faculty of assisting digestive ease. 'Ovaltine' is composed of pure natural foodstuffs only—ripe barley malt, pure creamy cow's milk—together with valuable natural phosphatides and vitamins. It is a really complete food, rich in readily assimilable calcium and phosphorus and in the vitamins A, B (complex) and D. It possesses a truly delightful taste and is appreciated by every type of patient.

*A liberal supply for clinical trial sent free on request.*  
Indian Distributors :

Messrs. GRAHAMS TRADING Co. (India) Ltd., 6, Lyons Range,  
Calcutta, also at Bombay, Madras and Karachi.

*The Goddess MAAT  
weighing the heart in the  
presence of the Ape of  
Thoth. By her side is  
the Eater of the Dead.*

## Notes

### CYCLONAL SODIUM

#### AN INTRAVENOUS ANÆSTHETIC

For induction, short basal narcosis and total anaesthesia Sodium N-methyl-C-C-cyclohexenylmethylmalonylurea has been widely used during the past few years, although its manufacture has not been undertaken within the Empire. Now, however, the preparation is being produced in Great Britain by May and Baker, Ltd., under the name of Cyclonal sodium, and supplies are available for immediate delivery.

Full details of the properties, clinical applications, administration, dosage and packings of this intravenous anaesthetic are contained in 60-page 'Cyclonal sodium' booklet which has recently been sent to us. Its administration intravenously and rectally is also described together with the therapeutic applications of the drug. A copy of the booklet will, we understand, be sent to any member of the medical profession on request to: Messrs. May and Baker (India), Ltd., 11, Clive Street, Calcutta, India.

### NEPTAL FOR DIURESIS

#### THE TREATMENT OF CARDIAC DROPSY AND HYDRÆMIC NEPHRITIS

THIS preparation is of considerable value in the conditions indicated, for it possesses the active diuretic properties of mercury in a relatively non-irritant form. It is well tolerated both locally and generally, and administration may be prolonged in suitable cases for a period of many months.

We understand that a copy of the new Neptal publication, which includes full details of dosage, indications and technique of administration, will be sent free to any member of the medical profession on request to: Messrs. May and Baker (India), Ltd., 11, Clive Street, Calcutta, India.

### EYE LEX

#### (UREA SULPHAZIDE 5 PER CENT EYE OINTMENT)

THE manufacturers of urea sulphazide draw the attention of the medical profession to urea sulphazide eye ointment. The blandness of the preparation makes it suitable for the treatment of all infective conditions of the eye. It is available ready-made in convenient packing.

Information on clinical experience and other details may be obtained from the Union Drug Company, Limited, 285, Bowbazar Street, Calcutta.

### PROSEPTASINE AND SOLUSEPTASINE

#### FOR USE IN HÆMOLYTIC STREPTOCOCCAL INFECTIONS

THE low toxicity of Proseptasine, due to the introduction of the benzyl group into p-amino-benzene-sulphonamide, has been amply demonstrated both in the laboratory and in clinical practice. This extra margin of safety has enabled Proseptasine to maintain its position as one of the best tolerated products for the treatment of hæmolytic streptococcal and other acute microbial infections.

Soluseptasine for parenteral administration is the only colourless sulphonamide available in concentrated aqueous solution. It is widely used in conjunction with Proseptasine for the treatment of erysipelas, puerperal sepsis and septicæmia.

Copies of the leaflet on Proseptasine and Soluseptasine may be obtained by members of the medical profession on request to: Messrs. May and Baker (India), Ltd., 11, Clive Street, Calcutta.

### THEOGARDENAL

THEOGARDENAL, which combines the properties of Theobromine and Phenobarbital, has been found valuable in the treatment of high blood pressure. Its action is similar to that of the nitrites, facilitating cardiac function by dilatation of the coronary arteries, though Theogardenal, as opposed to the nitrites, is comparatively prolonged in its effect.

Disorders of the menopause with their accompanying endocrine disturbances offer a further field for the use of Theogardenal.

Theobromine, of which 5 grains are contained in each tablet of Theogardenal, resembles caffeine in its action, though its effect upon muscle, kidneys and heart is more pronounced. Phenobarbital, one half grain of which is contained in each tablet of Theogardenal, helps to reduce arterial hypertension by its action on unstriated muscle.

Members of the medical profession may obtain copies of the pamphlet on Theogardenal on application to: Messrs. May and Baker (India), Ltd., 11, Clive Street, Calcutta.

## Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

*Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.*

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

### TAKING BLOOD FOR TRANSFUSION (IN POTAIN'S ASPIRATOR). FURTHER DETAILS INCLUDING COLD STORAGE

By S. D. S. GREVAL  
S. N. CHANDRA

and

A. B. ROY CHOWDHURY

*Imperial Serologist's Laboratory, School of Tropical Medicine, Calcutta*

(Received for publication on 22nd June, 1940)

THE intention is to supplement what has been said under the titles 'Taking Blood for Transfusion' (Greval and Chandra, 1940) and 'The Needle in the Vein' (Greval, 1940). The necessity for giving further details has been made clear by private correspondence on the subject and by further work which has since been done.

#### 1. Sterilization of the special stopper of Potain's aspirator and tubes

Originally they were sterilized by boiling. Now they are autoclaved in small drums, like surgical dressings. The dryness of the tubes (rubber and metal) does not interfere with the flow of blood. Several stoppers and tubes can be sterilized together and taken out with the same precautions with which surgical dressings are taken out.

#### 2. Sterility of the blood taken for storage

The contrivance described for taking blood for transfusion was originally intended for bleeding a donor, and using the blood within an hour or so. The precautions taken aimed at surgical asepsis but not bacteriological sterility. It was, however, found that blood taken by the same device for injecting animals and kept for several weeks in the cold remained free from signs of contamination. The blood stays at room temperature for half an hour, and presumably during this period its immunological forces deal effectively with the stray micro-organismal intruders. Sterile nutrient broth bottled like the blood is not likely to stay sterile.

Incidentally, the writers now use plain sodium citrate solution instead of Rous and Turner's solution in taking and keeping human blood for producing anti-M and anti-N fluids (Greval, Chandra and Woodhead, 1939).

#### 3. The pump

The pump of Potain's aspirator is not damaged by the water vapour or even water sucked from the boiled knotted tube. The heat generated in action appears to dehumidify it. Cheap pumps costing Rs. 10 are (or have been) available. Powder from new tubes blocks the

pump. An ordinary 20 c.cm. Record syringe used with a two-way adapter can also be used in the place of the pump. The air is sucked from the bottle and discharged outside by opening and closing the necessary way. Twenty to thirty strokes suffice as is the case when the pump is used.

#### 4. Coagulation of the blood in the tube and bottle

Clotting occasionally occurs in the tube between the vein and the bottle and stops the flow of blood. This appears to be due to two causes. The first cause is the obstruction to the flow by too many joints. The writers now do not employ tubes with glass windows (the incoming tube in the original apparatus has a glass window). The second cause is the abnormally high coagulability of some bloods. The clotting occurs when about 200 c.cm. of blood have been drawn. More can be drawn from the other arm in another bottle. The unavoidable excess of sodium citrate in the first bottle, if the intended quantity was more than the quantity drawn, is an advantage and should be intentionally allowed in the second bottle, otherwise a part of such blood will coagulate in the bottle later.

Donors whose blood coagulates abnormally rapidly (for example, it sometimes cannot be discharged from a 5 c.cm. syringe for a W. R.) are not to be recommended for giving blood for direct transfusion from vein to vein through special apparatus, as opposed to transfusion of citrated blood. Donors, part of whose blood is found coagulated in the bottle, should also be looked upon as risky for direct transfusion. Even when their blood is collected in a citrate solution and a clot has not formed immediately, trouble may arise later. This point should be remembered in giving transfusion to extremely anæmic cases whose blood is known to coagulate on coming into contact with normal blood in the presence of air (Greval and Chandra, 1939). The risk of coagulation will increase with a blood of high coagulability. From this point of view blood stored for at least 24 hours would be more suitable for such cases. Absence of coagula in it will rule out abnormally high coagulability.

The citrated blood should not be further diluted with saline outside the body as is sometimes done.

At times fine loose clots form in the bottle and choke the filtering end of the tube employed with a two-way syringe for transfusion. This difficulty is overcome by (i) keeping the filtering end of the tube just dipped in the blood or (ii) filtering the blood into another container and allowing time for the clots to drain. The clots when left to drain discharge most of the contained blood. Even a single massive looking clot is loose and discharges its blood when drained.

Incidentally, the concentration of sodium citrate recommended by the writers for preventing coagulation of blood is 0.25 per cent. It can be safely increased to 0.3 per cent by taking in the bottle 1/10th volume of the intended total a 3 per cent solution instead of 2.5 per cent, or even to 0.35 per cent by taking more than 1/10th volume of either solution. The limit of the salt allowed for an adult is 5 grammes.

#### 5. *Blood left in the collecting tube*

The tube between the vein and the bottle contains 5 to 10 c.cm. of blood (depending upon its length and calibre) when the stop-cock is closed. This quantity may be allowed to flow into the bottle slowly, without a rush of air with it, if the blood is to be used within half an hour or so. If the blood is to be stored it is better to reject this portion. The 'rejected' blood yields red blood cells and serum of known group for the routine of the laboratory. In fact the only utility of running a blood transfusion service from a laboratory is the regular supply of fresh red blood cells and sera of known groups. Samples of sera and red blood cells for direct matching of the stored blood with that of the recipient are also kept from this source. Handled with surgical precautions of asepsis and stored in the cold the cells and the sera keep almost fresh for ten days. The writers' limit of storage of blood for transfusion is also ten days.

#### 6. *Stoppering and labelling the bottle*

The bottle is stoppered by means of a glass stopper. The inner surface of the neck of the bottle is wiped with a sterile cotton swab if blood is seen on it. A flame is made to play on the surface and the ingoing portion of the stopper, as a matter of bacteriological etiquette. Melted hard paraffin which is just short of boiling, but has been boiled, is smeared liberally over the junction with a sterile swab. For opening a bottle so stoppered and smeared a flame is needed, which is an advantage.

The bottle is labelled by writing upon it with Indian ink. The writing is allowed to dry and then covered with a coat of collodion which is also allowed to dry.

The stoppering and labelling take about half an hour, which is the time needed for keeping the blood at room temperature if it is to be stored.

When the blood is taken from a particular donor for a particular recipient in a surgical theatre or a ward and is likely to be used up at once the need for stoppering and labelling the bottle does not arise.

#### 7. *Frothing of blood*

The blood froths if the negative pressure in the bottle is too high. The vacuum then should be slowly decreased.

Sometimes the froth is produced by air entering the needle through a faulty puncture in the

vein. A thrill in the rubber tube is then also felt. This is a serious fault and should be avoided by making sure that the needle has entered the vein fully in the first instance. For subsequent correction, advancement of the needle is indicated.

#### 8. *The tourniquet*

A tape tied round the upper arm as high as possible serves as a tourniquet. The pressure applied to reduce the size of the pulse is likely to abolish the pulse altogether if the subject passes into a state of fear. The tourniquet is then released and reapplied while measures are being adopted to reassure the subject. A partial state of fear with a slight fall of blood pressure is not incompatible with the commencement of the operation. The flow increases as the fear of the prick of the needle has been experienced and overcome.

When actual collapse has occurred no attempt to draw blood should be made.

An inflatable cuff such as is used with the sphygmomanometer, though more easily adjustable than the tape, restricts the field of operation and is not recommended. The operator should have an ample length of the vein and surface of the upper arm at his disposal.

#### 9. *Symptoms in the donor*

The symptoms essentially are those of collapse and occur in this order: (i) cold sweat, (ii) successive loss of colour from temples, forehead and cheeks, (iii) loss of consciousness, (iv) twitching of facial muscles, (v) convulsions (confined to limbs only), and, after recovery, (vi) dry mouth and (vii) unsteadiness.

The worst symptoms in the writers' experience have occurred *after the event*, in four cases, during the last three years. In three of them only 5 c.cm. of blood had been taken for grouping and testing the blood. The symptoms came after the puncture had been sealed. Probably the sight of blood in a glass container was responsible. Two subjects (male, Europeans) collapsed quietly while one (female, Indian) showed convulsions. From the fourth (male, European) 300 c.cm. of blood had been drawn. After the puncture had been sealed and the bottle of blood removed to another room he said softly 'I am dying', showed twitchings on face and convulsions in limbs. Face was bloodless and skin cold and clammy. He was at once placed in a horizontal position on his back (pulled down in the long chair which is used for bleeding donors) and constrictions round neck removed. Consciousness returned in less than a minute. Aromatic spirit of ammonia, one teaspoonful in a tablespoonful of water, was given. His hand holding the draught trembled and had to be guided to the mouth. Colour returned rapidly. Request for water was made but not much of it was drunk (dryness of the mouth disappeared rapidly). All was well

in about three minutes. Immediately afterwards the subject was wondering if he had fainted. In fifteen minutes he walked perfectly well to his ear. In thirty minutes he rang up to say that he was quite fit. Reports received morning and evening for two days over the telephone were of a perfect state of health.

Both the subjects showing convulsive movements and momentary loss of consciousness were suffering from domestic worries.

Subjects showing symptoms of collapse are not suitable for sending out as donors in cases of emergency.

Incidentally, women appear to be affected less than men by drawing of blood.

Of compensatory dangerous rise of blood pressure (Durand, 1939) after blood has been taken the writers have not seen a case. They do not attach any importance to it. They take blood for tests from patients and for transfusion from healthy donors. The annual number of venipunctures done in this laboratory was of the order of 200 two years ago. Since then it has been considerably increased. The increase is due to an increase in the donors of blood.

#### 10. Taking blood for serum from man and animals

Potain's aspirator can also be used for taking blood for immune serum from subjects convalescent from certain diseases, and from large animals of the size of or larger than sheep or goats, in quantities greater than the ordinary syringe will hold. The citrate solution of course will not be needed. Broken glass-rods in the bottle will aid in the coagulation of blood. The serum can be poured out carefully into another container, sucked and transferred with a sterile pipette or drawn with a two-way syringe as has been described in a previous communication (Greval and Chandra, *loc. cit.*).

#### 11. Cold storage of blood

(i) *The refrigerator.*—The writers use a gas refrigerator. Being free from vibration it preserves the red blood cells better than the ordinary electric refrigerator. The range of temperature available is 2°C. to 8°C. on the shelves. Along with the bottles of blood of groups O, A and B, separate samples of red blood cells and sera for direct matching are preserved. An electric refrigerator with its motor outside the cabinet can also be used. In localities where electricity or gas is not available a kerosene-operated refrigerator may be used. The range of temperature of this refrigerator is satisfactory.

(ii) *The period of utility of the preserved blood.*—Many opinions have been expressed within the last two or three years on the subject. Three rules of action emerge: (i) when the transfusion is needed for platelets, blood over 24 hours old should not be used; (ii) when the transfusion is needed for opsonins or leucocytes, blood over 48 hours old should not be used (Kolmer, 1939) but (iii) when a transfusion for red blood cells and complement (and

other constituents) is needed blood stored up to ten days can be used (Kolmer; Wiener, 1939; Editorial, *J. A. M. A.*, 1939). A suggestion is added that a transfusion also provides normal human proteins, immune bodies more stable than opsonins, hormones, enzymes, extractives, salts and ions; most of these constituents are likely to remain unaffected for weeks in the clear supernatant plasma of the stored blood. Even prothrombin left intact in the plasma has been found to be 61 per cent of the normal after three weeks (Lord and Pastore, 1939). This observation is important in view of using stored blood and plasma in hæmorrhagic conditions. A trace of colour from the underlying red blood cells is not likely to be harmful, at least from a bottle of the writers' stock (maximum content 400 c.cm.). Transfusion of compatible (exactly appropriate to the red blood cells or safe like the plasma of a safe universal donor) serum for most of the proteins and some of the other constituents is another undeveloped therapeutic measure. The serum may even be dried for the purpose of preservation and transport.

For most cases blood ten days old is suitable.

#### (iii) Decrease in food and allergic reactions.

—Such reactions amounting to fatal accidents are known to occur in transfusions even when compatibility of bloods and purity of the chemical used have been beyond dispute. They are due to unsuspected hypersensitiveness on the part of the recipient to the donor's blood. (Incidentally, the writers match sera also as a routine in determining compatibility, and recommend a scratch skin test in addition, when a donor serves on a recipient more than once.) This danger of food and allergic reactions is said to decrease with stored blood (DeBaakey and Honold, 1938).

(iv) *Advantage of further observation on the state of health of the donor.*—That a donor at the time of giving blood may be incubating an acute infective disease is a possibility especially during epidemics. The longer the blood is kept (up to ten days) the surer one is of the state of health of the donor. The writers keep in touch with the donors for a week.

Destruction of malaria parasites in preserved blood (Halbrecht, 1939) may not be relied upon. Blood containing parasites of monkey malaria has been sent for the propagation of the plasmodium from Calcutta to Hamburg by air mail and from London to New York by ship (private communication by Dr. B. M. Dasgupta of the School of Tropical Medicine, Calcutta).

(v) *Stored blood is not a second-rate therapeutic aid.*—From what has been said so far it is abundantly clear that under proper organization the stored blood is not inferior in utility to freshly drawn blood. In fact it is superior.

(vi) *Easy availability.*—The stored blood of a safe universal donor (all subjects belonging to group O, group I Jansky or group IV Moss, are not safe universal donors) for use in

emergencies, such as accidents or hæmorrhage in maternity cases, is available within minutes. It is better that for the purposes of issuing such blood the scope of an emergency is not allowed to go beyond the illustrations given. For a patient who can receive the blood of his own group the blood of a safe universal donor is an unnecessary and unfair handicap; and when the stored blood is used up in imposing the handicap, a life may be lost which could only be saved by its use.

(vii) *Increase in supply.*—By storing blood the number of donors is increased. A professional donor is not without other professions. To come and give blood to hospitals and nursing homes, mostly during working hours, he has to give up his own work. This inconvenience is liquidated by taking his blood at his convenience and storing it. Thus more donors become available and the donor's fee is reduced. Free donors also come forward. The Red Cross Blood Bank of Calcutta has on its list 30 free donors who come to donate blood every 6 to 8 weeks if necessary. When the Bank issues blood in exchange for relations' or friends' blood (which may not be compatible) two bloods are taken for one given. This results in further increase in donors. Prospective professional donors are also bled once free of charge, for storage, to get them used to bleeding. The blood might even be bought in anticipation of the demand when the demand could be anticipated fairly well. At present the Blood Bank (i) issues blood free for friendless and relationless indigent patients, (ii) receives two bloods for one given when friends and relations give blood, and (iii) receives from the well-to-do patients donations which are sent to the Red Cross Society. In the writers' opinion this plan suits the needs of Calcutta. During the last six months 34 bloods have been issued. During the same period 71 donors have been supplied by the Blood Transfusion Service of this laboratory (different from the Blood Bank).

(viii) *Blood in a rubber-capped bottle.*—For issuing small quantities of blood (up to 20 c.cm.) the bottle is capped, not stoppered. With sterile precautions, syringes are filled from it when needed. Blood for experimental purposes is always so kept by the writers.

(ix) *Human red blood cells are not so fragile as sheep's red blood cells with which most laboratory workers are familiar.*—The writers have received samples of blood from prospective recipients not living in Calcutta and Bengal for grouping, matching and supplying donors. The bloods have been brought by special messengers by train. The donors have been supplied. Besides packing the tubes of blood [(i) untreated whole blood for serum and (ii) citrated blood for cells] in a tin and the latter in ice, other devices for preserving by cold are a wide-mouthed 'thermos', dry ice and the refrigerated wagon of certain trains on certain days.

(x) *The writers' scheme of storing blood is different from the London Scheme of Blood Transfusion Service for War* (as published in the *Brit. Med. Journ.*, 1939, Vol. II, pp. 35 and 570).—The latter scheme stores blood of subjects of group O only. The writers store blood of subjects of groups O, A and B. A few donors of group AB are on the register and blood from them can be used for special recipients of group AB. Ordinarily recipients of group AB receive blood of other groups *after the danger of the isoagglutinins of high titre* has been eliminated. Further, the writers divide their subjects of group O into (i) safe universal donors of first choice, (ii) safe universal donors of second choice, and (iii) dangerous 'universal donors' (= merely group O donors for group O recipients). This important consideration of the titre of the isoagglutinins of the donors has been discussed at length in a previous communication (Greval and Chandra, *loc. cit.*).

#### 12. *Firms supplying apparatus*

Special stoppers for Potain's aspirator, two-way stop-cock and adapters can be obtained from Messrs. H. Mukerji & Co. of 39, College Street, Calcutta. The stop-cock can also be obtained from the Bombay Surgical Company, New Charni Road, Bombay.

It does not appear to be well known in India that Record syringes can be rebarrelled at a reasonable cost. The Bombay Surgical Company undertakes the repairs.

Kerosene-operated refrigerators are stocked by the Army and Navy Stores, Ltd., Calcutta.

#### *Summary*

1. The paper is a continuation of two recent papers on taking blood for transfusion.
2. The special stopper of Potain's aspirator and tubes can be autoclaved.
3. The blood taken, as described previously, can be stored.
4. The pump of Potain's aspirator is not essential.
5. Blood sometimes coagulates in the apparatus or the bottle. This is due to (i) obstruction in the tube and (ii) abnormally high coagulability of some bloods. Obstruction can be removed. High coagulability needs consideration when anæmic patients are to be transfused. The clot in the bottle can be drained.
6. Blood left in the collecting tube when the flow is stopped should not be run into the bottle if the blood is to be stored. The rejected blood provides material for work in the laboratory.
7. The bottles are stoppered with glass stoppers which are secured in place and made dust-proof with melted hard paraffin. They are labelled with Indian ink and the writing covered with a layer of collodion.
8. The blood froths in the bottle when the negative pressure is too high and when the whole of the aperture of the needle is not in the vein.

9. A tape is the best tourniquet for the purpose of bleeding a donor.

10. Symptoms in the donor are those of collapse. They are not serious. Women have suffered less than men. A compensatory dangerous rise of blood pressure has not been observed.

11. The same apparatus can also be used in taking blood for serum from man and animals.

12. Cold storage of blood. (i) A gas refrigerator is to be preferred to an electric one. (ii) Utility of preserved blood varies from 1 to 10 days depending upon the requirements of the case; for most cases it is ten days. (iii) Food and allergic reactions with stored blood are said to decrease. (iv) The risk of the incubation period of acute infective disease in the donor can be excluded. (v) Stored blood is not a second-rate blood. (vi) It is more easily available. (vii) By its use the total number of donors is increased. (viii) It can be stored in rubber-capped bottles for issuing small quantities. (ix) Human red blood cells are not so fragile as sheep's. Bloods of prospective recipients from outside Calcutta and even Bengal have been received, grouped, matched and donors supplied. (x) The writers' scheme of storing blood is different from the London Scheme of Blood Transfusion Service for War.

13. Names of the firm supplying the apparatus needed and undertaking repairs of syringes are given.

#### Acknowledgments

The organization for the cold storage of blood was made possible by collaboration with the Red Cross Society, Bengal Branch. Colonel Boyd, I.M.S., Officiating Surgeon-General, Bengal (1939), ex-officio member of the Society and Sir Upendra Nath Brahmachari, the Chairman, to whom the scheme was presented, provided the personnel and equipment. Colonel R. N. Chopra, I.M.S. (Retd.), Director, The School of Tropical Medicine, Calcutta, provided accommodation in the Carmichael Hospital for Tropical Diseases connected with the School.

Drs. (Mrs.) L. S. Ghose, W.M.S., D.R. Dhar, Honorary Deputy Physician, Medical College, Calcutta, and S. Sen Gupta of Carmichael Medical College Hospital, Belgachia, assist in the physical examination of the donors.

Dr. Eileen Macfarlane and Mrs. S. D. S. Greval, members of the Blood Transfusion Committee of the Society, are responsible for publicity especially in the European community.

## THE BUFFER PRECIPITATION TEST FOR MALARIA (B. P. T.) ADJUSTED FOR LARGE-SCALE EXAMINATIONS

By E. K. WOLFF, M.D.  
*City Microbiologist, Colombo*

In a previous paper (Wolff, 1939) I described a new serological test for the diagnosis of chronic malarial infection. The test is based on the precipitation of a protein fraction of the blood serum (euglobulin) by buffer solutions, as it can be shown that normal blood and malarial blood behave differently when mixed with such solutions. If a large set of buffer solutions, covering a range from 5 to 8.4, is used it will be seen that the precipitation in normal sera fades out round about 7.4 whilst the precipitation of malarial sera extends much further towards the alkaline side, and, as a rule, is of a higher intensity within the ranges in which normal sera also are precipitated. Since, for diagnostic purposes, it has been decided to lay more stress on the extension of the reaction towards the alkaline side than on the differences of intensity, I suggested dispensing with most of the solutions and simplifying the technique by the selection of two solutions only, namely, pH concentration 7.0 and 7.4. Such procedure seems to be simple

#### ADDENDUM

16th August, 1940.—Since this communication was despatched on 22nd June, 1940, other workers' communications on the use of concentrated serum (Best and Solandt, 1940), liquid stored plasma and dried plasma (Pathological Society of Manchester, 1940) have become available. Due to the unusual delay in transit they were received in Calcutta on or about 16th July, 1940. An announcement over the radio concerning the use of plasma has also been heard.

In the writers' opinion the concentrated serum, liquid or dried plasma and dried serum dissolved in water should conform to the standard suggested for the safe universal donors.

As has been suggested by the writers the plasma and the serum will have their place in therapeutics. They will not, however, replace transfusion of whole blood.

#### ADDITIONAL REFERENCES

- Best, C. H., and Solandt, D. V. (1940). *Brit. Med. J.*, i, p. 799.  
 Pathological Society of Manchester (1940). *Ibid.*, i, p. 827.

enough, but did not satisfy us fully, as the reading of the 'abridged' test is not as easy as the reading of the original test.

An attempt was therefore made to improve on the readability of the abridged test without impairing its reliability and simplicity.

The new technique differs from the old one in so far as a control tube has been introduced, which serves a double purpose. Firstly, it allows us to read by comparison, which is easier than direct reading when we have to deal with slight turbidities; and, secondly, it helps us to detect turbidities of sera which are independent of the buffer effect, and are apt to upset the reading if not detected.

In spite of the addition of a control tube, the test has remained as simple as before, as one buffer solution is used instead of the two solutions recommended before.

### TECHNIQUE

#### 1. Solutions

- (a) *Test solution*—
- |                              |    |              |
|------------------------------|----|--------------|
| Stock buffer solution pH 7.7 | .. | One part     |
| Glass-distilled water        | .. | Four parts   |
| Formalin                     | .. | 0.2 per cent |
- (b) *Control solution*—
- |                              |    |              |
|------------------------------|----|--------------|
| Stock buffer solution pH 7.0 | .. | One part     |
| Glass-distilled water        | .. | Four parts   |
| Normal saline                | .. | Five parts   |
| Formalin                     | .. | 0.2 per cent |

The stock buffer solution pH 7.0 and 7.7 may be prepared either from Baird and Tatlock's Universal buffer mixture or by mixing acid potassium phosphate with sodium hydroxide according to Clark and Lub's formula for the preparation of phosphate buffers. These stock solutions have to be tested before use. They keep even in a hot climate for a considerable time if 0.2 per cent of formalin is added.

#### 2. Blood

The blood should be taken by venipuncture, and, if possible, in the morning before breakfast. About 2 c.cm. of blood is sufficient. It has to be placed in a dry and clean test tube or centrifuge tube. After clotting, the clot is loosened carefully with a glass rod from the wall of the tube, and the sample put in the refrigerator (or a cool place) overnight. The next morning the serum is ready for the test if well separated and clear; if badly separated or turbid gentle centrifuging may be done. The serum is not removed from the clot till it is added to the solutions during the actual test.

#### 3. The actual test

Test tubes 4 inches by half an inch are placed in two rows in a rack, the front row for the test solution and the back row for the control solution. For each serum one tube of each solution is required so that each row contains as many tubes as the number of sera to be examined. The solutions are distributed over these tubes in quantities of  $\frac{1}{2}$  c.cm. for each tube. One graduated 5 c.cm. pipette may be

used without harm for the distribution of both the solutions.

About 4 drops of serum are removed from the blood sample and two drops placed in each of the two test tubes. The most practical are Dreyer's drop pipettes with rubber teats. The same pipette can be used for all the samples if carefully rinsed with distilled water after taking each sample.

After the addition of the serum the tubes are shaken and left standing on the table at room temperature.

#### 4. The reading of the test

The reading may be done from half an hour to two hours after the completion of the test. The average positive case can be read almost immediately after the addition of the serum; but weakly positive cases develop slower, and for this reason it is advisable to wait 30 minutes before attempting the reading. Usually very small changes take place between 30 and 120 minutes, and there is no need to be specially careful as regards the exact time of reading.

The reading is best done by daylight. The two tubes belonging to the same sample are held side by side against the window, part of the window-frame providing a background. The light should not be too bright. Artificial light can be used instead, but care has to be taken that the light falls from a higher level from behind on to the tubes.

The reading is based on the comparison of the test tube and the control tube, and, in an average case, should present no difficulties. In most cases the control tube is quite clear and therefore even a delicate turbidity in the other will show up very well. Originally turbid sera show some turbidity in the control tubes, and the difference of the intensity of the turbidities has to be taken into account. Occasionally very strongly positive sera (hyperflocculating sera) tend to precipitate in the control tube to some extent, but always considerably less than in the actual test tube.

It is difficult to give hard and fast rules for the recording of the results. I suggested for the original test the following classification: 'opalescent', 'faintly cloudy', 'cloudy' and 'markedly cloudy', or 'plus-minus', 'one plus', 'two plus' and 'three plus'. For the modified test it may be found more convenient to call the very faint reaction (i.e., a turbidity just noticeable when compared with a clear control) 'doubtful' and the following grades of turbidity 'weakly positive', 'positive', 'strongly positive' and 'hyperflocculating'.

### DISCUSSION

#### 1. Limitations

Generally speaking, the simplified B. P. T. has the same limitations as the other serological tests for malaria described so far (Tyagaraja, 1938). This is bound to be the case as the

reaction cannot claim to be 'specific'. Incidentally, no such claim can be made for any of the serological tests for syphilis, which nevertheless are undoubtedly of the greatest value. In addition to the lack of 'specificity', which may occasionally interfere with the correct valuation of the positive readings, there are some difficulties in the reading of the test to be expected when we are dealing with 'boundary cases'. The reaction may become so weak that doubts must arise whether we should call it 'positive' or take shelter under the term 'doubtful'. This again is a well-known experience with all kinds of serological tests. On the other hand, difficulties arising out of such doubts may often be overcome by repeating the test at a later date.

## 2. Usefulness

In spite of these limitations, the usefulness of these tests seems to me well established. There is only one other disease that gives us positive results so regularly as malaria, namely, kala-azar, but, as a rule, the reaction in kala-azar is very much stronger, and a 'typical' malarial and a 'typical' kala-azar reaction differ considerably. The 'typical' kala-azar reaction is the hyperflocculation, i.e., the type of reaction in which a heavy precipitation forms almost instantaneously and settles quickly at the bottom of the tube; whilst the 'typical' malarial reaction does not show this very striking phenomenon. Still, we may come across such a reaction occasionally in malaria also (and possibly in some advanced condition of disturbed liver function); and in such cases an attempt should be made to eliminate or verify the diagnosis of kala-azar by the performance of the formol-gel test. In Ceylon, where kala-azar is unknown, this problem does not arise, and we have to pay attention only to the possible interference by liver disturbances when we come across 'hyperflocculation'.

The value of negative tests seems to be extremely high, provided, firstly, that the result is confirmed by a second test at a later date, and, secondly, that the blood is taken at the right time. The acute feverish period of a malarial attack has to be avoided, as we know that such an attack considerably diminishes the strength of the reaction, and reduces it even to *nil* if it has not reached a certain height before the test.

## SUMMARY

The simplified B. P. T. for malaria is performed with one test solution and a control solution.

The test solution is a diluted stock buffer solution pH 7.7.

The control solution is a diluted buffer stock solution pH 7 with the addition of normal saline.

## OBSERVATIONS ON THE DIFFERENTIATION OF *BACT. COLI* AND *BACT. AEROGENES* ON LEVINE'S SIMPLIFIED EOSIN-METHYLENE-BLUE-AGAR AS APPLIED TO THE BACTERIOLOGY OF WATER IN BENGAL

By SUKUMAR NEOGI, M.Sc.

(From the Public Health Laboratory, Khulna, Bengal)

ESCHERICH originally observed the occurrence of two types of lactose-fermenting intestinal bacteria which are widely distributed in water and soil. One type *Bact. coli* was chiefly an inhabitant of the mammalian intestines and was thus regarded as the 'microbe of indication' of faecal pollution of water and the other type *Bact. aerogenes* was rare in human faeces but constituted the predominating coliform organism of soil and grain. Our regular procedure in this laboratory, for the bacteriological examination of water, is based on orthodox British practice, and MacConkey's neutral-red bile-salt lactose agar plates are almost universally used throughout India for confirmation of 'presumptive tests' for *Bact. coli*. The difference between these two types of coliform organisms on MacConkey's solid medium has been observed to be neither so clear-cut nor so distinct as to enable easy differentiation on plates. Another valuable medium—eosin-methylene-blue-agar—was first described by Holt-Harris and Teague for the isolation of the typhoid group of organisms from faeces. Levine (1918) modified this medium as follows:—

Distilled water	..	..	1,000 ml.
Peptone (Difco)	..	..	10 gm.
Di-potassium hydrogen phosphate	..	..	2 gm.
Agar	..	..	15 gm.
Lactose	..	..	10 gm.
Eosin yellow, 2 per cent	..	..	20 ml.
Methylene blue, 0.5 per cent	..	..	20 ml.

He claimed the possibility of easy differentiation between two types of coliform organisms by direct inspection of colonies grown on his modified medium. His results recorded on 52 cultures obtained from eosin-methylene-blue-agar after preliminary enrichment in lactose broth are shown in table I.

(Continued from previous column)

The test takes very little time, and no special outfit is required. It is kept at room temperature and may be read within half an hour.

The usefulness of the test is almost the same as of the original B. P. T. Its simplicity makes it more suitable for routine work on a large scale.

## REFERENCES

- Tyagaraja, S. (1938). *Journ. Ceylon Branch Brit. Med. Assoc.*, Vol. XXXV, p. 342.  
Wolff, E. K. (1939). *Trans. Roy. Soc. Trop. Med. and Hyg.*, Vol. XXXII, p. 707.

TABLE I

From appearance of colonies on plates	Number of cultures	Number correctly designated	Per cent confirmed
1. Tentatively regarded as <i>Bact. coli</i> .	26	24	92.4
2. Tentatively regarded as <i>Bact. aerogenes</i> .	26	26	100.0

These results clearly showed that it might be possible to differentiate between *Bact. coli* and *Bact. aerogenes* simultaneously, confirming the 'presumptive test' for *Bact. coli* by inspection of colonies grown on the plates. The author, however, seems to have tested the culture with Voges-Proskauer (V. P.) and methyl-red (M. R.) reactions.

Recent investigations by Pawan (1925), Hicks (1927) and Taylor (1927) have rendered it evident that the *Bact. coli* standards are not strictly applicable to tropical water supplies. Under tropical conditions a fairly large proportion of organisms conforming to the reactions M. R. positive and V. P. negative of *Bact. coli* are found in water which, from a sanitary survey, should be regarded as relatively free from faecal contamination. Many of these organisms belong to a group of strains which appear to occupy a position, which is in some respects intermediate between *Bact. coli* and *Bact. aerogenes* types. The distribution of the latter types of organisms, however, is similar to that of *Bact. aerogenes* and their presence in water cannot evidently be regarded as indicative of dangerous faecal pollution. It has also been made sufficiently clear that the examination of lactose-fermenting organisms for the M. R. and V. P. reactions does not afford a sufficient basis, especially under tropical conditions, for forming a conclusive opinion. It is thus felt desirable to employ Koser's (1926) citrate utilization test and other biochemical tests for the purpose.

Moreover, methylene blue, an ingredient employed in the preparation of this medium, was first used in 1885 by Ehrlich as an indicator for biochemical reductions. Recently in 1932 Lindsey and Meckler claimed to have applied successfully the methylene-blue reduction test for differentiating *Bact. coli* from *Bact. aerogenes* types of coliform organisms. Raghavachari and Iyer (1935), however, applied this test to over two thousand cultures from waters and faeces at Madras and concluded that the claim relating to uniform reduction of dye by 100 per cent of an *aerogenes* group, made by previous authors, could not be confirmed.

Thus, in the light of our recent knowledge, as indicated above, assessing especially the proper significance of the intermediate types in tropical countries, it was thought highly desirable to undertake further work to refute or corroborate the results recorded by the previous author on the use of his simplified eosin-methylene-blue-agar. No such results, however, appear to have been recorded in Bengal.

The colonies grown on the eosin-methylene-blue-agar plates after 48 hours incubated at 37°C. from samples of water and faeces, after preliminary enrichment in MacConkey's broths, fall into four types:

(1) Small, 1 to 2 mm. in diameter, transparent or amber-coloured colonies. These are usually of intermediate group of cholera-typhoid (non-lactose-fermenters).

(2) Medium-sized colonies, 3 to 4 mm. in diameter, slightly raised, surface flat or slightly concave, having dark almost black centres which extend more than three-quarters across the diameter of the colonies, by transmitted light; button-like, often concentrically ringed with greenish metallic sheen with no tendency to run together. These are usually colonies of *Bact. coli* (types 1 and 2) but they not infrequently contain strains of intermediate types.

(3) Large colonies, 4 to 6 mm. in diameter; considerably raised and markedly convex; occasionally the centre drops down precipitately, centres brown or pale brown, smaller in proportion to the rest of the colonies with no metallic sheen in reflected light except rarely in the depressed centres. These are usually *Bact. aerogenes* or intermediate types.

(4) Red colonies, 1 to 2 mm. in diameter. They are generally cocciform and atypical or irregular lactose-fermenters.

In the first series of experiment 31 pure cultures of *Bact. coli*, *Bact. aerogenes*, intermediates (coliform) and members of typhoid and paratyphoid groups were plated on this medium for the purpose of differentiation and the results obtained are shown in table II.

TABLE II

Number of colonies tested	Types of bacteria	NUMBER OF COLONIES GIVING CHARACTERISTIC APPEARANCE		
		<i>Bact. coli</i>	<i>Bact. aerogenes</i>	Member of typhoid group
10	<i>Bact. coli</i> types 1 and 2	9	1	Nil
7	<i>Bact. aerogenes</i> types 1 and 2.	Nil	7	Nil
10	Intermediate types 1 and 2.	7	3	Nil
4	Typhoid and paratyphoid group.	Nil	Nil	4

From the above results it is evident that all types of bacteria generally gave characteristic reactions on this media except some of the intermediate types.

With a view to determining the degree of accuracy and reliability of the plate method of differentiation, 966 colonies were picked from eosin-methylene-blue-agar plates after incubation for 48 hours (the differences of colonies after incubation for 24 hours were not very distinct). They were grown from 40 samples of water

collected from various sources, after preliminary enrichment in MacConkey's broth. They were tentatively designated as *Bact. coli* or *Bact. aerogenes* types from their appearances on the plates. These designations were then checked by identifying the colonies on culture with the usual differential tests—indol production, M. R., V. P., Koser's citrate and fermentative reactions of sugars, lactose, saccharose, dulcitol and adonitol. The results of 642 colonies tentatively regarded as *Bact. coli* are shown in table III.

From table III it is seen that 483 (75.2 per cent) out of 642 colonies, tentatively regarded as *Bact. coli*, could be confirmed. One hundred and nineteen colonies (21.6 per cent) were found to be intermediate types and 20 colonies (3.2 per cent) were *Bact. aerogenes* types. It should also be noted that 96.8 per cent of the total number of colonies tested were M. R. positive. Evidently, if all the colonies giving positive reactions to M. R. are classed as *Bact. coli*, the percentage of colonies confirmed would have been approximately as high as those observed by Levine. But 21.6 per cent of them had been identified as intermediate types by Koser's citrate-utilization test.

per cent of the colonies were positive to the citrate test and could be thus eliminated. 28.8 per cent of them, however, were found to be positive to the M. R. test also.

#### Summary

The relative significance of the common types of lactose-fermenting bacteria found in tropical waters has been reviewed with special reference to the intermediate types.

Levine's modified eosine-methylene-blue-agar has been employed with a view to differentiating *Bact. coli* and *Bact. aerogenes* simultaneously for confirming the 'presumptive coli' by inspection of colonies on the plates. Nine hundred and sixty-six colonies were tested in this way and the results show that the differences between these two types of colonies could often be made out after incubation for 48 hours, but the less significant intermediate types could not always be eliminated. Out of 642 colonies, tentatively regarded as *Bact. coli*, from their appearances on agar, 483 colonies (75.2 per cent) could be confirmed as such by differential tests, 22.6 per cent were found to be of intermediate types and 3.2 per cent were of *Bact. aerogenes* types. Out

TABLE III

Type of organism	DIFFERENTIAL TESTS USED					PERCENTAGE			
	Indol.	V. P.	M. R.	Growth in citrate	Number of each type of bacteria	Each type of bacteria	Colonies giving reactions

# VIBRIO CHOLERÆ AND OTHER VIBRIOS

(OBSERVATIONS ON 'WATER VIBRIOS', WITH SPECIAL REFERENCE TO THEIR VARIATION DURING STORAGE IN CULTURE MEDIUM AND POSSIBLE RELATIONSHIP TO *Vibrio cholerae*)

By A. C. VARDON, C.P.H. (Harv.),

Captain, Indian Medical Department

(From the King Edward VII Memorial Pasteur Institute and Medical Research Institute, Shillong, Assam)

TOMB and MAITRA (1926) as a result of their investigations concluded that the agglutinable vibrio found in the dejecta of cholera patients, and the non-agglutinable vibrio found in carriers and in natural waters contaminated with human faeces are one and the same organism. They arrived at this conclusion after inseminating tanks\* with fresh cholera stools containing large numbers of agglutinable vibrios and examining the water at two-hour intervals. They state that between the 12th and 20th hour all the agglutinable vibrios from the stools had changed to non-agglutinable.

d'Herelle, Malone and Lahiri (1930) have stated that inagglutinable vibrios found in nature originated from typical cholera vibrios and suggested that the mutation which they have undergone had been produced by the action of bacteriophage.

d'Herelle (1930) in dealing with the epidemiology of cholera has brought forward ample evidence to show that vibrios isolated from convalescent cholera cases are probably avirulent and suggest that this loss of virulence is the result of bacteriophage action.

## *Cholera vibrio mutants produced by the action of cholera phage types*

Early in 1935, when 11 definite types of cholera phage had been isolated, a cholera

\* The word 'tank' used in the paper means a large pond or reservoir, either natural or artificial.

(Continued from previous page)

Thus the confirmation of the 'presumptive tests' for *Bact. coli* on Levine's eosin-methylene-blue-agar in the bacteriological examination of water under the conditions existing in Bengal should not be considered as strictly reliable, but may be very conveniently adopted for 'partially confirmed tests'.

vibrio, strain 653, which was the only strain in this Institute that was lysed by all the then known types, was made resistant to all but one type of cholera phage. Thus 12 resistant cultures were prepared and these were labelled 11-A<sup>r</sup>, 11-B<sup>r</sup> and so on to 11<sup>r</sup>.

11-A<sup>r</sup> culture was that which was made resistant to B, C, D, E, F, G, H, J, K, and L types of cholera phage and hence only 'A' type lysed it. The 11<sup>r</sup> was one which was made resistant to all the 11 types of cholera phage. The biochemical and serological reactions, etc., of these cultures were then tested.

**Sugar reactions.**—Ten out of the twelve variants gave sugar reactions of Heiberg (1936) type I. The two variants which gave different reactions were 11-D<sup>r</sup> and 11-H<sup>r</sup>.

For the first 48 hours 11-D<sup>r</sup> gave the sugar reactions of type VI, but after 7 days there was slight acidity in saccharose only (type II). 11-H<sup>r</sup> after 7 days showed slight acidity in mannose only (type V).

**Colony appearance.**—The most marked change noticed was in the size of the colonies as compared with those of the parent strain. Some variants, on being plated, produced minute colonies, even after the plates had been incubated for 48 hours.

**Serological reactions.**—High titre sera (H + O) were prepared by injecting rabbits intravenously with living cultures of each of the 11-1<sup>r</sup> and the 11<sup>r</sup> variants\*, and cross agglutination tests were carried out. Formolized saline suspensions were used. Parent 653 (H + O) serum only agglutinated four variants to a titre of 50 per cent or over. Four out of eleven variant sera did not agglutinate the parent culture up to 50 per cent of their titre. Some variant cultures were agglutinated by one or two of the 12 sera, up to 100 per cent of titre.

## Example

Strain	Sera agglutinating to 100 per cent	Other sera
11-D <sup>r</sup>	11-D and 11-K	From 0.0 to 50 per cent.
11-J <sup>r</sup>	11-J	" 2.5 " 25 "
11 <sup>r</sup>	11-J and 11 <sup>r</sup>	" 2.5 " 50 "

In view of these preliminary findings with laboratory-produced variants, the question arose whether the observations reported by Tomb and Maitra were due to the action of cholera phage in the water on the cholera vibrios.

In addition to studying the characters of the 11-1<sup>r</sup> variants, other resistant cultures were prepared from the same parent 653 cholera vibrio by subjecting it to the action of one type of cholera phage. The single resistant secondary

\* No serum could be prepared from 11-E<sup>r</sup> culture as this culture became resistant to E type phage.

cultures all gave the sugar reactions of Heiberg type I and all were agglutinated to over 50 per cent of titre by the parent H + O serum. This bears out d'Herelle's (1926) earlier statement that the loss of agglutinability with specific serum is related to the degree of acquired resistance to phage. Mention of the above findings is made in the report of the Cholera (Bacteriophage) Enquiry at Shillong (Russell, 1935).

#### 1936 investigation

An opportunity was afforded in 1936 to investigate whether any relationship exists between the non-agglutinating vibrios isolated from water and phage-resistant variants of a true cholera vibrio produced in the laboratory. In that year a Field Research Laboratory, which was equipped by the Pasteur Institute, Shillong, and financed by the Indian Research Fund Association, was sent to Habiganj, a subdivision of the Sylhet District. The functions of this laboratory were to investigate epidemic and sporadic cases of cholera, carrier cases and vibrios isolated from river and tank waters in the district. The field laboratory carried on this investigation for one year. After a preliminary examination in the field laboratory, all vibrio strains isolated were sent to this Institute for further examination. In addition to the usual biochemical and serological tests, the writer tested all the water vibrios received for phage lysability with the 11 types of cholera-phage and for agglutination against the 11-1 resistant sera which had previously been prepared, and also against Inaba and Ogawa 'O' sera. The results of the investigation carried out during 1936 are summarized below:—

One hundred and fifty-nine strains of water vibrios were examined.

**Fermentation reactions.**—With the exception of three, all the strains which showed lysis with any of the cholera-phage types, or which were agglutinated by any of the 11-1 sera (H + O) belonged to Heiberg's fermentation types I, II and V. The three exceptions belonged to Heiberg's type III. A further reference will be made to these three strains in the next section. Two other strains were agglutinated by Inaba 'O' serum to 50 per cent of titre, but these were neither lysed by any of the cholera-phage types nor agglutinated by any of the 11-1 sera.

**Agglutination and phage reactions.**—Twenty strains were agglutinated by one or more of the 16 sera used, up to 50 per cent of titre or higher.

The parent 653 serum only agglutinated six of these.

Fourteen of the 159 strains were lysed by one or more of the phage types, and 12 of these were agglutinated by the variant sera. No strain was agglutinated by Ogawa 'O' serum.

During the course of the above investigations, and after the preparation of the H + O variant sera, the importance of 'O' agglutination in the classification of vibrios began to be stressed.

The writer therefore decided to re-examine, as many of the above cultures as possible for 'O' agglutination, and at the same time to re-test their sugar reactions and phage lysability.

#### 1937 investigations

Preliminary investigation into laboratory-produced variants:—

In 1936 a new type of cholera-phage, namely 'M', was described by Pasricha *et al.* (1936). A sample of this phage was very kindly sent to this Institute by Major Pasricha. Before preparing the series of 'O' sera, all our 11-1 phage-resistant cultures were made resistant to the new phage type. High titre 'O' sera\* were prepared from all but 12-C<sup>r</sup> variant, as no satisfactory high titre serum was obtained against this strain. In addition to the 12 variant sera, 'O' sera were also prepared from the parent strain 653 and from Inaba (Rough). The object of including Inaba (Rough) serum was to ascertain whether any agglutination which might occur with any of the other sera was due to the rough factor. Thus in all 16 'O' sera were employed, comprising the 12 prepared from the phage-produced variants, one each from the parent strain 653 and Inaba (Rough) and the two stock laboratory 'O' sera Inaba and Ogawa. The titre of most of the sera was 1 in 1,000, but in a few instances a maximum titre of 1 in 500 could only be obtained.

Before re-testing the 1936 cultures, the biochemical and agglutination reactions of the 12-1<sup>r</sup> cultures were tested. After 48 hours all variants with the exception of the following gave the reaction of Heiberg's type I:—

Variant cultures	Heiberg's type
12-B <sup>r</sup> ..	V
12-D <sup>r</sup> ..	II
12-E <sup>r</sup> ..	II
12-L <sup>r</sup> ..	II

These variants (each lysed by one type of cholera-phage and agglutinated by at least one variant serum-homologous) have therefore given similar results to those water vibrios which in the 1936 enquiry were agglutinated by variant sera or were lysable by cholera-phage. They all belonged to Heiberg's type II or V.

Nine of the cholera vibrio variants were tested against 'O' sera prepared from cholera strains Inaba (Smooth), Ogawa, 653 and Inaba (Rough).

\* These sera were prepared from suspensions of 24 hours' old agar cultures in normal saline. The suspensions were placed in a boiling water-bath for two hours.

The results are summarized below :—

'O' serum	Strains agglutinated to 100 per cent of titre	Other strains (percentage agglutination)
653 ..	12-A	0 to 25.0
Inaba (Smooth) ..	12-J	25 „ 50.0
Ogawa ..	12-A	0 „ 12.5
Inaba (Rough) ..	Nil	5 „ 50.0

Although the parent strain belongs to the Ogawa group, Inaba (Smooth) serum agglutinated the variants better than either parent 653 or Ogawa sera.

The results obtained with Inaba (Rough) serum do not suggest that the predominant change produced by phage action on the vibrio is one from smooth to rough. If this were so, one would expect these variants to be agglutinated in higher dilutions than the results shown above.

The next step was to test some of the variant 'O' sera against cholera vibrio strains 653, Inaba (Smooth), Ogawa and Inaba (Rough). The results obtained are shown in the following table :—

TABLE

Serum	Titre	CHOLERA VIBRIO STRAINS. PER CENT OF TITRE TO WHICH AGGLUTINATED			
		Inaba (Smooth)	653	Ogawa	Inaba (Rough)
12-A <sup>r</sup>	1 in 1,000	12.5	100.0	50	0.0
12-G <sup>r</sup>	1 in 500	25.0	25.0	10	100.0
12-H <sup>r</sup>	1 in 1,000	12.5	12.5	5	25.0
12-K <sup>r</sup>	1 in 1,000	12.5	12.5	5	12.5

These results confirm the above findings, showing that except 12-A<sup>r</sup> variant, the others have markedly changed in their antigenic properties and in only one (12-G<sup>r</sup>) can the change be ascribed to that of roughness.

#### Re-examination of the 1936 cultures

All the vibrios examined during 1936 were stored as agar stab cultures, the test-tube plugs of which were waxed. These were stored at room temperature (4°C. to 26°C.) for a period of from 9 to 12 months. When required for re-testing, each strain was subcultured on to three agar slopes and another stab was made which was kept in stock. Formolized saline suspensions were prepared for agglutination from two 24-hour cultures and the third slope was used for the sugar reactions and for the phage lysability test. Seventy strains in all, selected from the various Heiberg's types, as classified in 1936, were examined. Four of these, as shown below, were agglutinated by one or more of the variant sera up to 50 per cent of titre.

#### Agglutination reactions

Sugar reactions (1936). Heiberg's types	Strain	Sera by which agglutinated
I	W. 27	12-G, 12-H, 12-K
II	W. 116	12-H (trace agglutination from 1 in 50 to 1 in 500).
III	525	12-D, 12-II, 12-K
VI	W. 11	12-K

No strain belonging to type IV or V was agglutinated. Under the 1936 investigation mention has been made of three strains which belonged to Heiberg's type III which were lysed by one or more phage types and which were agglutinated by variant sera. These strains were 525, 525(1) and 525(2). When these were re-tested in 1937 they all gave the sugar reactions of type I. An unusual finding was strain W.11, which belonged to type VI, but which was agglutinated by 12-K serum. This strain was investigated further in 1938, and a possible explanation of the present finding is given under the 1938 investigation.

**Sugar reactions.**—When re-tested it was found that the fermentation reactions of a large number of strains had altered. This change was noticed in all the Heiberg's types. Some from type I had changed to type II; others from type II had changed to types I, III and IV, etc. In spite of these changes, it was again noticed that those strains, which on re-testing were lysed by one or more types of cholera phage gave the sugar reactions of Heiberg's type I, II or V. It should be mentioned here that a typical cholera vibrio was always sown in a duplicate set of sugar tubes whenever a batch of water vibrios was tested for their fermentative reactions. The control invariably fermented saccharose and mannose but not arabinose.

**Phage lysability.**—Of the strains re-tested, ten were originally lysed by one or more cholera-phage types. In 1937, nine of these were again tested and the strains were lysed by more phage types than originally. One strain (373) which in 1936 was lysed by 'J' type phage, was found to be resistant to all types in 1937. Later (1938), however, it was lysed by G, H and J types. Four additional strains which were resistant to all types in 1936, were in 1938 lysed by one or more types. Similar loss of resistance to phage types has repeatedly been noticed among our 12-1 resistant cultures when stored for some months as agar stab cultures. For instance, a 12-A resistant culture is tested and found to be lysed by 'A' type cholera phage only. It is then stored for some months as an agar stab culture with the test-tube capped and waxed. When re-tested later it has often been found that, in addition to being lysed by 'A' phage, the culture had lost its resistance to one or more of the other types of phage. The

probable explanation for this may be found in the following statement made by d'Herelle and Rakieten (1934):—

'One of us (d'Herelle) has shown experimentally that the general behaviour of any natural symbiosis found in nature is realized in the case of bacterium-phage symbiosis. Three types of process may take place. The bacteria may be destroyed if the virulence of the phage increases; symbiosis may persist indefinitely if the phage virulence and the bacterial resistance are balanced, or the phage may be destroyed if the resistance of the bacteria increases. The result in the third instance is a phage-free bacterium'.

It is to the third process that the loss of resistance described above must be attributed. As the bacteria are infected by phage it is only natural that these are constantly striving to throw off this infection and if these vibrios do finally, by increased resistance, rid themselves of the infection of each and every type of cholera phage by which they were attacked, they would revert to a phage-free vibrio.

#### *Investigations on recently isolated strains*

In addition to the 70 strains already dealt with above, 72 more strains, which were freshly isolated from various samples of water by Dr. S. R. Pandit, Officer-in-Charge of the Cholera Enquiry at Shillong, were examined by the writer for phage lysability and in some cases also for agglutination. The sugar reactions were carried out by Dr. Pandit. Seven strains were lysed by phage types, details of these are given below:—

Strain number	Heiberg's types	Lysis by cholera phage types
739/2/1	V	B. F.
739/2/2	II	H.
704/1/1	II	J. M.
704/1/2	II	J. M.
704/2	II	J. M.
730/1/3	V	B. C. F. K.
730/2	V	B. C. F. K.

*Agglutination reactions.*—These seven strains were tested against the 16 'O' sera. Only one strain (739/2/2) was agglutinated to 100 per cent of titre by 12-D and 12-H sera. If we add these seven strains, which belong to Heiberg's type II or V to those mentioned in the 1936 investigation, we have a total of 21 strains susceptible to phage action. They all belonged to Heiberg's type I, II or V. As previously mentioned, four more strains, which were originally resistant, were lysable in 1937, three belonged to type II and one to type V.

Therefore out of a total of 231 strains which were tested or re-tested during 1936 and 1937, 25 were lysed by cholera phage and all belonged to Heiberg's type I, II, or V. The remaining 206 phage-resistant strains belonged to type III, IV or VI.

#### *1938 investigation*

Owing to the number of strains which were found to have altered in sugar reactions and in order to confirm these findings, some of the original strains, which had again been stored as agar stab cultures after they were investigated in 1937, were re-examined for their fermentative reactions in 1938. These had been stored for a further period of from 4 to 6 months since they were re-tested in 1937. Many of the strains had again altered in their sugar reactions. Some had reverted to their original Heiberg type, others which had changed when re-examined in 1937, still gave the 1937 reactions, while others gave reactions different to those obtained in 1936 and 1937. An example of these findings is given.

Strain	Fermentation reactions Heiberg's types		
	1936	1937	1938
227(2) ..	I	II	I
210(1) ..	III	IV	IV
542 ..	VI	III	IV

After another 2 months a final examination was made of those vibrios which had previously been either lysed or agglutinated. This time, however, each strain was subcultured from the agar stab culture into peptone water and was subcultured daily for 4 days in this medium. Each culture was then plated and four smooth translucent colonies were picked off and inoculated into papain-casein broth (Vardon and Datta Roy, 1938). Daily passages in this medium were made for 4 more days. Each of the four broth cultures was next transferred to agar slopes and these agar cultures were used the next day for lysability, sugar reactions and agglutination tests. Changes in reaction, as shown below, were again noticed. The reactions under 1938 are given as (1) and (2), the former refers to the first 1938 examination and the latter to the final one.

Strain	Heiberg's types			
	1936	1937	1938 (1)	1938 (2)
27	I	I	I	V
116	II	I	II	I
373	II	V	V	II

All four colonies tested invariably gave identical sugar reactions.

turned to the products of intestinal putrefaction such as phenols and aromatic oxyacids, which are highly toxic and which are found in the blood and cerebro-spinal fluid of uræmic patients in concentrations varying with the intensity of symptoms. Moreover, it has been pointed out by Volhard and Becher (1929) that these toxic phenols can find their entrance into the cerebro-spinal fluid only when some structural alterations have rendered the choroid plexus permeable, either as a result of damage brought about by kidney failure or some gross anatomical change superimposed on it. Changes in the choroid plexus had been reported by Von Monakow as early as 1920. The senior writer has personally seen two cases of uræmia in which the choroid plexus showed definite anatomical change and in at least one there were large and small cystic dilatations in the organ making it look like a bunch of grapes. Unfortunately difficulty in obtaining a larger number of autopsy examinations has stood in the way of further confirmation of the above observations.

All recent work tends to support the view that uræmia is a clinical syndrome produced either by a chemical disturbance in the blood and tissue fluids owing to a high grade renal failure, or a physical disturbance of the intracranial circulation associated with hypertension. In many instances both the factors may be at work in the causation of uræmia. The first condition is nowadays regarded as true uræmia or chronic retention uræmia and the second is designated as pseudo-uræmia or acute convulsive uræmia known as hypertensive encephalopathy of Fishberg. From a study of the varying symptomatology of chronic retention uræmia and also of all the experimental work on that line, it appears that uræmia is not due to the retention in the blood and tissues of any one particular chemical agent, but to the alteration in the relative amounts of several substances. These variations may differ considerably from one case to another. For instance, as a result of renal failure, there is not only a retention of the various non-protein nitrogenous constituents but also of a considerable amount of inorganic phosphates, with diminution in the available ionized calcium in the blood and cerebro-spinal fluid. Moreover, an accumulation of guanidine and phenol derivatives has been observed in the blood. Last but not least important are the dehydration, acidosis and chloride deficiency, which, though not essential features of the uræmic syndrome, are present in many cases associated with vomiting and diarrhœa.

A proper appreciation of these biochemical changes would be very helpful in the interpretation of the varied clinical pictures of true uræmia. Thus retention of inorganic phosphates with diminution in the ionized calcium, especially in the cerebro-spinal fluid, tends to cause symptoms of acidosis and increased neuro-muscular irritability, i.e., tremors, twitchings and increased tendon jerks. The grave nervous

symptoms of uræmia such as weakness, apathy, drowsiness and coma are caused either by the increasing concentration in the blood and cerebro-spinal fluid of the non-protein nitrogenous constituents, or by the retention of the phenol derivatives, the normal limit of which is 1.1 to 1.4 mgm. per cent. These symptoms may in some cases be further evoked by the accumulation of guanidine which not only produces apathy, tremors, muscular twitchings and convulsions but also stupor and coma. The respiratory symptoms of increased pulmonary ventilation and periodic breathing are due to diminution of the alkaline reserve of the blood owing to an increase in the inorganic phosphates. The gastro-intestinal symptoms, particularly nausea and vomiting as well as diarrhœa and colitis, may be caused by the accumulation of guanidine and also by the irritating effects of toxic substances during their excretion through the mucous membrane of the alimentary tract. The hæmorrhagic symptoms which are sometimes seen either as petechial hæmorrhages or as severe uncontrollable bleeding from the gums, may be explained on the basis of the increased capillary permeability brought about by the intoxication as well as by the hypocalcæmic condition of the blood. Last of all, the emaciation and anæmia in advanced cases are due to the low food intake and deficient absorptive power of the intestines. Thus almost all the important symptoms of uræmia are explained on the chemical basis, although we are not yet able to solve the primary problem which initiates such chemical changes.

There is one important point which may be discussed in connection with uræmia, and this is the nature of the renal function when the acid-base equilibrium of the blood and tissues becomes considerably altered. The commonest example is the upset of the kidney function when ketosis and coma develop in the course of diabetes mellitus. It is often found that in cases of severe diabetic coma, in addition to the biochemical alterations characteristic of the disease, it is not at all uncommon to find blood urea as high as 100 mgm. per cent which suggests a uræmic condition superimposed as a terminal event. As the condition of coma improves the urea retention diminishes *pari passu*. Thus it may be concluded that a sudden or considerable alteration in the reaction of the blood and tissue fluids may act injuriously on the function of the kidney, producing a severe degree of renal failure. And if the organ has already been the seat of disease, the reaction becomes very violent and the uræmic condition develops. A similar change may also be brought about in alkalosis. Oakley (1935) published an account of seven cases of alkalosis occurring in the course of treatment of peptic ulcer two of which died in coma with blood urea figures of 225 and 250 mgm. per cent respectively. Intensive treatment of urinary infections by ammonium chloride and mandelic acid

may produce a marked rise in blood urea. In case of a pre-existing damage of the kidneys, this might lead to a severe degree of renal failure. It is well therefore to remember that although healthy kidneys may function well, within wide variations of the acid-base balance, damaged organs can do so only within much narrower limits. It is most important in such cases to take necessary measures to maintain the alkali reserve at as normal a level as possible.

#### *Clinical picture*

It is essential to remember that if renal failure is gradual, the nitrogen retention will also be slow and insidious in its increase and it may reach an extreme degree before any clinical disturbance is produced. On the other hand, if the change comes on suddenly, the symptoms make their appearance acutely before any considerable accumulation of urea and non-protein nitrogen has taken place. An appreciation of these facts will explain the occurrence of a classical uræmic syndrome without any marked biochemical alteration in the blood and tissue fluids. Typical examples of such a condition may be found in cases of chronic prostatic obstruction when a patient may not show symptoms of uræmia in spite of a marked chemical change in the blood.

The clinical picture has been studied in 44 cases of uræmia treated in the Medical College Hospital during the last 4 years.

because we have recently found some extreme examples of urea retention with uræmic syndrome in patients suffering from leptospiral infection. Whether this infection produces a true nephritis or not could not be actually verified by autopsy examination but clinical and biochemical findings all go to prove that it does cause such damage.

*Onset.*—The onset of uræmia is often insidious. In our series, 42 cases had a gradual onset and in only 2 was the condition ushered in with sudden convulsive seizures. Such a sudden onset is nowadays attributed to the development of vascular spasm leading to cerebral ischæmia, œdema of the brain either local or general and increased cerebro-spinal fluid tension, a group of morbid processes which are included in the term hypertensive encephalopathy (Fishberg, 1931). There is however a certain group of cases, though their number may be small, which occur particularly in young subjects and where unmistakable signs of serious kidney damage with marked urea retention may be found. There is also vascular change with marked hypertension. These are only examples of uræmia from sudden renal failure with an associated hypertensive encephalopathy as a complication (case 38).

*General appearance.*—Many of the patients had a peculiar sallow waxy appearance, very marked in some cases. In long-standing cases, emaciation was quite obvious. In this series

TABLE I  
*Age incidence*

Age in years	Nephritis	Nephrosclerosis with hypertension	Weil's disease	Nephrosclerosis without hypertension	Enlarged prostate	Cystitis	Extra renal cause	Unknown	Total
11-20	5	..	..	..	..	..	..	..	5
21-30	4	..	1	..	..	1	1	..	7

71-80	..	..	..	2	1	..	..	..	3
TOTAL	18	11	5	4	3	1	1	1	44

The oldest patient was 80 and the youngest 14 years old. The largest number occurred during the sixth and seventh decades of life, but in the nephritic group of cases the patients were younger.

*Sex.*—Out of 44 cases, 42 occurred in males and only 2 in females. But hardly any conclusion can be deduced from such figures in our country where females seek hospital treatment much less than males.

*Predisposing diseases.*—A study of table I will give an idea of this subject. Nephritis and nephrosclerosis do not require any comment. Weil's disease has been included in the list

12 showed this feature and 6 of them belonged to the nephritic group.

*Nervous symptoms.*—The commonest symptom was found to be drowsiness coming on slowly and ending in coma. There were however a few cases which were boisterous, especially at night, and violent occasionally. Some patients were always found in a depressed mood, not taking the slightest interest in their surroundings and even neglecting their food. Mental confusion was noticed in some in whom there were both incoherent speech and thought. Hallucinations and a paranoiac condition may also exist. There was one patient belonging to

the nephrosclerotic group who would not sleep at night and would always soil his bed. When asked why he did so he would persistently say that he could not get the urine bottle in his bed as the latter would constantly leave him and go about in the wards. Troublesome insomnia, especially at night, is fairly common. The patient may remain up the whole night, wide awake and restless but pass the day in sleep. Contrary to the popular conception, headache is rarely complained of. Convulsive seizures were present in two cases only. Occasional twitching movements of muscles may be noted. Weakness and marked prostration were very constant, but paralysis was never met with unless there were associated cerebral vascular lesions. Some cases complained of transient dimness of vision but sudden amaurosis was infrequent, being present in 2 cases only.

*Respiratory symptoms.*—Apart from those due to supervening complications or associated diseases, bronchitis, emphysema, broncho-pneumonia, pleurisy, etc., respiratory difficulty was not common. The classical observation of Rose Bradford, namely, dyspnoea of a hissing character in a drowsy patient with bleeding gums, although very characteristic, was seen in 5 cases only. Cheyne-Stokes type of breathing was present in 3 cases.

*Gastro-intestinal symptoms.*—Constipation was present in the majority, being found in 25 cases and diarrhoea in 9 cases. A superficial glossitis with glazed and raw red tongue in an elderly patient with some drowsiness is almost diagnostic. There may be anorexia, nausea, vomiting, stomatitis and hiccough. In this series 9 patients had nausea and vomiting, 7

*Cardio-vascular symptoms.*—The symptoms referred to the cardio-vascular system are due to the primary condition which gave rise to uræmia. In the majority of instances, both in the nephritic and the nephrosclerotic groups, there were varying degrees of cardiac enlargement with or without cardiac failure. The latter condition is due to myocardial degeneration brought about by ischæmic fibrosis as a result of coronary arteriosclerosis. In some of the cases, we could find the most remarkable enlargement of the organ, the apical impulse being felt in the 7th left inter-space in the mid-axillary region. The heart rate is usually high. Gallop rhythm, cardiac arrhythmias including auricular fibrillation and apical systolic murmurs due to relative incompetence may all be found. In some of our cases, gallop rhythm was present throughout the course of the illness.

Involvement of the pericardium as a terminal infection is not infrequent, being present in 2 of our cases. It may be dry pericarditis or one with effusion, the former being the commoner of the two. It is usually ushered in by a rise of temperature which cannot be explained. There is hardly any complaint of pain as the patient remains more or less in a semi-comatose condition. Precordial pain may however be complained of if there is coronary arterial involvement. In the present series 3 such cases were found, the diagnosis being established by electrocardiographic examination. An attack of coronary thrombosis may be the cause of sudden death in uræmia (case 14). There are usually marked arterial changes in all cases due to nephritis and nephrosclerosis.

TABLE II  
Blood pressure in mm. of mercury

Predisposing diseases	SYSTOLIC			DIASTOLIC		
	Highest	Lowest	Mean	Highest	Lowest	Mean
Nephritis	220	95	175	140	65	110
Nephrosclerosis with hypertension	265	140	196	190	120	117

hiccough and 3 bleeding gums one of which was very severe and uncontrollable and ended fatally. Two cases apparently suffering from colitis could be followed up and on autopsy examination one showed generalized congestion of the colon with small superficial ulcers and the other had hæmorrhages in the submucous layer.

*Hæmorrhages.*—Petechial hæmorrhages in the skin were found in 2 cases. Petechial hæmorrhage and ecchymoses were present in 2 cases. Only 1 case had frank hæmaturia. Mention has already been made about bleeding from mucous surfaces, especially from the gums. As a rule, the loss of blood is never pronounced but Konar (1939) reported a case in which it was so severe and uncontrollable that the patient died of exsanguination. Gross blood in the stool is uncommon.

Highest pressure recorded was in case 39 who had nephrosclerosis with hypertension S/D = 265/190. No remarkable change in blood pressure was noticed in cases of Weil's disease. This high blood pressure usually comes down with the onset of cardiac failure. A falling blood pressure in a drowsy patient who had previously suffered from hypertension is always ominous.

*Temperature.*—Uncomplicated cases of uræmia do not show any rise of temperature. If it is present, one should suspect the onset of some complication such as pericarditis, broncho-pneumonia or infection in the urinary tract. Case 38 which was admitted with convulsions ran a temperature varying from 101° to 103°F. This patient succumbed within 12 hours of admission. As a rule, the temperature

is low, varying from 99° to 101°F. The Weil's disease group of cases, did not show any rise of temperature as they were usually admitted after the 7th day of illness when the disease had become apyrexial.

*Blood changes.*—Anæmia of a hypochromic microcytic type is common especially in the nephritic group of cases. Moderate degree of leucocytosis with polymorphonuclear preponderance is common.

with albumin and casts, and a rise of blood urea and N. P. N. above 100 mgm. per cent. On the other hand, the acute convulsive uræmia is characterized by the sudden onset, presence of severe headache, epileptiform convulsions, paralysis, transient palsies, amaurosis, maniacal delirium, cardio-vascular changes, hypertension, neuro-retinopathy, scanty urine of a high specific gravity and a normal blood chemistry or a slight increase of blood urea and N. P. N. It

TABLE III  
*Biochemical changes*

Predisposing diseases	UREA			N. P. N.		
	Highest	Lowest	Mean	Highest	Lowest	Mean
Nephritis .. .. .	281	37	102	120	39	75
Nephrosclerosis with hypertension ..	224	35	89	206	34	75
Weil's disease .. .. .	410	115	244	245	84	168
Nephrosclerosis without hypertension	140	30	74	70	32	58

In some of the cases in our series, the amount of urea and non-protein nitrogen remained within normal limits, but this was due to the fact that either the blood was collected when uræmia did not actually set in or when the patient recovered from the condition with treatment.

*Urine.*—In all our cases the quantity of urine was markedly diminished and reached as low as 4 ounces in 24 hours. Uræmia may, however, occur while the patient has been passing a large quantity of urine. But in such cases, it is very pale, almost watery and contains little or no solid and pigmentary constituents. The lowest specific gravity that was noted in the series was 1.002. Albumin was present in all the cases, being marked in the nephritic group. It was as high as 0.8 per cent in case 30. Tube casts were detected in 30 cases—hyaline and granular in 27, only hyaline in 3. They were more frequently present in the nephritic than in any other group. Although frank hæmaturia was present in one case only, red blood cells were found in the centrifugized deposit in 17 cases, of which 11 were nephritic. It is a point of interest that red cells persist in the urine most tenaciously and would not disappear under any treatment.

*Diagnosis.*—In practice the diagnosis of true retention uræmia from the acute convulsive type is essential from the point of view of prognosis and treatment. The diagnostic features of true retention uræmia are the insidious onset, the emaciated and anæmic facies, muscular weakness, apathy, drowsiness gradually passing into stupor and coma, nocturnal insomnia with boisterousness, muscular twitchings, brisk reflexes, ammoniacal odour of the breath, stomatitis with bleeding gums, anorexia, vomiting and diarrhœa, respiration deep and slow, or of the hissing type, scanty urine of a low specific gravity

must be remembered, however, that both conditions may co-exist.

*Prognosis.*—The ultimate outlook is influenced by the underlying cause and the possibility of its removal. In retention uræmia of chronic nephritis, the prognosis is obviously bad because it is the end result of a high grade renal failure. In most cases the fatal outcome is a question of a few days or a few weeks, depending on the degree of coma, the presence of periodic or air-hunger type of breathing, stomatitis with bleeding gums, purpuric manifestations, persistent hiccough, pericarditis and a falling temperature, associated with a blood urea or N. P. N. of over 150 mgm. per cent and creatinine over 5 mgm. Creatinine figures above 12 mgm. indicate death within three weeks. Nephritic cases which may show temporary improvement often relapse and very few of them survive a year. In our experience only 2 of our cases did survive for a year. Cases of retention uræmia due to chronic urinary obstruction by enlarged prostate have a better outlook if the cause is removed. Similarly the prognosis of uræmia in diabetic ketosis, acidosis and alkalosis is favourable because the acid-base disturbance may be successfully tackled. The prognosis of acute convulsive uræmia on the other hand is favourable, unless recurrent attacks of convulsions bring about a cardiac failure. In acute nephritis and eclampsia gravidarum the patient may, by proper management, frequently be tided over the so-called uræmic stage to a stage of recovery.

The end results of uræmia are evident from table IV.

*Treatment.*—The main principles of treatment in cases of uræmia consist of—(a) removal of the underlying cause if possible, (b) correction of the altered blood chemistry

Case No.	Age	Sex	Onset and general features	Nervous symptoms	Respiratory symptoms	Gastro-intestinal symptoms	Cardio-vascular symptoms	Retinal changes

Total leucocyte count—12,500 per c.mm. Polymorphonuclear neutrophils—80%. Lymphocytes—18%. Monocytes—2%. 1-3-39. Hæmoglobin—40%. R. B. C.—2,250,000 per c.mm. W. B. C.—11,820%. Polymorphonuclear neutrophils—78%. Lymphocytes—20%. Monocytes—2%.	Chronic nephritis with secondary hypertension.	Death 1-3-39.

TABLE

Case No.	Age	Sex	Onset and general features	Nervous symptoms	Respiratory symptoms	Gastro-intestinal symptoms	Cardio-vascular symptoms	Retinal changes
29	60	M.	Onset gradual. Slight emaciation.	Boisterousness in between. Drowsy, coma.	Evidence of chronic bronchitis with emphysema.	Vague symptoms of dyspepsia for the last 3 years before admission.	Palpitation, arteries markedly thickened. B. P. on admission, 165/105, 1 month later 195/130. E. C. G.—myocardial degeneration and coronary sclerosis.	Nil
30	51	M.	Onset gradual. Admitted with the complaints: 1. Generalized swelling of the body 10 days after an exposure to chill. 2. Scanty micturition. 3. Abdominal pain.	Drowsiness	Evidence of bilateral broncho-pneumonia.	Constipation	B. P.—180/100 on admission. Gradually came down to 118/80 on the day of death. Arteries thickened.	Nil.
31	29	M.	Onset gradual. Markedly pale.	Cramps and tingling sensation of the extremities. Sense of weakness and exhaustion. Later extreme languor, drowsiness and coma. Dimness of vision.	Nil	Nausea, vomiting, constipation.	Palpitation. Arteries thickened and tortuous. Heart irregular at the end. B. P.—210/115.	Flame-shaped old hæmorrhage in both eyes, more marked in the right.
32	45	M.	Onset gradual. Pale and waxy in appearance. Marked emaciation.	Headache. Insomnia. Extreme languor. Marked exhaustion and drowsiness.	Nil	Hiccough, nausea, vomiting, diarrhoea, fair number of pus cells in stool.	Arteries thickened. B. P.—134/80 which gradually came down to 82/54.	Nil

—contd.

Urinary findings	Temperature	Blood chemistry	Blood count	Associated diseases and complications	Result
Sp. gr.—1004. Albumin—present. Hyaline and granular casts—few.	Normal	On admission— Urea—38 mgm. %. N. P. N.—40 mgm. %. Cholesterol—152 mgm. %. Chloride—410 mgm. %. 11-4-39. Urea—74 mgm. %. N. P. N.—70 mgm. %. Cholesterol—285 mgm. %. Chloride—430 mgm. %.	Hæmoglobin—50%. Total erythrocyte count—2,850,000 per c.mm. Total leucocyte count—7,312 per c.mm. Polymorphonuclear neutrophils—88%. Lymphocytes—8%. Monocytes—4%.	Chronic bronchitis with emphysema. Hypertensive cardiac failure. Nephrosclerosis. Post-mortem findings: Generalized arteriosclerosis. Cardiac dilatation and hypertrophy. Arteriosclerotic kidney. Œdema lungs. Hæmorrhages within large gut. Œdema brain.	Death 11-4-39.
Hæmaturia. Sp. gr.—1022. Albumin—0.8%. R. B. C.—plenty. Tube casts—hyaline and granular.	Remittent temperature for 7 days after admission. Maximum —102°F. Minimum —99°F.	20-5-39. Urea—65 mgm. %. N. P. N.—45 mgm. %. Chloride—410 mgm. %. Cholesterol—140 mgm. %. Creatinine—3 mgm. %. 25-5-39. Urea—68 mgm. %. N. P. N.—63 mgm. %.	Hæmoglobin—90%. Total erythrocyte count—4,610,000 per c.mm. Total leucocyte count—13,728 per c.mm. Polymorphonuclear neutrophils—80%. Lymphocytes—8%. Monocytes—2%. Polymorphonuclear eosinophils—10%.	Chronic nephritis. Broncho-pneumonia.	Death 3-6-39.
Quantity—about 40 oz. on admission, which gradually came down to 15 to 20 oz. Sp. gr.—1010. Albumin—0.12%. Pus cells, R. B. C.—a few. Fair numbers of hyaline and granular casts.	Normal	Urea—170 mgm. %. N. P. N.—120 mgm. %. Cholesterol—260 mgm. %. Chloride—351 mgm. %.	Hæmoglobin—50%. Total erythrocyte count—3,230,000 per c.mm. Total leucocyte count—4,992 per c.mm. Polymorphonuclear neutrophils—60%. Lymphocytes—20%. Monocytes—18%. Polymorphonuclear eosinophils—2%. Basophils—2%. 29-3-39. Hæmoglobin—45%. W. B. C.—10,625. Polymorphonuclear neutrophils—76%. Lymphocytes—22%. Eosinophils—2%.	Chronic nephritis with secondary hypertension.	Death 5-7-39.
Quantity varied from 5 to 22 oz. Sp. gr.—1010. Albumin—0.1%. Few R. B. C. and pus cells. Fair number of hyaline and granular casts.	Intermittent temperature. Maximum —102°F. Minimum —97°F.	Urea—37 mgm. %. N. P. N.—39 mgm. %. Chloride—468 mgm. %.	Hæmoglobin—55%. Total erythrocyte count—2,900,000 per c.mm. Total leucocyte count—6,864 per c.mm. Polymorphonuclear neutrophils—82%. Lymphocytes—10%. Monocytes—2%. Polymorphonuclear eosinophils—6%.	Chronic nephritis	Death 25-9-39.

and of the physical disturbance of the intracranial circulation and (c) relief of distressing and urgent symptoms.

TABLE IV  
*Prognosis*

Total number of cases	Immediate mortality	Remote mortality	Apparent cure	Improved	Untraced
44	33 died 75%	2 4.5%	5 11.5%	2 4.5%	2 4.5%

In view of the underlying cause being irremovable in most cases of uræmia except in those caused by mechanical obstruction to urinary outflow, our main object in every case

should be directed towards restoration of the blood chemistry to a level as near to normal as possible, and to a reduction of the raised intracranial pressure if there be any. For this purpose we must promote the elimination of toxic substances through the bowels, skin and kidneys. Rectal administration of 6 ounces of 25 per cent solution of magnesium sulphate by the drip method is a very useful means of elimination by the bowels, especially in comatose cases. It also withdraws by osmosis a large amount of fluid from the circulation and thus reduces the intracranial tension. In conscious patients, however, the hypertonic saline acts as an irritant and causes a burning sensation in the rectum which is often unbearable. In such cases we prefer the oral administration of an ounce of a saturated solution of magnesium sulphate.

—concl'd.

Urinary findings	Temperature	Blood chemistry	Blood count	Associated diseases and complications	Result
Sp. gr.—1010. Albumin—present. Bile salts and pig.—present. Fair number of pus cells. Few granular casts.	Normal except for 3 to 4 days in the 3rd week when it went up to 103°F.	23-12-39. Urea—115 mgm. %. N. P. N.—84 mgm. %. Chloride—351 mgm. %. Cholesterol—166 mgm. %. van den Bergh—immediate direct positive. Bilirubin content—20 units, 16-1-40. Urea—78 mgm. %. N. P. N.—42 mgm. %.	Hæmoglobin—75%. Total leucocyte count—8,737 per c.mm. Polymorphonuclear neutrophils—76%. Lymphocytes—20%. Monocytes—2%. Polymorphonuclear eosinophils—2%. In the third week. W. B. C.—10,625 per c.mm. Polymorphonuclear neutrophils—82%. Lymphocytes—14%. Monocytes—4%.	Weil's disease (serum positive, agglutination to classical strain).	Cured, discharged on 22-1-40.
Sp. gr.—1012. Albumin—trace. Bile salts and pig.—present. Occult blood +. Fair number of R. B. C. Fair number of pus cells. Fair number of granular casts.	Subnormal	Urea—245 mgm. %. N. P. N.—144 mgm. %. Cholesterol—180 mgm. %. Chloride—387 mgm. %. Hæmolysis started at 0.48% saline, complete at 0.24% saline.	Hæmoglobin—70%. Total leucocyte count—9,375 per c.mm. Polymorphonuclear neutrophils—86%. Lymphocytes—10%. Monocytes—2%. Polymorphonuclear eosinophils—2%. Reticulocytes—2.5%. Size of R. B. C.—7.4μ.	Weil's disease.	Death 12-1-40.
Sp. gr.—1012. Albumin—0.45%. Pus cells—plenty. Few R. B. C. Few granular casts.	Do.	Urea—135 mgm. %. N. P. N.—85 mgm. %. Cholesterol—150 mgm. %. Chloride—409 mgm. %.	Hæmoglobin—55%. Total leucocyte count—9,718 per c.mm. Polymorphonuclear neutrophils—72%. Lymphocytes—22%. Monocytes—2%. Polymorphonuclear eosinophils—4%.	Chronic nephritis with secondary hypertension, cardiac failure with heart block.	Death 2-3-40.

Elimination of toxins by the skin may be obtained by simple measures such as hot baths, hot packs, hot-air baths (radiant heat) and by the use of mild diaphoretic mixtures. Vigorous measures to promote sweating such as injections of pilocarpine nitras must be avoided in view of their depressant effect on the circulation. Elimination by the kidneys may be attempted by dilution of the blood by the administration of adequate amount of fluid orally, rectally or subcutaneously. Diuresis may be promoted by the administration of glucose, 5 per cent solution in distilled water, which is chosen for the rectal or subcutaneous route, whereas 25 to 50 per cent solution is used for the intravenous route. Intravenous administration of 25 to 50 per cent solution of cane sugar has been advocated for the same purpose. Sodium chloride is to be

avoided because it may produce oedema and oliguria. In cases associated with marked venous congestion and hypertension, withdrawal of 10 to 15 ounces of blood by venesection would reduce the toxic load and relieve the strain on the heart. The application of 6 to 8 leeches over the liver area is also useful for the same purpose. Lumbar puncture is of great value only in presence of signs of raised intracranial pressure, associated with hypertension. Apart from eliminative measures and venesection, the uræmic toxæmia may be reduced by control of the diet which should consist of a liberal amount of fluids such as plain water, barley water, fruit juice and of easily assimilable carbohydrates, e.g., glucose; the protein intake should be strictly limited to an allowance of about 0.6 gm. or even less per kilo. of the body-weight.

Our next attempt should be directed towards the relief of symptoms by appropriate remedies. The nervous symptoms such as restlessness, delirium and insomnia will improve under the administration of sedatives like bromides and chloral hydrate in addition to the eliminative measures. Severe headache and convulsive attacks are definite indications for lumbar puncture and intravenous use of hypertonic glucose solution. Morphine and barbiturate preparations such as luminal have to be used with caution in view of their defective elimination by the kidneys. The danger of their use has, however, been exaggerated. The muscular twitchings and manifestations of tetany, if any, may be controlled by the injection of 5 to 10 c.cm. of 10 per cent calcium gluconate solution. The respiratory symptoms of dyspnoea and periodic breathing may be relieved by the correction of acidosis with the administration of 2 per cent solution of sodium bicarbonate by the intravenous or the rectal route. If possible, sodium bicarbonate may be given by the mouth in doses of half to one drachm four hourly. The hæmorrhagic symptoms may be combated by the use of large doses of vitamin C parenterally and by injections of calcium salts. The results are however disappointing. Last but not least, suitable remedies must be applied for associated complications.

The writers take this opportunity to express their thanks to Colonel J. C. De, M.R.C.P. (Lond.), I.M.S., Superintendent, Medical College Hospital, for permission to use the records. They are also thankful to Dr. Amulya Ratan Roy, M.B., Dr. Ismail Ilias, M.B., and Dr. Md. Ibrahim, M.B., for their ungrudging help in collecting the case records. For the biochemical reports, they are greatly indebted to Capt. P. De, F.R.C.P. (Edin.), Professor of Physiology, Medical College, Calcutta.

## A Mirror of Hospital Practice

### A CASE OF NEUROMYELITIS OPTICA

By S. SHONE, M.D. (Lond.), M.R.C.P. (Lond.)  
CAPTAIN, I.M.S.

*Govt. General Hospital, Madras*

THE following case is considered worthy of record because it presents certain unusual features, even if agreement is reached upon the suggested diagnosis, and because I am unaware of any previous mention of the disease in India.

#### Case history

Karpakam, a female Hindu child of 7 years, was admitted into the Madras General Hospital, under Liéut.-Colonel McRobert, I.M.S., on the 23rd November, 1939. The complaint was blindness and inability to use the lower limbs. There had been no previous illnesses of note, the family history was negative and the dietary habits similar to those of her class, i.e., non-vegetarian.

The child had been attending school six days before admission and had been in perfect health. She suddenly developed blindness and at the same time was unable to use both her legs. She had not been heard to speak since the onset of the illness. There had been no associated headache, fever or other bodily disturbance.

On admission, there was no pyrexia. The patient was found to be a well-nourished child and her physical

functions, as far as the limited scope of the examination demonstrated, were not grossly abnormal. It was difficult to assess whether any form of aphasia really existed, since the attitude was mainly one of negativism.

Acuity of vision was completely lost. The pupils reacted to light and were moderately dilated at rest. The discs showed no gross abnormality: there was a suggestion of blurring of the edges and some degree of hyperæmia was noted.

The other cranial nerves appeared normal.

All forms of sensation were unimpaired.

Power was normal in the upper limbs, but completely lost in the legs. There was no wasting or fibrillation.

The deep reflexes in the arms were present and equal, but the knee and ankle jerks were both absent on the two sides.

The abdominal reflexes were lost.

The visceral reflexes were unimpaired.

Both plantar reflexes were extensor.

Tonic reflexes were absent.

The spine and cranium showed no abnormality or deformity.

Examination of the other systems revealed no deviation from the normal. The urine was without abnormality. The blood picture was not in any way unusual and films showed no parasites. Blood culture was sterile and agglutinations against the typhoid group were negative. Wassermann reaction was negative. No cardiac abnormality.

The cerebro-spinal fluid was clear and under very slight pressure. Cells were 7 per c.cm., protein 30 mg.

per cent, chlorides 650 mg. per cent, sugar 100 mg. per cent, Wassermann reaction negative. Colloidal gold test negative. Culture sterile.

No treatment beyond a hexamine mixture was given. *Progress.*—

29th November. Condition unchanged as regards vision and speech. Ankle jerks normal.

2nd December. Child is able to speak and ask for things. She can just recognize the outline of objects and flinches when threatened with the hand.

12th December. Knee jerks now normal. Plantars still extensor. Now speaks normally and attempts to walk. Can definitely perceive objects but cannot apparently appreciate their colour.

22nd December. All the reflexes are normal and equal. Plantars are still 'undecided'. The child can walk, speak and see normally.

26th December. Plantar reflexes now flexor. Vision apparently quite normal, although no tests with perimeter were possible to establish the existence of any restriction of fields or of scotomata. Patient discharged and parents were admonished to bring the child again, but, so far, they have not done so.

### Discussion

Blindness of absolutely sudden onset is most unusual when occurring in a child, and blindness coupled with paraplegia is even more dramatic. The absence of any associated pyrexia or other evidence of acute inflammatory disease of the central nervous system directed the attention to the possibility of a degenerative or demyelinating lesion. The disease that first came to mind was Schilder's encephalitis, but this was ruled out by the sudden onset of symptoms and, subsequently, by the course of the malady in this case. An allied condition, disseminated sclerosis, was also considered, but this diagnosis was thought to be most improbable, both from the point of view of the age of the patient and the excessive rarity of the disease in this country. Neuromyelitis optica appeared most likely to fit the circumstances and this is the diagnosis suggested.

There are some particulars in which the present case differs from the standard description of the disease. Paraplegia is said to be due to a diffuse spinal lesion and is therefore usually associated with sensory loss and sphincter disturbance, neither of which were present in this case. We must assume that the paraplegia was the result of cortical or subcortical involvement, and that such a disturbance was also responsible for the speech defect.

Complete recovery has, it seems, rarely been recorded. It is regrettable that access to the literature on the subject is somewhat difficult under present conditions, but the disease is now described in most large textbooks and its existence as a clinical entity appears to be definitely established.

### Summary

A case of blindness, paraplegia and speech defect, occurring suddenly in a child of 7 years, is described and a complete recovery is recorded.

The diagnosis of neuromyelitis optica is suggested.

I am indebted to the Superintendent, Madras General Hospital, and to Lieut.-Colonel G. R. McRobert, I.M.S., Physician, Madras General Hospital, for their kind permission to record this case.

## A FEW CASE NOTES ON THE USE OF M. & B. 693 IN PYELITIS AND IN SEPTIC SKIN CONDITIONS\*

By R. K. DE, L.M.F., D.T.M.

Assistant Medical Officer, Talup Tea Estates, Talup, Assam

THE present-day literature is flooded with articles dealing extensively with experiments and clinical applications of M. & B. 693 in all kinds of pneumonia, in meningitis and gonorrhœa. But in such literature as is available to us, we do not find much about its use in skin diseases. We have tried it in a few cases and the result has been remarkable. And its use in 2 cases of pyelitis has also given equally satisfactory results.

### Pyelitis

*Case 1.*—Child, age 2½, was admitted into hospital on 7th August, 1939, with fever and slight bronchitis. Malaria negative. In spite of all treatment the temperature continued for 12 days. The child gradually developed toxæmia and showed signs of pyelitis. After confirming the diagnosis, the child was put on M. & B. 693 as follows:—

13th day	.. ½ tab. × 3
14th day	.. ½ tab. × 2
15th day	.. ½ tab. × 1
16th day	.. ½ tab. × 1
Total	3½ tab., i.e., 1.75 grms.

The temperature fell on 14th day and did not return. The child made uneventful recovery.

*Case 2.*—F., age 28, was admitted into hospital on 14th November, 1939, with fever for 3 days, severe toxæmia and pain over the kidney area. Malaria negative. After urine examination the case was diagnosed as one of pyelitis and was put on M. & B. 693 as follows:—

2nd day	.. 6 tab.
3rd day	.. 4 "
4th day	.. 4 "
5th day	.. 3 "
Total	17 tab., i.e., 85 grms.

The temperature came to normal on 3rd day and did not rise again. The patient made uneventful recovery.

On the 2nd and 3rd day of taking M. & B. 693, the woman vomited frequently and on two occasions she vomited round worms. Taking the vomiting as being due to round worms, M. & B. 693 was not discontinued.

### Umbilical sepsis

*Case 1.*—Child, age 13 days, was admitted into hospital on 18th November, 1939, with umbilical sepsis

\* Read at a Meeting of the Assam Frontier and Budla Beta Medical Society, held at Doom Dooma on 9th March, 1940.

and fever. In spite of all treatment at home the sepsis began to spread. The child was at once put on M. & B. 693 as follows:—

1st day	.. 1/6 tab. × 3
2nd day	.. 1/6 tab. × 2
3rd day	.. 1/6 tab. × 2

Total 1-1/6 tab., i.e., 0.6 grm. approximately.

The temperature fell on 2nd day and the umbilicus completely healed up in 6 days, when the child was discharged from hospital.

*Case 2.*—Child, age 26 days, was admitted into hospital on 6th December, 1939, with umbilical sepsis which was resistant to treatment for a long time. The sepsis was a localized one. M. & B. 693 was given as follows:—

1st day	.. 1/4 tab. × 2
2nd day	.. 1/4 tab. × 2
3rd day	.. 1/4 tab. × 2
Total	1 1/2 tab., i.e., 0.75 grm.

The umbilicus healed up and the child was discharged on 6th day.

### *Impetigo*

*Case 1.*—Child, age 1 month, was admitted into hospital on 1st May, 1939, with impetiginous sores on scalp. Local treatment for a considerable period not being satisfactory the child was put on M. & B. 693 as follows:—

1st day	.. 1/4 tab. × 3
2nd day	.. 1/4 tab. × 2
3rd day	.. 1/4 tab. × 2
4th day	.. 1/4 tab. × 2
Total	2 1/2 tab., i.e., 1.25 grms.

The sores healed up rapidly and the child was discharged on 6th day of admission.

*Case 2.*—Child, age 8 months, had impetigo on the head. In spite of local treatment at home for several days, the sores continued spreading, the neck glands got swollen and inflamed and the child was running a temperature. Pus showed staphylococci. The child was admitted into hospital on 30th June, 1939, and was put on M. & B. 693 as follows:—

1st day	.. 1/2 tab. × 2
2nd day	.. 1/2 tab. × 2
3rd day	.. 1/2 tab. × 2
4th day	.. 1/2 tab. × 2
Total	4 tab., i.e., 2 grms.

Temperature became normal after 48 hours, sores healed up rapidly, and swelling of glands also subsided fairly quickly. The child was discharged on 9th day.

*Case 3.*—Girl, age 10 years, had impetigo on face. Ordinary local treatment not being satisfactory after a few days' trial, she was admitted into hospital on 27th November, 1939, and was put on M. & B. 693 as follows:—

1st day	.. 2 tab.
2nd day	.. 1 1/2 tab.
3rd day	.. 1 1/2 tab.
4th day	.. 1 tab.
Total	6 tab., i.e., 3 grms.

All the sores healed up rapidly and she was discharged on 5th day.

### *Dermatitis*

*Case 1.*—Woman, age 40 years, was admitted into hospital on 7th June, 1939, with acute dermatitis on the whole of the dorsum of the left foot. The oozing showed staphylococci. The part was being dressed with lotio acriflavine 1 in 1,000, after cleaning with normal saline. But the infection continued spreading and she was running irregular low temperature. Hence from the 9th day she was put on M. & B. 693 as follows:—

9th day	.. 6 tab.
10th day	.. 6 tab.
11th day	.. 6 tab.
12th day	.. 3 tab.

Total 21 tab., i.e., 10.5 grms.

The temperature became normal from the 2nd day, the part healed up rapidly and she was discharged on the 20th day after admission.

She was fit for discharge on the 15th day, i.e., 7 days after beginning treatment but was kept longer because she looked depressed and also we intended to observe whether the condition recurred or not; but it did not do so.

*Case 2.*—Child, age 5 months, was admitted into hospital on 2nd January, 1940, with extensive dermatitis on face, ears and neck. Pus showed staphylococci.

*History.*—Other children were playing with *Bhilawa* fruit. (Marking nut, *Bhela*.) Its juice fell on the face of the child making a few sores. Afterwards from the oozing of the sores, the surrounding parts became inflamed and the condition spread over the face, ears and neck. The possible explanation is that the original sores got infected with staphylococci which, in turn, set up extensive dermatitis. The front of the neck was worst affected.

The child was at once put on M. & B. 693 as follows:—

1st day	.. 3/4 tab. × 2
2nd day	.. 1/4 tab. × 3
3rd day	.. 1/4 tab. × 3
4th day	.. 1/4 tab. × 2
Total	2 1/2 tab., i.e., 1.25 grms.

The condition healed up rapidly and the case was discharged from hospital on 7th day.

By local treatment as mentioned in skin cases, I mean the application of one of the following generally, according to the case:—

(1) Lotio acriflavine 1 in 1,000.

(2) Unguentum hydrag. ammoniata.

(3) A lotion containing zinc sulphate grs. 6 and copper sulphate gr. 4 to an ounce.

In all cases the local treatment was continued while M. & B. 693 was being given.

As regards dosage we have always used it in smaller doses than that recommended by the makers, for pneumonia.

Points of interest:—

(1) the rapid control of temperature and toxæmia in pyelitis,

(2) the rapid healing up of skin conditions, none requiring more than 7 days.

My thanks are due to Dr. H. L. Slaughter for his guidance and for permission to read these case notes.

## CONSTIPATED CHILD

Agarol simplifies the treatment of constipation by making it pleasant; children not only take Agarol with the greatest of ease but actually enjoy it.

This palatable emulsion of mineral oil and agar-agar with phenolphthalein is the ideal treatment for constipation in children. It is gentle in action and furnishes the natural stimulus to a comfortable and normal peristalsis. Its capacity for lubricating the bowel, softening the faecal mass and easing its passage to the rectum and final expulsion, is unsurpassed.

Further advantages of Agarol are that it is not habit-forming and, by mixing freely with the intestinal contents, it makes the occurrence of seepage extremely improbable.

more difficult because this side of drug manufacture needs large and expensively equipped laboratories and staffs of highly trained chemists and technicians. None of these things are beyond the power of India to furnish, as chemistry and physical science appear to have a special attraction to Indian scientists, and there are even now many chemists of high standing in this country, when the openings for employment with pay commensurate with their abilities are few. Should the prospects of this type of work improve no lack of suitable workers need be anticipated. India also has financiers and business men of imagination ready to put money into any industrial enterprise if a reasonable profit from their investments may be looked for.

The manufacture of drugs alone is not the only requirement, but it is even more important that the drugs made shall be up to the required standard and free from adulteration. Now that the war has forced upon us at short notice the urgency of an adequate supply of drugs to India it is all the more regrettable that Government was so slow to act on the findings of the Drugs Inquiry Committee's report, which, as long ago as 1931, showed the position of drug supply and manufacture in this country to be far from satisfactory. Nevertheless they did move eventually and made a beginning by the initiation of a Biochemical Standardization Laboratory in 1938; this is now busily engaged

testing medicinal substances on sale in India, and has already produced important results. This work is of the greatest value and will become of steadily growing importance as the manufacture of drugs and biological products in India increases, by forcing manufacturers to keep their products up to the necessary standard. This will eventually lead to it being greatly increased beyond its present small staff and strictly limited laboratory accommodation.

The present time appears to us as most opportune for pushing forward in India the manufacture of all kinds of heavy chemicals and their derivatives, the fine chemotherapeutic substances used so largely in present-day medicine, because there is the certainty that overseas supplies will be much restricted, if not altogether cut off for a time. This will mean that local drug manufactures can begin with relatively little competition from outside, a condition which will give them every opportunity of becoming firmly established. Then when the world returns to normal and international trade is freely resumed they will be able to withstand the competition from overseas, provided a reasonable protective tariff against foreign drugs is imposed; and if they have laid their foundations well they might even hope to capture a valuable export trade before the countries disrupted by war are again producing to full capacity.

### REPORT OF AN ENDOCRINE CLINIC

By W. C. SPACKMAN, F.R.C.S.E., F.R.C.O.G.  
LIEUTENANT-COLONEL, I.M.S.

*Professor of Midwifery and Gynaecology, Grant Medical College, Bombay*

*(From the Bai Motlibai and Petit Hospitals, Bombay)*

#### I. Introduction

THROUGH the kindness of a number of firms which manufacture endocrine products (B.D.H., Boots, Ciba, Glaxo, Organon, Parke Davis, Schering), it was possible to open an endocrine clinic at these hospitals in February 1939. The clinic has now been working for just over a year and it is thought that a review of its work and some indication of its results may be of interest.

#### *Selection of cases*

Although there are many indications for endocrine therapy in the female, it is obviously useless to adopt a policy of widespread and almost uncontrolled administration, like giving a dose of an aperient or aspirin to the casual patient. Hormone preparations are very expensive and I consider manufacturers are not justified in giving even small amounts broadcast

as they do at present, to all and sundry, regardless of the proper selection of cases and control of treatment. One presumes that from the manufacturer's angle their best chance of increasing their sales is to accustom the average medical practitioner to the use of their particular product but the method has practically no scientific justification.

We have in our clinic made a very careful selection of cases treated and have controlled the administration by observation of results as long as possible. All cases are put on a special endocrine register under the executive charge of an individual member of the medical staff, and no patient is accepted unless (a) her case is considered entirely suitable for endocrine therapy and (b) she undertakes not to abandon treatment prematurely and irresponsibly. In spite of these precautions a number of cases have withdrawn themselves from our control before being discharged by us.

#### II. Hormones

The hormones used are as follows:—

1. Anterior pituitary hormones and other gonadotrophic substances.
  - (a) Follicle-maturing hormone ('prolan A').
  - (b) Luteinizing hormone ('prolan B').

(c) Lactogenic hormone, prolactin ('physolactin').

(d) Thyrotrophic hormone.

## 2. Ovarian hormones.

(a) Oestrogens.

(i) Natural.

(ii) Synthetic—Stilbœstrol.

(b) —Progesterone.

A few words on each of these is called for, indicating its source, its various forms, modes of administration, action and therapeutic uses.

The follicle-maturing hormone (prolan A) is derived from the serum of pregnant mares (gestyl, serogan, antostab). It is a complex substance, put up in dry form and administered after solution. Given intramuscularly it causes ripening of the graafian follicles; given intravenously it is said to cause their rupture if given near the date of ovulation. It is used for both these purposes, but it is not to be given where the ovary is above normal size otherwise it may cause the development of a cystic ovary by excessive ripening of follicles. In theory it is a most valuable product but its use must be carefully and intelligently controlled. We have used it with apparent success in cases of functional amenorrhœa, as detailed later in this paper.

Luteinizing hormone (prolan B) is derived principally from the urine of pregnant women. It is put up in liquid form (antuitrin-S) and as a powder for solution (gonan, pregnyl, prolan). It is administered by injection. It causes luteinization of the graafian follicle after the latter has ruptured, and in consequence the development of progestational changes in the proliferated endometrium.

Prolan A and prolan B therefore act primarily on the ovary.

Lactogenic hormone is prepared by a special process from the anterior pituitary and is put up in liquid form (physolactin). It is administered by injection. It increases mammary secretion and is given for this purpose.

Thyrotrophic hormone is also prepared from the anterior pituitary. It is put up as a powder (ambinon) for administration with or without prolan B by injection. It activates the thyroid and ovary and is used, for example, in fat women with amenorrhœa or hypomenorrhœa.

Oestrone is the follicular hormone of the ovary, which is also made by the placenta and occurs widely distributed in other tissues. It is made commercially from the urine of pregnant mares in which it is found in large amounts especially from the 4th to the 6th month. It is used plain (œstrone) or after esterification by which its action is intensified and prolonged (œstradiol benzoate and œstradiol dipropionate). It can be administered (a) orally as œstrone, (b) by injection in aqueous or more commonly in oily solution after esterification, (c) by injection, (d) by surface application in spirit solution, (e) by vaginal tablets or

pessaries, and (f) by implantation subcutaneously of pure œstrone tablets. It is placed on the market under about a dozen different trade names.

Stilbœstrol is a synthetic œstrogen. Although possessed of powerful œstrogenic action it is not at all closely related chemically to œstrone. It is used orally or by injection of the dipropionate for the same purposes as œstrone.

It may be expected that as a result of further experimental work other similar products will be introduced which will possess similar œstrogenic action and that such action may be in certain products specialized in certain directions so as to make a variety of artificial œstrogens available for treating a variety of clinical conditions at present treated uniformly with œstrone.

*Action and uses of œstrone and stilbœstrol.*—They produce :—

1. Enlargement of the under-developed uterus and mammary gland;
2. Proliferation of the endometrium and its glands;
3. Hyperœmia and proliferative thickening of the vaginal stratified squamous epithelium;
4. Depression in the activity of the anterior pituitary;
5. Sensitization of the uterine musculature to the action of pituitrin;

They have no direct action on the ovary.

Their uses are very numerous and include :—

1. Treatment of hypoplasia of the uterus;
2. Treatment of amenorrhœa, usually in combination with progesterone;
3. Treatment of cases of dysmenorrhœa due to hypoplastic (under-developed) uterus;
4. Treatment of senile vaginitis and kraurosis vulvæ;
5. Treatment of menopausal symptoms;
6. Treatment of missed abortion—not very practical as very large doses are required;
7. Treatment of uterine inertia and in the induction of labour;
8. Treatment of epimenorrhœa and of some cases of metropathia hæmorrhagica by inhibiting the action of the anterior pituitary and so delaying ovulation and subsequent menstruation;
9. Diminution and suppression of lactation, again by inhibition of the pituitary (prevention of its secretion of prolactin);
10. Promotion of the general metabolism of premature babies.

Progesterone is obtained from the corpus luteum of the ovary (usually of whales) but nowadays it is mostly prepared synthetically, as its chemical composition is known. It is administered by injection in oily solution, but recently a modification has been prepared which is active orally ('progestoral', and lutoeyelin oral).

Its action chiefly is :—

1. To produce progestational (secretory) activity in the endometrium after the latter has proliferated under the action of œstrone;
2. To favour therefore the embedding of the fertilized ovum;
3. To maintain a good decidua in pregnancy;
4. To prevent the premature action of pituitrin on the uterine muscle in pregnancy by antagonizing œstrone.

It is therefore used :—

1. In the treatment of amenorrhœa after a course of œstrone;
2. In the treatment of sterility, repeated and threatened abortion and to prevent premature labour;
3. To prevent 'after-pains';
4. In the treatment of functional menorrhagia by turning an unhealthily proliferated endometrium into a secretory one.

Although I have listed these different hormones as if they all had a separate and specific action, the functioning of the various endocrine glands is very closely interconnected, so that in nature the body is acted upon by a combination of the products of these glands in ever-varying amounts and usually with a species of rhythm. In healthy individuals these rhythms remain almost undisturbed; but in pathological conditions we are often very uncertain as to the exact ratio of disturbance of the various component hormones and therefore we may find it extremely difficult to correct the clinical picture. It is not merely a case of a gland secreting an excess or a deficiency of its own particular hormone but of the alterations in secretion thereby induced in other glands. Moreover, each gland may secrete, possibly, some modification of its own hormone, producing thereby effects not attributable merely to an excess or deficiency of its hormone (examples, Graves' disease, and acromegaly).

In this connection much experimental work is being done in the use of hormones from the testes and the adrenals and although at present the indications for using these hormones in a female endocrine clinic are not well defined, in some cases definite therapeutic effects have been produced by them where the apparently correct female hormone has been ineffective.

### III. *Classes of cases suitable for treatment and scheme of treatment planned*

#### *Disorders of menstruation*

*Amenorrhœa, primary.*—The most suitable cases are those of persons under 20 where moderate hypoplasia of the uterus and ovaries is present, which in fact might be considered as 'delayed onset of menstruation'.

#### *Diagnosis by biopsy*

An initial biopsy of the endometrium is undertaken to see whether a healthy endometrium is present and in what phase of development it is. In some cases a tuberculous endometritis is found and such cases are unsuitable for endocrine treatment.

*Endometrial biopsy* (E. B.) is so important a guide in our clinic that a few words on it are desirable\*.

We use either the Sharman or the suction type of biopsy curette. No anæsthetic is necessary with either, the specimens can be taken in the out-patient department and should be from the fundus if possible. They are placed at once in formalin saline. The best time to take them is just before menstruation is due or during the first few hours of the flow, because it is essential to find out whether the endometrium has reached the necessary secretory phase. A good secretory type of endometrium indicates a normally ovulating ovary and good uterine co-operation. The secretory phase is only developed from the proliferative phase in the last week, and the nearer we can run to the last day or hour the better.

Women can 'menstruate' without ovulation and we can produce the secretory phase followed by menstruation by hormone administration (œstrone followed by progesterone) but the normal source of these hormones is from the graafian follicle and its subsequent corpus luteum. It may be considered that there was no value in inducing menstruation of this type without ovarian co-operation simply by the use of ovarian hormones, but it is sometimes found, for reasons probably connected with the interaction and interrelation of the endocrine glands previously referred to, that the rhythm of menstruation is spontaneously re-established if it has been artificially produced two or three times. This may be presumed to be the result of rhythmic effects produced on the pituitary by the ovarian hormone, for we know that just as the anterior pituitary activates and controls the ovary so modifications of the ovarian hormones circulating in the blood are capable of modifying and of suppressing certain actions of the pituitary.

A much more natural process of producing menstruation is to aim at activating the ovary itself by the use of the hormones prolan A and prolan B secreted by the pituitary for this purpose, and it is probable that with prolan A and prolan B, modified perhaps as a result of further experimentation, we may cause a direct action on the ovary for the ripening and rupture of the graafian follicles and hence the consequent proliferative and secretory changes in the endometrium. It will be seen that we have attempted this method of producing menstruation apparently with success in one or two of our cases.

*Amenorrhœa, secondary,* can be similarly treated. Thyroid may need to be combined, or thyrotrophic hormone, in cases where hypothyroidism is a component.

To induce menstruation with hormones we give œstrone for a fortnight in full doses (but usually avoid the dipropionate whose action is too prolonged), and progesterone in the fourth week. We have had successes with prolan A (gestyl and serogan) giving it in daily doses for 3 days and expecting a period about 15 to

\* I am greatly indebted to Dr. P. V. Gharpurê, M.B. (Bom.), Professor of Pathology, Grant Medical College, for personally undertaking the examination of all our biopsy specimens and much of our work has been guided by his reports.

20 days later. We usually combine its administration with the simultaneous use of an oestrogen and it is possible that any success achieved is due to the latter rather than the former\*.

### *Epimenorrhœa*

Where the periods occur at too short intervals (this is much more often claimed to be so by patients than found by definite clinical observation) we try to delay the stimulus from the anterior pituitary, which causes the ovary to ovulate, by administering an excess of œstrone in the week following menstruation in order temporarily to inhibit the action of the anterior pituitary. The dipropionate should be used and appropriate doses are 5 mgm. daily for 5 days.

### *Menorrhagia*

Only functional menorrhagias are suitable for endocrine treatment and it must be established that a proliferated endometrium is present if any effect is to be expected from the use of progesterone or prolan B. In any case progesterone has to be used in very large doses in most cases and results are disappointing with both. It appears usually better to remove the irregularly hypertrophied and often cystic endometrium by curettage, and to try with œstrone followed by progesterone and prolan B to obtain a better type of endometrium. Some cases respond to large doses of œstrone and others to 'testosterone' or 'percorten' but results are by no means constant and failures are frequent. Such cases are usually much more safely treated by a hysterectomy if occurring near the menopause, or by partial oophorectomy if in young adults since they always show ovaries containing atretic enlarged follicles.

### *Dysmenorrhœa*

Where the uterus is hypoplastic, treatment with œstrone is indicated, and cases with a uterus of normal size may respond to progesterone. The latter is also very effective for relieving 'after-pains'.

*Menopausal syndrome*, including vaginitis, osteo-arthritis of middle age and pituitary headaches. These can be generally relieved by œstrone. Many of the symptoms, e.g., flushing, depression, sleeplessness can be almost entirely eliminated in most cases, and the treatment gives excellent results in senile vaginitis. Estradiol dipropionate or stilbœstrol is suitable for injection, and œstrone is one of its commercial forms, or stilbœstrol by mouth. The last named should not be given in doses over 1 mgm. twice a day and smaller doses are sometimes sufficient. We have used implantation of special compressed tablets of œstrone (kindly supplied by Organon) for menopausal cases and believe the method is of considerable value as

giving with one treatment, scarcely more severe than a hypodermic injection, a uniform absorption of œstrone lasting probably for several months. We have tried Kolpon tablets, which contain œstrone, but have found that some of our patients did not like them.

*Sterility*.—Assistance in treatment of functional sterility may be afforded by administration of œstrone, followed by progesterone or prolan B to promote the formation of a good endometrium and secure the embedding of the fertilized ovum in a well-developed progestational phase.

*Repeated abortion*.—The use of prolan B and of progesterone in the early weeks is well known and of proved value in preventing abortion. It may be combined with oral administration of vitamin E.

### *Disorders of lactation*

Painful engorged breasts can be relieved by giving œstrone in medium and repeated doses, and lactation can be entirely suppressed by the use of larger doses. We have also relieved conditions of chronic painful mastitis with testosterone.

Deficient lactation can be successfully stimulated by 'physolactin' but it would appear that the psychological co-operation of the patient is necessary if the good effect is to be maintained; this is not always forthcoming. The injections are continued in diminishing doses for several days. The effect is not impressive and begins within 24 hours, the injections occasionally are rather painful.

### *IV. Results of treatment obtained*

*Amenorrhœa, primary*.—Five cases were admitted for treatment and four received treatment, their ages being 18, 18, 17 and 15. Two were treated with œstrone and two with œstrone and prolan A; all responded to treatment and began to menstruate regularly.

*Example 1*.—Patient aged 18, moderate hypoplasia of the uterus and ovaries. E. B.: endometrium in resting phase. Treatment for two months with œstrone and prolan A resulted in six regular periods.

*Example 2*.—Patient aged 17, moderate hypoplasia of uterus and ovaries. E. B.: atrophic endometrium. Treatment: œstrone by injection and implantation of a tablet of œstrone, and with prolan A. Result: two regular periods.

*Amenorrhœa, secondary*.—Thirteen cases were admitted for treatment and ten received treatment; their ages being 35, 28, 27, 25, 21, 20, 20, 18, 18, 18.

Five obtained menstruation under treatment; Three did not obtain menstruation under treatment;

One result doubtful ('spotting');

One did not report following treatment.

*Example 1*.—Æt. 27. Amenorrhœa four years, following dilatation and curettage two or three times for irregular periods. Had part of an ovary implanted in 1936, no effect. E. B.: no endometrium obtained. Full treatment for several months with œstrone and prolan A. E. B.: still no endometrium. Endometrium was then grafted into her uterus from another patient,

\* These hormones will not produce abortion in any dosage, and I am not referring to the amenorrhœa of pregnancy.

but it was found that there was an old chronic salpingitis. No effect, treatment failed. This case illustrates the danger of promiscuous and probably vigorous curettage. I believe the lining of the uterus was entirely destroyed and replaced by scar tissue in this case and perhaps a salpingitis was induced in addition.

*Example 2.*—*Æt.* 25. Very fat. Amenorrhœa eight months. (Four sisters suffer similarly.) E. B.: early proliferation. Treatment with œstrone and prolan A and thyroid. No period obtained.

*Example 3.*—*Æt.* 21. Two and a half years' amenorrhœa. E. B.: endometrium, atrophic. Implantation of œstrone tablets  $2 \times 25$  mgm. on 11th October, 1939. Prolan A (gestyl) on 9th, 11th, and 13th December, œstradiol dipropionate  $4 \times 5$  mgm. with three doses of gestyl in January. E. B.: 24th January showed numerous glands with secretory changes. Menstruation two days later. Similar treatment in February gave another period. Continuing treatment.

*Example 4.*—*Æt.* 18. Eight months amenorrhœa, uterus hypoplastic. Fifty mgm. œstrone tablet implanted. No other treatment. Began to menstruate again two months later. Had one period then became pregnant and is now four and a half months' pregnant.

In some cases of secondary amenorrhœa one finds a small corpus luteum cyst on an ovary and its removal cures the condition.

*Oligomenorrhœa.*—Five cases were treated. Three, results doubtful; two satisfactory.

*Example 1.*—K. H., *æt.* 20, unmarried. Periods 3/60—90, scanty flow. E. B.: proliferative. L. P.: on 4th December. Treatment with prolan A (serogan) on 12th, 13th, and 14th January. Period on 4th February for four days. Treatment with prolan A (serogan) on 14th, 15th and 16th February—period on 3rd March for five days.

*Example 2.*—*Æt.* 25, one child, periods 1/30; getting stouter. Treatment with 'ambinon' (prolan B + thyrotrophic hormone) gave 3/30 periods and some loss of weight.

*Menorrhagia and metropathia hæmorrhagia.*—Five cases treated, one with slight improvement. One case turned out to be ectopic gestation.

*Example.*—K. H., *æt.* 16. Uterus normal. Bleeding for a month. Treated with prolan B and progesterone daily for 12 days. No effect. Dilatation and curettage gave immediate relief.

It appears that such cases should be immediately curetted provided the endometrium is found to be thick and hypertrophied, and subsequently rhythmically treated with appropriate hormones. If the ovaries are full of small cysts, they can either be resected or punctured very simply by posterior colpotomy. It appears to be rarely worth while giving treatment only with progesterone or prolan B or any other hormone, though some cases respond to such methods, but failures are very common even with very large dosage.

*Dysmenorrhœa.*—One case; hypoplastic uterus. Treatment for three months with œstrogens. E. B.: on 2nd August and 20th October, 1939, showed improvement in proliferative activity. Dysmenorrhœa was also much less. Discontinued treatment.

*Sterility.*—Four cases. Treatment designed to improve character of endometrium. Results uncertain.

*Vaginitis.*—Three cases, *æt.* 23, 22 and 19. All treated with œstrone. One with sulphanilamide. Results in all cases good.

*Senile vaginitis and pruritus.*—Seven cases, *æt.* 70, 54, 45, 45, 41, 39 and 37. Three did not keep in touch. Four markedly improved. Treatment given: œstrone by injection, implantation and inunction. Results very satisfactory. In two cases colporrhaphy was combined with the hormone treatment.

*Example 1.*—Patient *æt.* 54, complaining of acute itching leucorrhœa for the last ten years, much worse lately. Four children and five abortions. Menopause 12 years ago; mucous membrane of the vagina thin, pale and stippled. A thin discharge, containing many pus cells, few epithelial cells and no Doderlein bacilli. Rapid improvement with disappearance of symptoms. The patient refused colporrhaphy and will probably relapse as she has discontinued treatment.

*Example 2.*—*Æt.* 37. Menses still present but scanty and infrequent. Much pruritus and typical atrophic vaginal mucous membrane. Treatment with stilbœstrol and implantation of œstrone tablet for two months. Result: cured.

*Menopause.*—Four patients. Two natural menopause, *æt.* 43 and 40; two post-operative, *æt.* 33 and 30. All treated with œstrone or stilbœstrol. Two by implantation and injections and two by injections only.

*Example 1.*—*Æt.* 43; very depressed and neurotic. No improvement in mental condition but marked improvement in vaginitis.

*Example 2.*—*Æt.* 40; flushes, depression, headaches—all markedly improved by injections and oral treatment (stilbœstrol).

*Example 3.*—*Æt.* 33; bilateral oophorectomy. Flushes ++. Symptoms entirely relieved.

*Example 4.*—*Æt.* 30; bilateral oophorectomy and prophylactic implantation of œstrone tablet; menopausal symptoms did not develop.

*Genital hypoplasia.*—One case *æt.* 20, treated with œstrone. Result?

*Habitual abortion.*—Four cases: two did not continue treatment; two treatment successful.

*Example 1.*—History of three abortions, no full-term pregnancy. Two months' pregnant, put under treatment until end of 4th month with progesterone and delivered of a full-term living child.

*Example 2.*—Three full-term normal deliveries followed by four spontaneous abortions, then one full-term normal delivery whilst under treatment with progesterone in 1938. Another abortion in 1939, no treatment; later in 1939, came at three months with slight bleeding. Treated with *progestoral* 5 mgm. daily for eight days and then on alternate days for two months. Delivered of a living child at full-term.

*Hyperemesis gravidarum.*—Three cases, treated with *progestoral* and luto-cyclin oral. Two reported marked improvement, one uncertain.

#### *Infantile debility and prematurity*

For this experiment 12 sets of twins were taken and the smaller of each pair was given œstrone orally every day in doses up to 100 units three times a day. There was no indication whatever of any beneficial effect.

*Deficient lactation.*—Seven cases. Five treated within first ten days of delivery; two successful; two temporary success; one failure. Two treated at about 3rd month of lactation owing to failing activity of breasts; both successful.

*Example 1.*—*Et.* 27, delivered by Cæsarean section on 23rd August, 1939; very scanty secretion; Physolactin on 2nd, 4th, 5th, 6th and 7th September. Result slight improvement; case recorded as a failure.

*Example 2.*—*Et.* 31; delivered 12th August, 1939. No activity at all in breasts on 5th day; Physolactin on 16th, 17th, 18th, 19th, and 20th August. Gave copious secretion which continued fully adequate for some weeks.

*Example 3.*—*Et.* 35; diabetic. Delivered by Cæsarean section. No secretion on 5th day; Physolactin resulted in good secretion but the patient appeared to favour bottle-feeding and her milk soon failed.

*Example 4.*—*Et.* 31. Japanese. Very insufficient milk during 4th month of lactation. Patient anxious to continue lactation as she was shortly returning by steamer to Japan. Physolactin gave fully adequate supply for large vigorous child well maintained into the 7th month; still continuing.

*Excessive secretion.*—Patient *act.* 32 with excessive milk supply established two days after delivery. The supply was diminished successfully by injections of stilbæstrol dipropionate 1 mgm. twice a day for four days. Later the milk supply again became excessive and was again reduced by similar means.

#### V. Summary and conclusions

I would like to emphasize that in considering our patients in an endocrine clinic we must not

lose sight of the fact that in all cases great importance must be attributed to questions of diet and general hygiene of healthy living, as well as to the correction of anæmia and any other adverse symptoms discovered. It is certain that many cases at first thought to be suitable for endocrine therapy, can receive far more benefit if the hormone administration is combined with suitable general treatment, in fact in many cases all that may be needed is the latter.

In the following summary I have not tabulated the list of conditions which can theoretically be benefited by endocrines but those in which such treatment has appeared to us usually to be worth trying. I have therefore excluded conditions such as the functional hæmorrhages, the 'metropathias' and functional menorrhagias where the results seem to be bad even with such enormous doses of endocrines that very few patients could dream of undertaking them in view of expense alone.

Biopsy control is necessary in the amenorrhœa and sterility cases, and vaginal smear in all types of vaginitis.

#### Summary

Condition	Scheme of endocrine therapy	Summary of our results
<i>Gynæcological</i>		
Primary amenorrhœa with genital hypoplasia.	Small repeated doses of œstrogens with short intermittent courses of gonadotrophic hormones <i>e.g.</i> , for the former 1 mgm. of dipropionate of œstradiol twice a week, and three doses of follicle-ripening hormone at one-day intervals once a month. The latter not to be repeated more than twice without re-examination and biopsy.  The œstrogen may be stopped and progesterone given in three doses of 2 mgm. each on alternate days. Ten days after the follicle-ripening hormone and menstruation expected at the conclusion of this.	Favourable.
Secondary amenorrhœa and oligomenorrhœa.	Follicle-ripening and luteinizing hormones (plus thyroid if indicated).	Favourable in absence of organic disease.
Sterility .. ..	As for primary amenorrhœa but control by biopsy is absolutely essential. (All other usual methods of investigation and treatment to be adopted as required.)	
Epimenorrhœa .. ..	Four or five doses of 5 mgm. each of dipropionate in the week immediately following the period.	Favourable, but the period may be considerably delayed so that the patient thinks she is pregnant.
Menorrhagia .. ..	Heavy doses of luteinizing hormone and/or progesterone.	Unsuccessful; we do not recommend endocrine treatment at present for functional bleeding.
Dysmenorrhœa— (i) With genital hypoplasia	Small repeated doses of œstradiol dipropionate throughout the month, not sufficient to inhibit the pituitary, continued for several months.	Appears to help in properly selected cases.
(ii) With normal-sized uterus	Progesterone at time of periods.	

*Summary—concl.*

Condition	Scheme of endocrine therapy	Summary of our results
<i>Gynaecological—concl.</i>		
Senile vaginitis ..	Œstrogens in full doses by all usual modes of administration. If stilboestrol is used, begin with 1 mgm. per day as patients are not always tolerant of it.	Very helpful.
Menopause ..		
Pruritus vulvæ ..		
<i>Obstetrical</i>		
Threatened abortion ..	Progesterone in full doses, followed with smaller continued doses. Luteinizing hormone may be added in first three months.	Worth trying where symptoms are not hopeless.
Repeated abortion ..	Luteinizing hormone and progesterone in moderate doses right up to 7th or 8th month. Progesterone or lutoecyclin oral may be substituted for injections. Two milligrams by the mouth equal one by injection.	Good.
Hyperemesis gravidarum ..	Progesterone or lutoecyclin oral (some advise œstrogens but we have not found them helpful).	Appeared helpful in several cases.
Infantile debility ..	Œstrogens	No success.
Uterine inertia ..	Œstrogens in large doses	No apparent success, but it is theoretically useful.
Deficient lactation ..	Physolactin 5, 5, 2, 2, and 1.0 c.cm. on successive days.	Results most encouraging.
Excessive lactation ..	Œstrogens	Results most encouraging.
After-pains ..	Progesterone	Very effective.

## AGAINST ORTHODOXIES IN SYMBOLISM, MICROMETHODS AND MICROMATHEMATICS

By S. D. S. GREVAL  
 LIEUTENANT-COLONEL, I.M.S.  
*Imperial Serologist, Calcutta*

### I. SYMBOLISM

'LET T represent the dominant character tall and t the recessive character dwarf' says almost every author (latest available example Ride, 1938) yearning to impart the necessary Mendelian knowledge to the would-be genetician or even to the humble seeker after truth in respect of the incidence of blood groups and its application to the disputed paternity or maternity of an offspring. Let nothing of the kind be done. If T represents the dominant character Tall, d should represent the recessive character dwarf. For exactly the same reason if Y represents the dominant character Yellow, g should represent the recessive character green. There is no particular merit in being cryptic and using a code when plain language will do and in fact do better. Decoding and following the formation of new combinations at the same time is irksome to say the least.

Further, it has been known for many years that the dominance and the recessiveness of characters are conditioned by the environment. Supposing by a change in environment tallness became recessive and dwarfness became dominant, how would the characters be

represented then, and how would anybody understand what had happened?

Nothing but unnecessary crypticism is responsible for representing the dominant Red eye of the female fruit fly (*Drosophila melanogaster*) by W.

Segregation of contrasting characters and production of the dominant form in the offspring is as easy to follow as deciding who won a trick in a game of cards, provided the crypticism is kept out. Thomson (1934), an eminent biologist of a bygone age, decided to discard it in his latest publication. It should be discarded by everybody. It is a wilfully introduced embarrassment in the consciousness.

### II. MICROMETHODS

#### 1. Estimation of the life of a red corpuscle

This was done by an estimation of bilirubin supposed to be formed in a given time. The estimate gave the life of the human corpuscle as 30 to 40 days (Evans, 1925). The actual life of a transfused corpuscle of the same group but not of the same type as the recipient's red blood cells, detected by immunological means, extends over 100 days (Levine, 1935). It is reasonable to suppose that when the donor and the recipient belong to the same group and the same type the life of the transfused corpuscle is prolonged further. The life of a subject's own corpuscles must be longer still. It must be more like 365 days than 30 to 40 days.

The group specific substances in the red blood cells are the isohæmagglutinogens A and B while

the type specific substances are the hæmagglutinogens M and N (for details see Greval, Chandra and Woodhead, 1939; Greval and Chandra, 1939).

The estimate of 30 to 40 days was a very bad estimate indeed.

## 2. Minute mathematical calculations

One of the pieces of evidence regarded as most incriminating to Sacco, in the Sacco and Vanzetti case of U. S. A. notoriety (Kamath, 1938), was that of a gun expert who proved by 'minute mathematical calculations' that the marks in the bore of Sacco's gun were made by the bullet which killed the murdered man. Later another man called Milazzo was accused in Cleveland (Ohio) of having shot someone else. The same gun expert again demonstrated that the shot was fired from Milazzo's gun. Fortunately, the maker of the gun was able to prove that it had not been sold until a month after the murder! But Sacco and Vanzetti had by that time been executed.

The original American description is not available. The usual method is to look for marks made on the bullet by the barrel, not to look for marks made on the barrel by the bullet. No two barrels being exactly alike, a 'gun print' comparable to a finger print is left on the bullet. The fact, however, remains that, at least in the second case, the gun expert, going by 'minute mathematical calculations', made a mistake. But for the ordinary evidence the expert's evidence would have led to a miscarriage of justice. It is as likely as not that his evidence did lead to a miscarriage of justice in the first case.

In *Rex v. Ruxton* case (Manchester Assizes, March 1936) Brash's evidence (Smith, 1938; Glaister, 1938; Blundell and Wilson, 1937) on the identification of the skulls presumed to be of the missing women was a distinct advance in forensic medicine. Photographs of the skulls when superimposed on life-size photographs of the heads of the two women showed a remarkable degree of fitting in each case. Yet Brash was careful to point out that this did not imply positive identity but only indicated that the skulls could belong to the missing persons. Such should be the attitude towards evidence which is based on items of minute dimensions or is not exclusive enough.

Positive evidence on handwriting cannot be superior to Brash's evidence. Negative evidence has been known to deceive experts. A student's handwriting obtained as a sample, when he was in custody, did not correspond to the writing on an incriminating document. Earlier in custody he had made an application to sit for the examination for which he had been studying. This was granted. The writing on the application, the answer papers and the incriminating document was identical (Lucas, 1935). In about a month's time he had practised and perfected a disguised hand.

The detection of forgery, incidentally, is a different and usually an easy matter. As a rule the fingers of the forger move with hesitation, which is apparent on enlarging the writing and comparing it with the enlarged original. Some forgers, however, can get over the hesitation, with practice, in forging a small number of words, such as is needed in forging a cheque.

## III. MICROMATHEMATICS

### 1. Mathematics and micromathematics

That averages should be corrected for probability; that a rupee when tossed with the same balance and force will give as many heads as tails, only when the number of tosses is large; that fluke chances turn up; and that the chances with a rupee are essentially different from those with a dice, we are pleased to know. We will even buy books and renew our acquaintance with algebra and differential calculus. This is mathematics. That figures must be plotted on complicated curves; that equations well stocked with f's, d's and v's should be constructed; and that many letters of the alphabet should be distorted or dislocated to represent something or other in the process of calculation, before we as medical men, in a surgery, ward or laboratory, can say or do anything we may not consider significant. This is refined or micromathematics, which is a further obfuscation of the minute mathematical calculations referred to above. So far as our activities are concerned it is a figment of the mathematicians.

### 2. Advances in medicine are independent of micromathematics

None of our advances in medicine, surgery, anaesthetics and therapeutics has had the remotest connection with micromathematics. Even our laboratory work in subjects like physiology and pathology has progressed very well without it (and in recent years in spite of it). This is due to the fact that protoplasmic organisms do not live, grow, decay or die along complicated curves.

An outstanding example of the failure of even simple arithmetic to account for a well-known biological occurrence is found in Mendelism. The nearest approach that Mendel could make to his 3 : 1 ratio, in a life time, was 2.84 : 1.

Another, even more outstanding, example of the failure of simple arithmetic occurs in immunology in the following relationship between the diphtheria toxin and its anti-toxin :—

(1) A minimal lethal dose (M.L.D.) of diphtheria toxin is the smallest amount which kills a guinea-pig weighing 250 grammes in 4 days.

(2) A completely neutralized dose ( $L_0$ ) is the largest amount of toxin completely neutralized by 1 unit of diphtheria anti-toxin.

(3) A re-toxicated dose ( $L_+$ ) is the smallest amount of toxin which when mixed with 1 unit of diphtheria anti-toxin just kills the standard

animal in the standard time. In other words, it acts like 1 M.L.D.

Dose (3) minus Dose (2) should be equal to Dose (1)

or

$L_4$  minus  $L_0$  should equal 1 M.L.D.

In actual practice  $L_4 - L_0 = 8$  to 12 M.L.D. (Hewlett and McIntosh, 1932).

The same looseness of relationship exists between all toxins and their anti-toxins.

3. *The figment of the mathematicians does not appear to be used even in important human activities of peace and war*

The producer of the raw material mostly works without machinery and has little scope for mathematical refinements. The manufacturer of goods works with machinery yet uses very little mathematics. The seller of the goods prefers advertisement and creation of demands to the statistical analysis of the existing demands. Even if the first two categories of workers were supplied with micromathematically perfect machinery, only the production will be increased, not the distribution of the product. An increase in production without an increase in distribution does not lead to national prosperity or international amity.

In sport, judging of form, handicapping or even forecasting of events by the professional advisers is not based on a complicated system of calculation at all. If the existing system were faulty the refined mathematicians would have the wealth of all the 'totalisators' in the world at their disposal. Such is not the case.

When the leaders of nations choose between peace and war they do not do so in an atmosphere of higher and pure mathematics.

### Summary

1. Crypticism in symbolism is a wilfully introduced embarrassment in the consciousness.
2. Important findings should not be based on micromethods. The latter may be particularly dangerous in their application to forensic matters.
3. Complicated mathematics has no place in biological processes. It has no place even in collective human conduct in peace and war.

## Medical News

### THE DRUG AND PHARMACEUTICAL INDUSTRY IN INDIA

'THE drug and pharmaceutical industry in India has developed considerably and in order to enable it to make further headway, simultaneous growth of heavy and fine chemical industries and industries connected with coal carbonization and production of solvents, etc., is essential. If the required basic materials and chemicals are readily available, it is possible to produce in India all the drug requirements of the country.' This is the conclusion of the 'Medical Preparations' Sub-Committee of the Indian Chemical Manufacturers' Association, Calcutta, in their report recently submitted to the Government of India. It is stated that India possesses a wonderful range of vegetable materia medica and nearly three-fourths of the drugs mentioned in the British Pharmacopœia grow in this country in a state of nature and the remaining one-fourth can be easily cultivated in some part of the country or other. In the appendices to the report, the sub-committee have included two lists, (1) Drugs belonging to the British Pharmacopœia which grow in India and (2) those included in the British Pharmaceutical Codex and the Extra Pharmacopœia which either grow spontaneously or can be easily grown. It is the opinion of the sub-committee that if due attention is paid to the proper cultivation and utilization of vegetable drugs, India would not only be completely self-supporting in this

respect but would also be able to develop an export trade in crude vegetable drugs. The sub-committee refer to the position about the production of oils, including essential oils, fixed oils and liquid paraffin; alkaloids including caffeine and its derivatives, emetine, morphine and codeine and their derivatives, strychnine, ephedrine, quinine, glucosides including digitalis; inorganic and organic drugs, inorganic and organic metallic compounds; synthetic chemo-therapeutic products, organo-therapeutic products; coal-tar products; biological products including sera, vaccines, bacteriophage, etc.; vitamin preparations, patent foods, surgical dressings, disinfecting fluids and other miscellaneous requirements. The sub-committee have also appended lists of essential drugs and medicinal chemicals available in India, of drugs and medicinal chemicals of secondary importance available in India, of basic chemicals necessary for the manufacture of drugs and the possibilities of their manufacture in India and tables showing imports of drugs, patent and proprietary medicines and chemicals along with their industrial uses. The sub-committee invite the attention of the Government to the necessity of close co-operation between the drug manufacturing concerns and hospitals. At present the manufacturers in India find it difficult to make a clinical trial of their products in any hospital under the Government and semi-Government bodies and it urges the State to render necessary help in this respect.

The sub-committee was presided over by Brevet-Colonel R. N. Chopra, Director, Biochemical Standardization Laboratory, Calcutta, and consisted of the following members:—Mr. J. N. Lahiri, Dr. H. Ghosh, Dr. B. N. Ghosh, Dr. U. P. Basu, Dr. B. C. Guha, Dr. I. B. Basu, Dr. B. Mukherjee and Mr. S. R. Dhadda, Secretary, Indian Chemical Manufacturers' Association (*ex-officio*).

### THE XVII ALL-INDIA MEDICAL CONFERENCE, 1940, VIZAGAPATAM

THE SEVENTEENTH ALL-INDIA MEDICAL CONFERENCE will be held at Vizagapatam (Waltair) in the last week of December 1940. The Reception Committee is anxious to improve the standard and utility of the scientific section.

Members of the Indian Medical Association or other Registered Medical Practitioners may present one or more papers at the session, provided they enlist themselves as members of the conference or of the scientific section.

Those who propose to read papers should forward them together with three copies of abstracts of the papers so as to reach the Chairman of the scientific section not later than 15th October, 1940, for submission to the scientific committee. Abstracts should be type-written and must not exceed 200 words. They should not include formulæ or diagrams. It might not be possible to allot more than ten minutes for the reading of any paper. Intimation of the acceptance of the paper will be communicated one month before the actual session of the conference.

P. KUTUMBIAH,

*Chairman, Scientific Section.*

MAHARANIPETA P. O.,  
VIZAGAPATAM.

### THE CALCUTTA PUBLIC MEDICAL SERVICE SCHEME

WE publish below the details of a scheme for contract medical service to persons of limited means. This scheme we are informed was approved by the Calcutta branch of the Indian Medical Association in November last. Though such a scheme is undoubtedly a move in the right direction it is doubtful if the present time is opportune for its inauguration:—

I. *Name*:—The Calcutta Public Medical Service.

II. *Aims and objects*:—

1. The system of Medical Service is a contract medical service directed to the achievement of positive health and the prevention of diseases no less than to the relief of sickness.
2. There should be provided for every individual the services of a general practitioner or a family doctor of his own choice.
3. Consultants and specialists, laboratory services and all auxiliary services together with hospital provision when required should be available for the individual patient normally through the agency of the family doctors.

III. *The availability of the service*:—

1. It would be desirable to fix income limit for persons intending to join the scheme. This income limit may be set at Rs. 250 per month and a graded scale of fees should be charged.
2. Attempts should be made by the Central Public Medical Service organization to move the Calcutta Corporation and the Government to enact necessary legislative measures whereby all of their employees coming under the above income limit will have to join the scheme compulsorily.

3. Persons with an income above Rs. 250 per month may join the scheme on application to the Central Organization with limited facilities.

### IV. *Rules and regulations*:—

1. All contributions are payable in advance according to the following schedule:—
2. *Schedule*:—
  - (a) Contributors with monthly income below Rs. 100 shall pay Rs. 3 per quarter for self and Annas 12 as per quarter for each dependant.
  - (b) Contributors with monthly income between Rs. 100 and Rs. 250 shall pay Rs. 6 per quarter for self and Rs. 1-8 for each dependant.
  - (c) Contributors with monthly income above Rs. 250 may join the scheme on application to the central organization and on certain conditions.
3. In exceptional cases, the clinic may allow payment of contributions in monthly instalments *pro rata* after the first quarterly payment.
4. The contributors are entitled to free medical service (exclusive of supply of medicines and appliances) at their respective clinics during their specified surgery hours.
5. A contributor is also entitled to medical service at his residence on the following conditions:—
  - (a) The illness is of such a nature that in the opinion of his physician the patient is incapable of attending the clinic personally.
  - (b) The clinic is informed by the party concerned before 9 a.m. that a visit is required (except in cases of emergency).
  - (c) The contributor agrees to pay for calls made between 9 a.m. and 9 p.m. a sum of Annas 8 or Annas 12 per visit according as his residence is within three miles or over three miles respectively from the clinic.
  - (d) The contributor agrees to pay Rs. 2 and conveyance charges for all visits (night calls) made between 9 p.m. and 9 a.m.
6. The charges for residential calls as specified above are payable in cash at the time of the visit. The clinic may however allow monthly adjustments provided payments are made before the 10th of the next month failing which the clinic may suspend all privileges to the defaulting contributor and his dependants.
7. If a contributor fails to pay his quarterly contributions within a fortnight of the due date, his status as a contributor will cease on that date, and he will not be re-admitted unless he pays a re-admission fee amounting to half his quarterly contribution.
8. In case of monthly contributor the period of grace will be one week from the due date of payment, *viz.* the third day of every month, and the re-admission fee shall be equivalent to one month's contribution.
9. If a contributor and his dependants have not availed of the services of the clinic during the previous quarter, he shall be entitled to a ten per cent rebate of his usual contribution fee.
10. The clinic reserves the right to refuse admission or re-admission to any applicant without assigning any reason.
11. All enquiries should be addressed to the Honorary Secretary, Calcutta Public Medical Service Scheme, Indian Medical Association, Calcutta Branch, 67, Dharamtala Street, Calcutta.

V. *Benefits conferred by the scheme:—*

1. The nature and scope of medical service to which the contributor and his dependants are entitled includes 'all proper and necessary medical services other than those involving the application of special skill and experience which general practitioners as a class cannot reasonably be expected to perform'.
2. Medical service to contributors does not include the supply of medicines and appliances.
3. Attendance in labour and attendance within 10 days after labour, in respect of any condition resulting from labour is not within the purview of the scheme. Antenatal care and the treatment of any condition not arising out of labour are covered by the scheme. Premature delivery before twenty-eight weeks of pregnancy is also covered by the scheme.
4. Cases of cholera, smallpox and cerebro-spinal meningitis which require institutional care will only be treated by the clinic pending their removal to a hospital for such cases.
5. All minor operations such as can be reasonably performed by a general practitioner and do not require special skill will be done free of charge at the clinic or at the patient's residence as the case may be.
6. Administration of the anæsthetic or other assistance at an operation will be undertaken free of charge by the clinic doctor if the said services do not involve a degree of special skill or experience not possessed by general practitioners as a class.
7. Laboratory and other special services such as radiological investigation, dental and ophthalmic services, etc., if required, shall be arranged by the clinic at the specially reduced rates recommended by the Indian Medical Association, Calcutta Branch.
8. The consultant's and specialist's services, if required, shall be arranged by the clinic from a panel of consultants and specialists at the reduced charges recommended by the Indian Medical Association, Calcutta Branch.

VI. *Administration:—*

1. The Medical Service is thrown open to the whole of the medical profession. Accordingly any medical practitioner registered under the provisions of the Bengal Medical Act, 1914, is entitled to work under the Calcutta Public Medical Service Scheme as one of its unit, provided that he abides by the rules and regulations of the Scheme as framed, altered and modified from time to time by the Indian Medical Association, Calcutta Branch.
2. A Central Committee shall be formed for the general control and co-ordination of the economically independent units working in different parts of the city.  
The Central Committee shall consist of—
  - (a) President of the Calcutta Branch, I. M. A.
  - (b) President of the Bengal Provincial Branch, I. M. A.
  - (c) Honorary Secretary, Calcutta Branch, I. M. A.
  - (d) Honorary Secretary, Bengal Provincial Branch, I. M. A.
  - (e) One representative from the Calcutta Medical Club.
  - (f) One representative from the All-India Medical Licentiates' Association, Calcutta Branch.
  - (g) Five representatives from the Executive Committee, Calcutta Branch of the I. M. A.

(h) Three representatives from Panel Doctors.

(i) Three representatives from amongst the Contributors.

3. The Central Body shall be responsible for the working of the scheme. All constituent units have to be recognized by the Central Committee before they can function.
4. All disputes and difficulties arising in course of working of the scheme are to be reported to the Central Committee, whose decision in such matters will be final.
5. The Central Committee shall have power of disciplinary action against constituent units.
6. The Central Committee shall form in a joint meeting with the Executive Committee, Calcutta Branch of the I. M. A., a Board of Consultants and Specialists, the duty of which will be to establish a list of consultants and specialists who satisfy a certain standard of eligibility and who desire to render service under the Scheme.
  - (a) It is suggested that the consultant and specialist's service should be available only on the recommendation of the family doctor and a fixed concession fee recommended by the Calcutta Public Medical Service, Central Committee, should be charged for such a consultation or specialist's service.
  - (b) It is suggested that the consultant and specialist's service to be available should be defined as such examination as can be given at a single consultation together with a report, where necessary, for the information of the attending practitioner.

## NUTRITIVE VALUE OF RICE

ANOTHER Bulletin dealing with nutritional questions has been published in the Government of India Health Bulletin Series. This has been prepared in the Nutrition Research Laboratories, Coonoor, and has been approved by the Nutrition Advisory Committee of the Indian Research Fund Association. An earlier Bulletin (No. 23) entitled 'The Nutritive Value of Indian Foods and the Planning of Satisfactory Diets' proved very popular and some 35,000 copies of the first and second editions have been sold or distributed. This bulletin was concerned with Indian foods in general. The new bulletin (No. 28), entitled 'Rice', deals in detail with the nutritive value of rice and the defects of the poor rice eater's diet.

Rice is the staple food of about half the human race. In India the area under rice exceeds that under all other cereals put together. Diet surveys have revealed the composition of the rice-eater's diet, showing that he consumes, in addition to his staple cereal, only very small quantities of such foods as pulses, vegetables, fruits and meat. Milk and milk products are taken in negligible quantities, or not at all. In the circumstances the nutritive value of the main ingredient in the diet is of primary importance.

The bulletin describes the effect of milling on rice. The outer layers of the grain are richer in vitamins and other materials than the inner starchy part. Hand-pounding removes some of the outer layers, but does not very greatly impoverish the nutritive value of the grain. But when raw rice is machine-milled, there is a serious loss of vitamins and particularly of vitamin B<sub>1</sub>, which prevents and cures the disease beri-beri. But parboiled rice, even when highly milled, retains most of the anti-beri-beri vitamin originally present in the unmilled grain.

The steaming to which the grain is subjected during the parboiling process causes vitamin B<sub>1</sub>, and a number of other valuable food constituents, to diffuse through the grain, so that they cannot be removed when milling subsequently takes place. The washing of rice removes

a considerable amount of food material, including about 50 per cent of vitamin B<sub>1</sub>. Cooking with excess of water also reduces the nutritive value.

A section is devoted to beriberi and it is shown that this disease is a serious public health problem in only one part of the country—the Northern Circar districts of the Madras Presidency. The reason for this is that in this area the poor prefer raw rice. Elsewhere in India polished rice is usually eaten and this contains enough vitamin B<sub>1</sub> to prevent beriberi.

The bulletin describes an investigation of the milling problem in the Madras Presidency. It was found that about 70 per cent of the population now consumes machine-milled rice. The underlying factors were found to include the following. The rice mill has spread everywhere and the people have come to regard it as a labour-saving convenience. Small holders are often faced by poverty and debt and dispose of their paddy to merchants and do not retain sufficient for their own use, a large proportion of the poorer section of the community lacks accommodation for the storage and pounding of paddy, paddy cannot be purchased in small quantities for pounding, when home-pounded rice is put on the market is in article of commerce it is dearer than machine-milled rice because of the labour costs involved. At present such rice reaches the market only in very small quantities.

Ways and means of improving the poor rice-eater's diet are considered. The nutritive value of the staple itself can most easily be raised by preventing the losses occurring in milling, washing and cooking.

It is important that the effect of parboiling in minimizing losses on milling should be generally recognized. Legislative action to check the spread of rice mills, or to reduce the number already in existence, is not recommended. What can and should be done throughout India is to educate people about the food value of rice in its various forms. Everybody should have a clear idea of what happens during the milling, washing and cooking of the most important food in the country.

Finally, 'supplementary' foods are discussed. The actual diet of the poor rice-eater and a well-balanced diet are compared and it is shown that the former contains too little milk, pulses, vegetables, and other foods. Milk supplies many of the food factors in which rice diets are deficient. Skimmed milk and butter-milk of good quality are valuable supplements. The partial substitution of rice by one of the millets, particularly *ragi*, improves poor rice diets. The bulletin stresses the need for the increased production of vegetables, especially green leafy vegetables and urges the development of the fishing industry.

#### WELFARE WORK FOR SOLDIERS' FAMILIES

A STEADY increase in welfare work among the families of Indian soldiers shows that difficulties of caste, class and religion are now interfering less than in the past.

Demands for treatment are becoming more general and it is frequently suggested that the treatment of families of Indian troops and followers and the provision of hospitals may shortly have to be recognized as an obligation of the central authority. One solution suggested is the allotment of portions of Indian military hospitals. While this may be possible where spare buildings exist the authorized provision of beds for troops and followers may at times be fully required.

At present, apart from certain payments of wages and provision of personnel, the whole welfare and family treatment system is done by voluntary effort by subscriptions from units, by donations from central charitable funds and by personal and financial support of the wives of officers of the units concerned. Much voluntary work is done by medical officers and the members of the Indian Medical Department.

There are now some 80 welfare centres. At all the centres the numbers attending in 1938 were approximately 84,677 women and 100,367 children. The progress of the work is dependent largely on the money available. The demands for accommodation, trained personnel and treatment are continually increasing.

In several big stations difficulty has been experienced in obtaining suitable lady assistant surgeons and qualified nurses.

Accommodation is usually provided in converted married quarters which are quite suitable for small units. In larger stations the practice is to establish family hospitals and have welfare centres included in the hospital buildings and activities. In a few stations welfare centres provide only outdoor treatment and arrangements are made with neighbouring mission hospitals, charitable general hospitals or civil hospitals to deal with hospital cases.

In addition, several amenities for women and children are being provided in the way of playgrounds and schools, purdah gardens for the women and even hot-water bathing establishments.

In most centres subscriptions from men, from the unit funds, and from officers and their wives make up from two-thirds to three-fourths of the resources of the welfare centre. The Maternity and Child Welfare Bureau and the provincial branches of the Indian Red Cross Society make grants-in-aid to the best of their ability.

Where beds are available women are making greater use of such accommodation for confinements with beneficial results.

#### LESS SANDFLY FEVER AMONG TROOPS

THE persistent fall in sandfly fever among troops has been noticed by Army Health authorities in India. This is said to be largely due to preventive measures.

Admissions in Landikotal, a hotbed of sandfly fever, which stood at 239 cases in 1935 dropped to 19 cases in 1938.

While the reduction here may perhaps be due to the fact that some of those forming the garrison during 1938 came from outer parts of the Peshawar district and were presumably 'salted' troops, the major part of the decrease can be put down to the use of 'Pyefly' spraying in barracks, to the co-operation of the troops in anti-sandfly measures, and to the replacement of the old mud buildings by modern stone or concrete ones. The canalization and making 'pukka' of nullahs as far as they can be improved has also helped.

Sandfly fever in the Northern Command dropped from an incidence of 36.04 per thousand in 1929 to 7.10 per thousand in 1938. Spraying and fumigation, resorted to as anti-malarial measures, have incidentally done much to bring about this reduction in the incidence of sandfly fever.

#### WORK AT THE KASAUJI MILITARY FOOD-TESTING LABORATORY

SOME idea of the care which the army takes to see that the soldiers in India secure wholesome food and good supplies can be obtained from the work done at the Military Food Laboratory, Kasauli. In 1938 alone a record total of 18,012 samples was examined.

In several cases tinned milk with high acidity in inferior tins, pearl barley coated with mineral water in inferior tins, highly polished rice, parboiled and broken rice and indifferent biscuits had to be rejected.

The main cause of rejection was the inability of manufacturers to realize the high quality required.

The samples from abroad are mainly from Australia which produces good supplies with only 1.2 per cent rejections. Australian jams have been found to be better in quality than those from the United Kingdom.

The Indian products are not satisfactory. Indifferent stocks of biscuit, salt, pearl barley, rice, bran and even sugar are submitted in the hope that the mixed inferior grades will be accepted.

Special biological assays were undertaken—the vitamin-'C' content of ascorbic-acid tablets for protection against scurvy and the phosphorus pentoxide specification for rice was investigated.

A dietetic survey of the Lawrence Military School, Sanawar, was carried out and certain improvements brought into force as a result.

Food contamination in connection with chemical warfare has been studied and further work is in progress. The superchlorination of water for drinking purposes has been tested and a special report is being prepared on the subject.

Revision of the Royal Indian Army Supply Corps specifications was carried out and the pamphlet on 'The Method of Submitting Samples' was revised and brought up to date.

Many improvements were carried out in the equipment and fittings of the Ghee Heating Centre at Agra. The number of samples submitted to the centre was 3,973. In general, the ghee was satisfactory, but the average acidity was high and there were three rejections for high acidity. Three thousand nine hundred and seventeen samples were finally accepted.

#### THE PHARMACEUTICAL AND ALLIED MANUFACTURERS' AND DISTRIBUTORS' ASSOCIATION, LIMITED

THE first ordinary general meeting of the above association was held on 12th July and office-bearers were appointed.

#### PROTECTING THE SOLDIERS' HEALTH

THE effectiveness of modern preventive medicine in keeping down the incidence of disease is demonstrated by the general health of the Army in India.

T. A. B. inoculation with a new strain of organism included brought about a further fall in the military incidence of enteric fevers during 1938, whilst the relative absence of cases of smallpox and cholera among the troops in areas in which these diseases have been prevalent in epidemic form all go to illustrate what can be done by preventive medicine.

Thus, there has been a general reduction in the number of cases of malaria among the troops over the last ten years, the number of cases among British troops being less than one-half of what they were ten years ago, and the number of cases among Indian troops having dropped by more than one-third. There has also been a marked drop in the number of relapses.

Perusal of the clinical records of the cases placed on the dangerously ill list and of cases of outstanding interest disclose that the standard of professional ability displayed by medical officers and nursing staffs of hospitals is of a high order. It also helps one to realize that to-day the combined resources of the medical services of the Army in India place at the disposal of the soldier and his family and the sepoy and his family (for the latter the work is only now commencing) a proficiency in treatment and care equal, bearing in mind the physical standard of the population, and the incidence of diseases to which they are liable, to the voluntary hospital in the United Kingdom and only at the call of the wealthy in civil life.

#### FOUR YEARS' SUPPLIES OF QUININE PURCHASED

THE Government of India have taken steps to ensure that there shall be an adequate supply of quinine sulphate in India for all purposes for which Provincial and State Governments normally require it. Provision has also been made for the estimated requirements of the defence services.

Statistics were collected showing probable requirements over a period of years. The amount involved being substantial, the Government of India approached the authorities in the Netherlands East Indies and an agreement has now been concluded by which practically the whole amount required over the next four years will be shipped from Java during the next six months. Owing to the size of the contract it has been possible to arrange considerably reduced terms.

## Current Topics

### The Diagnosis and Treatment of Syphilis of the Nervous System

By FERGUS R. FERGUSON, M.D., D.P.H., F.R.C.P.

(From the *Practitioner*, Vol. CXLIV, April 1940, p. 354)

OWING to the fact that syphilis may attack any portion of the central nervous system—meninges, arteries or the nerve elements themselves—the clinical manifestations are legion and, if mistakes are to be avoided, it is clear that the possibility of syphilis being the causative agent must be borne in mind in practically every patient with a nervous disease in which there is uncertainty in diagnosis. This applies whether the history is short or of ten to twenty years' duration, whether the principal abnormality is a psychological one or whether the problem consists of isolated or multiple cranial nerve palsies, of a hemiplegia or paraplegia, or of such widely different symptoms and signs as impotence and incontinence, arthropathies and ataxia, paræsthesia or ptosis, dysarthria or dementia, diplopia or dyspnoea, deafness or depression.

#### TYPES AND CLASSIFICATION

The diagnosis of neurosyphilis includes first the differentiation from other neurological conditions, such as cerebral tumour, disseminated sclerosis, subacute combined degeneration of the cord, progressive muscular atrophy, spinal tumour, and so on, and secondly, the

diagnosis of the particular type of neurosyphilis, i.e., whether tabes dorsalis, Erb's syphilitic spinal paralysis, general paralysis of the insane (G. P. I.), or gummatous basal meningitis.

It has for years been customary to accept the essentially different pathological forms of neurosyphilis—parenchymatous, in which the underlying lesion is in the nerve elements, and primary meningo-vascular syphilis, in which the initial lesion is in the blood vessels or meninges. The changes in the cerebro-spinal fluid and the morbid anatomical findings suggest that such a distinction is most probably unjustifiable and incorrect, and most observers now hold the view that the vessels and meninges are primarily affected in all forms of neurosyphilis, and that parenchymatous syphilis as an initial lesion does not exist. Further, although it is true to say that clinically typical examples of tabes dorsalis and G. P. I. are often encountered, yet only too frequently patients are found to present some of the classical features of, say, tabes, but have in addition vascular or meningitic manifestations. There is much overlapping, and considerable difficulty may be experienced in placing a particular patient in one of the recognized groups. Thus a sharp distinction between the various types of neurosyphilis is often impossible and there are those who advocate that on clinical and pathological grounds classification should be restricted to syphilitic meningitis, encephalitis, myelitis and encephalomyelitis. Such a simple subdivision has its attractions but, in the present state of knowledge, more elaborate classification must be

retained. In the course of practice the following has been found useful:—

**Congenital:** G. P. I., taboparesis, tabes and a heterogeneous group including hydrocephalus, meningitis, mental defect, cranial nerve paralysis, epilepsy, paralysis of the extremities, and the 'nervous child'.

Acquired	Meningo-vascular	Parenchymatous
<b>Brain—</b>		
Cerebral syphilis	Pachymeningitis Gummatous leptomeningitis.	G. P. I.
<b>Spinal cord—</b>		
Spinal syphilis	Gummatous Cerebral thrombosis Pachymeningitis Meningomyelitis Erb's syphilitic spinal paralysis. Spinal thrombosis Radiculitis Caries	Tabes dorsalis.
<b>Brain and spinal cord.</b>	Cerebro-spinal syphilis	Taboparesis.

#### DIAGNOSIS

In view of the wide range of signs and symptoms caused and clinical pictures presented by these various types of neurosyphilis it is not possible, in this article, to give a full or adequate differentiation from the large number of nervous diseases with which they may be confused. It is proposed to enumerate some of the presenting signs and symptoms of neurosyphilis, and some of the commoner conditions which may give rise to similar symptoms, and which have given rise to difficulty in diagnosis.

**Headache.**—Cerebral tumour, sinus disease, cerebro-vascular disease, meningitis.

**Diplopia.**—Disseminated sclerosis, myasthenia gravis, cerebral aneurysm, encephalitis.

**Optic atrophy.**—Toxic amblyopia, disseminated sclerosis, pituitary tumour, intracranial meningioma, cerebral aneurysm, chiasmal arachnoiditis.

**Facial pain.**—Trigeminal neuralgia.

**Lightning pains.**—Rheumatism, fibrositis, arthritis, peripheral neuritis, subacute combined degeneration of the cord.

**Trunk hyperæsthesia.**—Psychoneurosis, neuritis, radiculitis, spinal tumour.

**Atrophy of hand muscles.**—Progressive muscular atrophy (amyotrophic lateral sclerosis), syringomyelia, spinal tumour.

**Charcot joints.**—Syringomyelia, arthritis.

**Disturbances of micturition.**—Prostatic or bladder diseases, cauda equina tumour.

**Impotence.**—Disseminated sclerosis, cauda equina tumour, hysteria, endocrine lesions, and general ill health.

**Perforating ulcers.**—Spina bifida, diabetic neuritis, peroneal muscular atrophy.

**Spastic paraplegia.**—Disseminated sclerosis, spinal neoplasm, subacute combined degeneration of the cord, amyotrophic lateral sclerosis, syringomyelia.

**Rombergism.**—Peripheral neuritis, subacute combined degeneration of the cord.

**Epilepsy.**—Cerebral tumour, cerebro-vascular disease, idiopathic.

**Gastric crises.**—Ulceration or perforation of the stomach or duodenum, acute cholecystitis.

**Absent tendon reflexes.**—Myopathies, progressive muscular atrophy, subacute combined degeneration of the cord, Friedreich's ataxia, myotonic pupil (Holmes-Adie syndrome). It is very important to recognize and differentiate this last condition from tabes dorsalis because there is no evidence that it is progressive and, although the ætiology is obscure, yet it is clearly not

syphilitic. The syndrome is characterized in its complete form (a) by pupils (or a pupil, for the pupillary phenomena are often unilateral) which show little or no reaction to light and slow convergence and still slower dilatation on relaxation, and (b) by the absence of some or all of the tendon reflexes.

It is hoped that this emphasis on, and presentation of, the principal or initial symptoms, rather than the 'full blown' disease and its clinical picture, may lead in a doubtful case to a suspicion of a syphilitic cause for the symptoms, to a search for syphilitic abnormalities, e.g., in the pupils, iris, or heart; to examination of the blood and cerebro-spinal fluid; to a careful history and, in turn, to earlier and more successful treatment.

Although from the clinical description the differentiation between tabes dorsalis and peripheral neuritis should be fairly easy yet in practice it is found that this problem is at times a difficult one. It is true that the patient may have courted both diseases, but it is more than probable that one or the other is giving rise to the incapacity. Important differentiating points are the presence or absence of deep tenderness and the type of sensory loss but, even after the examination of the blood and cerebro-spinal fluid, we may be dependent on the results of therapy for the correct diagnosis.

The recognition of G. P. I. is not generally difficult if the disease is borne in mind, especially when confronted with the problems of epilepsy starting in adult life, speech defects, obscure and generalized tremulousness and psychological changes—defective memory for recent events, confusion or periods of excitement. The condition is generally labelled neurasthenia, but the other diseases with which it has been confused include frontal tumour, cerebro-vascular disease, presenile dementia, Huntington's chorea, chronic alcoholism, and barbiturate intoxication, which may give rise to confusion, slurred speech, fixed pupils, ocular palsies, ataxia and facial tremor.

#### WASSERMANN AND CEREbro-SPINAL FLUID

Although neurosyphilis and its particular type may be capable of recognition on clinical grounds, yet two of the most valuable aids are the Wassermann reaction—and allied tests—and complete examination of the cerebro-spinal fluid. In this connection there are several important points which must be borne in mind:—

(1) In *tabes dorsalis* the Wassermann reaction is positive in both blood and cerebro-spinal fluid in 65 per cent of cases, positive in the fluid alone in 10 per cent, in the blood alone in 5 per cent, and *negative in both* in 20 per cent. The percentage of positives and negatives will differ in different series, but nearly all observers agree that the blood Wassermann is negative in at least 30 per cent of cases. It is important to stress this fact, for there are many practitioners who still doubt its truth. It is reported that if 1 c.cm. of cerebro-spinal fluid is used instead of the original amount—0.2 c.cm.—the Wassermann in the cerebro-spinal fluid will generally be positive, but on this there is no unanimity of opinion. In *tabes dorsalis* there is often an excess of cells and, in 90 per cent of cases, there is excess of globulin, but a negative blood and completely normal fluid may be found not only in the long standing ataxic and so-called 'burnt out' cases, but also occasionally when the disease is progressive.

(2) In contrast to this the Wassermann is positive in the blood in practically 100 per cent of cases of G. P. I. In clinical practice it is fortunate that it is thus possible to make or confirm the diagnosis without a cerebro-spinal fluid examination.

(3) In early *meningo-vascular syphilis* the blood is usually positive, but it may be negative if efficient treatment has only recently been given. Therefore examination of the cerebro-spinal fluid is essential in doubtful cases, when the blood is negative.

(4) The finding of a paretic or 'first zone' gold curve does not necessarily mean *neurosyphilis*, in fact when it is combined with a negative Wassermann the cause is generally disseminated sclerosis.

(5) There is considerable variation in the effect of treatment on the abnormalities in the cerebro-spinal fluid. At times the clinical and serological improvements occur *pari passu*, but symptomatic cures may be obtained without change in the cerebro-spinal fluid and, conversely, the fluid may revert to normal while the clinical symptoms continue to progress.

(6) The fluid changes in dementia paralytica and tabes dorsalis are usually the most difficult, and those in acute syphilitic meningitis or vascular neurosyphilis the easiest to influence.

It is important to remember that although serological tests are so valuable in the diagnosis of neurosyphilis, still on occasion the Wassermann reaction is found to be positive, and yet a non-syphilitic lesion has proved to be the cause of the symptoms. In a series of cases from the National Hospital, London, on four occasions the Wassermann was positive and yet a non-syphilitic spinal tumour was removed.

I have also seen typical chronic encephalitic Parkinsonism and lead myopathy as the cause of the incapacitating symptoms when the Wassermann reaction was positive in the blood.

Occasionally two conditions may be present.

A patient recently under my care had subacute combined degeneration of the cord with achlorhydria and a pernicious anaemia count and, in addition, showed signs of tabes dorsalis with a positive Wassermann and typical changes in the cerebro-spinal fluid.

Further, although abdominal pain and vomiting in tabes dorsalis may be due to gastric crises, other causes must be excluded. A gastric ulcer has been found to be the cause of such symptoms and it has healed with appropriate treatment. It is clear therefore that, even although the Wassermann is positive, a careful clinical examination and further investigations must be made in order to exclude any other cause for the symptoms. It is especially important to remember this because the recent tendency, when the Wassermann reaction is found to be positive, has unfortunately been to start immediately on a course of anti-syphilitic treatment and to omit a detailed neurological and general examination.

#### TREATMENT

The treatment of *neurosyphilis* may be considered under four headings—(1) General. (2) Symptomatic. (3) Anti-syphilitic. (4) Thermo-therapy.

The tendency just referred to, to omit or curtail a general examination, is also reflected in therapy; neglect of the general and symptomatic treatment is frequently found. Neurosyphilitic therapy is frequently controlled by and carried out—in some centres almost entirely—in V. D. clinics. The great advantage of this is that, owing to the excellent general organization of such clinics, the anti-syphilitic treatment is thorough and well supervised and the injections are efficiently and successfully given, so that it is not difficult to get the patient to continue with his treatment. On the other hand, it is hoped that this practice will not lead to neglect of a careful general examination, to the treatment of a *disease* rather than a patient, and to control of treatment by the blood and cerebro-spinal fluid rather than by the clinical state, for it is recognized how often the clinical and serological improvements do not go hand in hand.

**General.**—It is essential to keep the general health as good as possible—a regular life, avoiding all excesses, including sexual indulgence; abstinence from or at least extreme moderation in smoking and alcohol—and physical and mental exertion must never be pushed beyond the point of fatigue. The tabetic would be best advised to follow Erb's advice and live the life of an old man, simple, abstemious, quiet and regulated.

**Symptomatic.**—Attention to the bowels and bladder is extremely important but is often neglected in the treatment of a tabetic. Reference to these and other symptoms will be made in later paragraphs.

**Anti-syphilitic.**—It will not be possible to discuss in detail the merits of the numerous preparations, or the

advantages or disadvantages of all the different 'lines' of therapy. It is proposed to deal with general principles and aspects in therapy which receive too little attention or the undeservedly omitted. The preparations which are most commonly used are iodides, bismuth or mercury and arsenic. First, a brief note about these preparations—

**Iodides**, which some years ago were always used, are now at times almost forgotten or at any rate are given somewhat perfunctorily and in inadequate doses.

**Mercury** has been condemned by some authorities as harmful. Others deny this and attribute the ineffective results to inadequate administration, and regard it as one of the most valuable weapons in the anti-neuro-syphilitic armamentarium. Mercury may be given as liq. hydrarg. perchlor. or pil. hydrarg. et iod. virid., but one of the most useful methods is by inunction. This, however, must be done efficiently—preferably by a professional rubber—and the ointment must be rubbed in for fifteen to thirty minutes and the course continued until signs of mercurialism are produced.

**Bismuth** is at present fairly widely used because it frequently gives excellent results, often better than with mercury, but it is difficult to predict in which type of neurosyphilis, and in which particular case, it will be of the greatest value.

**Arsenic** is the metal most commonly and constantly employed and in general is regarded as being of the greatest value. In the opinion of many tryparsamide—a pentavalent arsenical—is of more value than the more commonly employed trivalent arsenicals, especially in tabes and G. P. I. Its principal disadvantage is its liability to cause optic atrophy and, further, it has apparently little effect on syphilitic lesions other than those in the nervous system. Before tryparsamide is given, the fundi must be examined and the fields of vision charted. Any reduction or alteration in the fields should be a sign to stop the administration.

Secondly, should faith be pinned in a particular case to one or at the most two of the preparations or should all four be given?

Thirdly, it must be decided whether the preparations should be given concurrently in order to obtain a maximal or synergic effect, or consecutively. Two points in favour of the latter method are that it frequently affords a better idea of which substance is the most valuable and gives the greatest clinical improvement in a particular case. Secondly, nausea, loss of appetite and general malaise may follow the combined use of iodides, mercury and N. A. B., and yet when the iodides and mercury are omitted the patient may be able to tolerate full doses of arsenic. Although entering the therapeutic arena some years ago with a flourish of trumpets, intrathecal injections of salvarsanized serum have no especial advantage, according to most observers. There is still much difference of opinion as to the relative value of, and the special indications for, these preparations. Each has its own advocates and the virtues of one preparation are often extolled to the exclusion of the others. It is little wonder then that a practitioner, who may encounter a new case of neurosyphilis only once a year, finds himself in confusion and without a definite plan of action, and in consequence the therapy and the patient suffer.

Although many are accustomed to prescribe different lines of treatment for the different neurosyphilitic syndromes, yet in view of the probable basic common pathological process, the coincidental presence of syphilitic lesions elsewhere, the overlapping of the clinical pictures and the difficulties and uncertain nature of our classification, it is difficult to defend and find justification for widely dissimilar methods of treatment. In the present state of knowledge with some uncertainty about the pathology and the need for adopting a modified clinical classification, variations in therapy must be allowed in some degree, but for practical purposes there should be a basic course of anti-neurosyphilitic treatment which can be adopted when the exact designation of a particular case is uncertain.

# High germicidal efficiency without danger

'Dettol' can be used at really effective strengths without danger, discomfort or staining—a marked superiority over carbolic and cresylic antiseptics. It is thus a most useful disinfectant for first aid at home, for personal hygiene, and for gargling and bathing. 'Dettol' maintains high bactericidal efficiency in the presence of blood, pus and other organic matter, and is the antiseptic now widely used for all obstetrical purposes. 'Dettol' is a clean, clear fluid, non-poisonous and non-staining, with a distinctly pleasant smell.

ATLANTIS (EAST) LIMITED,  
20/1, CHETLA RD.,  
CALCUTTA.

'Steradent' is a modern scientific preparation for cleaning false teeth. The Dental Profession has endorsed the opinion that 'Steradent' cleans and purifies dentures as nothing else has ever done before. It is harmless to denture materials. It contains no free chlorine or acids. It is alkaline in action. Mucin film, tartar, stains, tarnish and all unsanitary accumulations are removed. Patients should immerse their dentures overnight in warm water in which Steradent powder has been dissolved.

cleans and sterilizes false teeth

**Initial course.**—The suggested initial course, combining the use of iodides, bismuth, mercury and arsenic, is as follows:—

- (1) Pot. iod. 10 grains three times daily for two weeks.
- Pot. iod. 15 grains three times daily for the following two weeks.
- Pot. iod. 20 grains three times daily for the succeeding two weeks.

(2) At the same time give two courses of mercurial injections:—Ung. hydrarg. (B.P.) 60 grains to be well rubbed in daily—on successive days into an arm, leg, or the trunk. A course to consist of twenty injections and the patient to have a week's interval between the two courses.

(3) After an interval of a week to start a course of novarsenobillon or stabularsan, or one of the trivalent arsenicals: eight weekly intravenous injections, starting with 0.3 gm., then 0.45 gm., and then six injections of 0.6 gm., with a total of 4 to 5 gm.

(4) After two weeks' interval follow with a course of bismuth—2 c.cm. or 3 grains twice weekly intramuscularly for twelve injections.

This course of treatment will take approximately six months and, unless there are contra-indications, it should be followed by two similar courses during the next two years and then one course yearly for the succeeding three years. If it is desired for practical reasons to shorten the course to four months then half the arsenic therapy may be given during the second month and the second half along with the bismuth during the third month. These courses may seem rather long and drawn out but the majority of the cases are not urgent and do not require initial drastic therapy.

I often think that we make our metallic onslaught in neurosyphilis too heavy and then rather tend to fall away, if immediate results are not produced. If we made a more gentle attack then I am sure both we and our patients would benefit. If one of the preparations gives adverse reactions, then this should be omitted from future courses. *It is extremely important to stress the fact that continuation of the treatment must be dependent on the clinical improvement of the patient.* There is no use continuing with anti-syphilitic treatment if there is no clinical improvement during the second course of treatment. It is clear therefore that we must be prepared to modify the dosage, the intensity of the treatment, the frequency and number of courses, and to discuss additional treatment—such as induced pyrexia—to meet the needs of special cases, and to vary the course when it is clear that the maximal incidence has been on the meningeal or vascular tissues or on the parenchyma.

#### SPECIAL CONSIDERATIONS IN TREATMENT

**Meningo-vascular.**—When it is not possible from the clinical symptoms and signs to decide whether the meninges or the vessels are more affected, then the above course should be given. When, however, the meninges are principally involved, then the arsenic injections may be started after the first fortnight or month and given concurrently with the iodides and the mercurial injections. In acute syphilitic meningitis the arsenical therapy may be started at the end of the first week. In the vascular syphilitic lesions, however, it is wise to postpone the arsenic administration for the full two months and then when the arsenic is given to make the initial doses small and increase them gradually—0.15, 0.15, 0.3, 0.3, 0.3, 0.45, 0.45, 0.6 gm., because of the liability to Herxheimer reactions.

Although there is a general impression that the prognosis in neurosyphilis is quite good, and particularly so in meningo-vascular syphilis, and although it is true if the meninges alone are involved that the outlook is good, yet the results are only too often disappointing when there is arterial obstruction and when there have been softenings, hæmorrhages, or tract degenerations.

**Tabes dorsalis.**—The lack of response in long-standing tabetics with marked ataxia and loss of weight or optic atrophy is often striking, whereas the results

are encouraging in those with a shorter history. Therapeutically, if there is no response to the initial course then tryparsamide should be given a trial—intravenous weekly injections with an initial dose of 15 grains, then 20 grains for twelve injections, in two courses of six injections with one month's interval. If the tryparsamide does not produce improvement then the advisability of thermotherapy must be considered. Only too frequently, however, in the chronic tabetic it is necessary to rely on general and symptomatic treatment, and attention to both of these aspects may gain the gratitude of patients, although the symptoms are by no means readily responsive to treatment.

**Bowels.**—Similarly the bladder must be emptied regularly—the call to micturition must be by the clock—every three hours. If the tendency is to true incontinence of urine then help will often be obtained by tinct. belladonnæ, 5 minims three times a day, but if there is atony of the bladder, with difficulty in passing urine and retention, then liq. strych. 5 minims should be given three times a day. Although there is for many reasons a natural desire to postpone catheterization as long as possible yet, on the whole, when retention develops or if the bladder becomes palpable, it is wisest not to delay the measure. The urine must be examined regularly for pus cells, and if present a course of urotropine and acid. sod. phos. prescribed, or if not effective, bladder lavage. Careful attention to the bladder function is stressed, for the life of the tabetic is constantly menaced by the possibility of cystitis or ascending pyelonephritis.

**Ataxia.**—Despite increased knowledge of the early symptomatology of tabes, yet only too frequently the symptom which causes the patient to seek advice is unsteadiness in walking. This ataxia may be much improved by training the patient to make greater use of his remaining powers, by concentrating his attention on his movements and careful re-education walking exercises. It is certain, however, that unless there is real effort and constant supervision or, on the other hand, if the physiotherapy is perfunctory and the treatment by the clock and in a large class rather than as an individual, then the results will be disappointing.

**Gastric crises.**—These are often extremely troublesome and resistant to all forms of treatment. If the patient is able to retain anything by mouth chlorotone, 10 grains in a cachet, freshly prepared may be tried. If this dose is not successful and there is no resultant depression of the heart and respiration, then 20 grains may be tried. Other measures which may be helpful are tinct. belladonnæ, 10 or 20 minims, or alternatively, adrenaline hydrochlor. 1 in 1,000 or atropine sulphate, grain 1/1,000 by injection.

A useful prescription is:—

Sod. bicarb.	..	..	10 grains
Acid. hydrocyan. dil.	..	..	3 minims
Liq. adren.	..	..	5 minims
Syr.	..	..	q.s.
Aq. chloroform	..	..	ad. ½ ounce

When the symptoms are still severe and anti-syphilitic and symptomatic measures have failed, thermotherapy or chordotomy must be considered. If the crises still persist then morphine may have to be used but it should only be as a last resort, for the danger of addiction in gastric crises and in lightning pains is very real.

**Lightning pains.**—Similarly these often make both the patient and practitioner desperate and here again morphine should be avoided. Veramon, 6 to 12 grains, is one of the most useful preparations, but it is generally best to ring the changes on the analgesics. Two useful prescriptions for severe cases are:—

Phenacetin	..	..	10 grains
Aspirin	..	..	10 grains
Heroin hydrochlor.	..	..	1/6 grain. Fiat pulv.

(The patient must not know the composition.)

or Medinal	..	..	10 grains
Codeine	..	..	½ grain
Phenacetin	..	..	10 grains. Fiat pulv.

Intravenous hypertonic saline, a single dose of T. A. B. vaccine or injections of stabilarsan have been employed with success, but have failed in many cases. Attention must be paid to warmth, constipation, and abstinence, for these are valuable auxiliaries in the treatment of this distressing state.

Perforating ulcers may be dressed with a paste of iodine and starch, but the only adequate treatment is complete rest to the foot. The tabetic should not cut his corns.

#### DEMENTIA PARALYTICA: INDUCED PYREXIA

The methods employed in the treatment of G. P. I. are: (1) anti-syphilitic as outlined above; (2) induced pyrexia—(a) malarial, (b) chemical—as with sulphosin, (d) physical, or as is generally advocated; (3) a combination of anti-syphilitic measures and thermotherapy.

Wagner-Jauregg introduced malarial therapy for G. P. I., and for some years this has been the method of choice in this country, so that figures for ten years (1927–1937) are now available from the Ministry of Health. There is no doubt that some striking results and remissions have been obtained, and that in a number of cases the improvement has been maintained, but it is equally true that many feel that the present position is somewhat disappointing, that the numbers of 'cures' are not so large as were expected and that there is a serious growing problem of the 'half cured' general paralytic.

Some years ago it was thought that the favourable results obtained with malarial therapy were due largely to the specific action of the malarial organism. Most of the recent evidence goes to show, however, that there is no especial virtue in malaria as such and that the method of induced pyrexia, which most consistently produces a sustained fever, will be most successful. If this is correct then the rivalry is between the malarial and physical forms of therapy. In the latter field several different methods have been advocated. It is now ten years since Neymann and Osborne of Chicago (1929) employed diathermy; since then, short radio waves—the radiotherm, the inductotherm, the Kettering hypertherm (using hot humidified air), or the Honsaker machine (using hot water vapour) have been employed. In this country this method has not received sufficient general attention but a series of careful investigations and observations have been carried out for some years by Nattrass and Evans in Newcastle. Nattrass recently communicated their results to the Medical Society of London. They have obtained good results with a simple hospital-made radiant-heat cabinet. This method has the merit of low cost, and a continuous record of temperature can be kept by an electrical rectal thermometer. (This thermometer cannot be used continuously when high-frequency currents are employed.) Other advantages were that there was relatively little discomfort and the patients were not made ill—as with malaria. There was no anaemia and no jaundice, and the fever could be precisely controlled. The fever is continued until the maximal clinical response has been obtained—an average of four to six pyrexias of 106°F. each lasting eight hours. For safe and effective treatment the staff should be specially trained and the work carried out in a special department. This pyrexial treatment must be supplemented by specific therapy; tryparsamide and bismuth seem to be of especial value. This should be given not longer than a month after the course of the fever; in general, it has been found too dangerous to inject the preparations at the height of the fever.

In comparing different methods of treatment in G. P. I. there is the difficulty that the groups of patients under review are often considerably different—the one in a mental hospital, and the other in private practice or attending a general hospital. The great disadvantage to malarial therapy is its mortality. Although the figures differ considerably, yet in most hands it is between 10 to 15 per cent. It seems clear that the mortality is lower when physical means are employed, and Nattrass reported that during the past

four years 213 patients with G. P. I. have been treated without a death.

The best results which I have seen in dementia paralytica have been obtained by giving the 'initial' course as outlined, followed by malarial therapy and then, after a three months' interval, by a course of six tryparsamide treatments given in the following manner:—

(1) A lumbar puncture is performed and the cerebro-spinal fluid is drained off.

(2) Then 30 c.cm. of hypertonic saline are given intravenously.

(3) After half to one hour the tryparsamide is given intravenously.

Hinsie and Blalock show that of the three methods—tryparsamide alone, malaria and tryparsamide, and electro-pyrexia and tryparsamide—the best results, clinically and serologically were obtained by the last combination. It is difficult therefore to decide at the present time which form of therapy to adopt in G. P. I. On the whole in a case of average severity and in which there is no especial urgency, I would suggest starting with the initial course—beginning the arsenical administration after the first two weeks whilst arrangements are being made for electro-pyrexia if available, or otherwise for malarial therapy, for in view of the mortality rate it is essential to discuss the position carefully with the relatives. Then as soon as possible—within a month of the physical pyrexia, and within three to six months after malaria—a course of tryparsamide and bismuth should be given.

It is still too early to be dogmatic about the relative merits of electro-pyrexia and malaria, but the evidence brought forward by Nattrass and Evans suggests that the former is the more effective and much safer. The methods of physical pyrexia require some co-operation on the part of the patient and therefore, in some cases, malaria must still be the method of choice. There are many who advocate that as soon as evidence is available by a cerebro-spinal fluid examination or clinical signs or symptoms that the nervous system is involved then pyrexial treatment should be instituted without delay. Had it not been for its associated mortality, malaria might already have been employed more generally and in the earlier stages. If Nattrass and Evans are able to continue to show that with care their method has no mortality, then it may well be that in five years' time, the routine treatment for neurosyphilis will be with electro-pyrexia, and one or more of the anti-syphilitic preparations.

## Reviews

**VIRUS DISEASES OF MAN.**—By C. E. van Rooyen, M.D. (Edn.), and A. J. Rhodes, M.B., Ch.B. (Edn.), M.R.C.P.E. 1940. Oxford University Press, London, Humphrey Milford. Pp. xxxv plus 932. Illustrated. Price, 65s. Obtainable from Oxford University Press, Bombay and Calcutta

THE immense amount of work that has been done on viruses and the discovery of many new ones in the last twenty or thirty years is indicated by the fact that it now needs a volume of 900 pages adequately to deal with those viruses which affect man only. Such a book is the one under review, and it is a product of the Department of Bacteriology of the University of Edinburgh.

The book opens with an interesting and instructive summary on viruses in general by Prof. T. J. Mackie and includes a discussion of the modern views on the probable nature of these bodies. This introduction ends with a list of thirty diseases of man definitely proved to be of virus origin. Others in which the aetiological connexion of viruses is strongly suspected, but is not yet proven, are not included in the book.

## SALPERN TABLETS

(Sodio Calcium Lactate with Vitamin D)

SALPERN TABLETS are specially recommended in the treatment of various forms of calcium deficiency such as chilblains, premature dental decay, rickets, and retarded bone development in children. They are easily administered, palatable, and do not upset the digestion.

SUPPLIED IN  
BOTTLES OF 50 TABLETS

## DÉCROSE

(Glucose with Vitamin D & Calcium Glycerophosphate)

DÉCROSE is of great value in the treatment of acidosis, cyclical vomiting in children, train, sea and air sickness, general nervous and physical debility, feverish conditions and liver damage.

DÉCROSE is especially suitable for expectant and nursing mothers, and is essential for growing children.

SUPPLIED IN  
1 lb. TINS

## THACKER, SPINK & CO. (1933), LTD.

POST BOX 54, CALCUTTA

The first ten chapters, occupying 120 pages are devoted to the practical study of viruses which embraces microscopical examination and measurement, staining, filtering methods, centrifugization, serological technique and methods of culture.

The remainder of the book is devoted to descriptions of the various diseases caused by viruses, together with a brief review of the important work connected with each of them and a full list of references at the end of each chapter.

This book can accordingly be described as a valuable compendium on the subject of virus diseases of man as it contains sufficient practical information on which to commence the study of viruses in the laboratory; it describes in adequate detail the different diseases caused by viruses giving historical facts when these are of interest and value, and it contains in its numerous lists of up-to-date references an exhaustive guide to wider reading on any special aspect of the subject. It can be recommended with confidence as a most valuable book for the acquisition of knowledge on any branch of virus disease in man.

It is plainly and strongly bound and is a credit to the authors and publishers.

P A M

**CLINICAL METHODS: A GUIDE TO THE PRACTICAL STUDY OF MEDICINE.**—By Sir Robert Hutchison, Bart., M.D., LL.D., F.R.C.P., and Donald Hunter, M.D., F.R.C.P. Eleventh Edition. 1940. Cassell and Company, Limited, London (La Belle Sauvage, E.C.4). Pp. xiii plus 622. Illustrated. Price, 13s. 6d.

The reviewer first learnt to value this book as an inseparable companion during his hospital work as a student; it was then in its third edition. Apart from the fund of information it contains one of its greatest claims to popularity is its convenient size so that it can be taken into the wards and clinical laboratories, and in spite of the numerous additions to clinical methods of investigation that are constantly being made this small volume is no larger than it used to be. To maintain their usefulness without increasing their size is an achievement which few of the regularly appearing medical books can claim. There are now many other publications of a similar nature to 'Clinical Methods' but none with which the reviewer is acquainted are its equal in value, and he feels he cannot give better advice to the student just beginning his hospital studies than to tell him that whatever calls there may be on his budget, the expenditure of the modest sum of thirteen shillings and sixpence needed to acquire this book is likely to prove one of the best investments of his student career.

**OBSTETRICS AND GYNÆCOLOGY.**—By Departmental Staff of the University of Chicago and other Contributors. Edited by F. L. Adair, M.A., M.D., F.A.C.S. Volumes I and II. 1940. Henry Kimpton, London. Pp. 1000 in volume I. Illustrated with 359 engravings and 14 plates. Pp. 1031 in volume II. Illustrated with 304 engravings and 10 plates. Price, £5-0-0.

This great work edited by Dr. Adair is the result of the combined efforts of 63 contributors and collaborators. No names, however, are associated with individual chapters or sections and it is indicated that such individual chapters may not always be the work of one contributor, but frequently the result of the efforts of a group.

By far the greater part of the two volumes is taken up with obstetrics in fact gynecology is considered as being of secondary importance.

The fact that several authors have taken part in the production of this work, of necessity makes for some re-duplication of descriptions, this however in no way detracts from its merit.

The general arrangement is somewhat different from that which is usual in most textbooks, in that a chapter on a gynecological complaint may be found between two chapters on obstetrical conditions. This

is a little surprising, but if the work be read as a series of articles in continuity, any difficulty will disappear.

A great amount of space is taken up with treatises on the correlation of the anatomy and physiology of the mother and foetus, the biology of human reproduction, and embryology. There are also extensive chapters on the effect of pre-existing disease on pregnancy. Heart disease and tuberculosis being especially well described, and excellent advice given.

All the above is very interesting reading and a change from the too-often-bald descriptions of many of the textbooks.

The volumes record the thought and teaching of the Chicago School based on the experience of many years.

While the Chicago School is dogmatic, and quite rightly so, in insisting on rigid attention to detail in every respect, it is extremely tolerant of the methods of other schools, and in its treatment combines many methods of proved value. As for instance in eclampsia, a method of treatment combining that of Stroganoff with venesection, and the Dublin School is the choice.

The Watkins operation for the cure of backward displacement of the uterus is advocated. This however is not popular with European gynecologists.

The appendices contain diet and other charts, food values, and quite a long dissertation on clinical pathology and bacteriology, and nursing.

The two volumes are a monument to a great effort which is meant to be a textbook. Thus it undoubtedly is, but there is a great deal more to it than a simple textbook.

H E M

**GREEN'S MANUAL OF PATHOLOGY.**—Revised and Enlarged by H. W. C. Vines, M.A., M.D. Sixteenth Edition. 1940. Baillière, Tindall and Cox, London. Pp. viii plus 1166, with 701 illustrations. Price, 31s. 6d.

This has been one of the standard textbooks on pathology for several generations of medical students in many parts of the British Empire.

It is stated in the preface that this edition has been somewhat enlarged and one of the reasons given for this change is to try and make it less academic than its predecessors. One of the changes is the omission of chapters on pure bacteriology and pure parasitology, 'as they should be studied in appropriate textbooks'. We wholly agree with this point of view, but consider that having left out these chapters it would have been better to have omitted the subjects altogether and referred readers to appropriate books on them, than to have given the totally inadequate and consequently often misleading statements that have been included. Let us take some random examples from the few pages devoted to animal parasites. The only intestinal protozoa mentioned are *Entamoeba coli* and *E. histolytica*, hookworm disease or, as it is now almost universally called, 'ankylostomiasis', is found under the out-of-date and strictly speaking incorrect name of 'Uncinariasis', and of flukes we are told, 'The only species commonly parasitic in man are *Distoma pulmonale* which is the cause of Asiatic distomiasis and the *Schistosomum hæmatobium* or *Bilharzia hæmatobia*'. These should suffice to support the reviewer's contention.

Another section of particular importance to students in the tropics are the anæmias, and this portion of the book is very disappointing as there is no attempt at a comprehensive up-to-date classification of these blood diseases nor is the modern nomenclature made use of to any extent.

Other sections, dealing with tissue changes in various diseases and the tumours which occupy the bulk of the book, are as good as they always have been and it is with real regret that the reviewer feels compelled to criticize so severely an old friend of his student days for serious shortcomings in certain small sections, but he has reviewed the book from the point of view of the student in the tropics and feels he cannot recommend it from this particular aspect.

**STANDARD METHODS OF THE DIVISION OF LABORATORIES AND RESEARCH OF THE NEW YORK STATE DEPARTMENT OF HEALTH.**—By Augustus B. Wadsworth, M.D. Second Edition. 1939. Baillière, Tindall and Cox, London. Pp. xxiv plus 681. Illustrated with 39 plates and 55 figures. Price, 41s.

THE issue of the second edition of this well-known book on standard methods will be welcomed by all who are familiar with the first edition published in 1927 and which soon established a reputation as a standard work on laboratory technique. Those who have had many occasions to refer to it for guidance and instruction will find the second edition even more valuable than its predecessor. A considerable amount of revision has been made and by segregating in one section—'on general laboratory procedures' the technical details of methods common to different branches of the work, the author has succeeded in including important new material without increasing the size of the book—in fact the new edition is a few pages smaller than the first. This in our opinion is a distinct advantage and avoids a considerable amount of repetition of technical details, and has resulted in a much clearer description, which gives to a better understanding of the different procedures.

Although there are available many books on technical methods there is not one quite like this one, not one that contains so much information, not one which will be referred to quite so often by laboratory workers engaged in routine work in clinical laboratories, or in research work or in the preparation of sera and vaccines on a commercial scale. Administrators of laboratory service will find in this book much that will be of great help in planning laboratory procedures to suit their particular needs. This is a book that should be in the hands of every bacteriologist for it is certain that it will be constantly referred to and be of inestimable help. It is both a 'desk and a bench book'.

C. L. P.

**ACUTE INFECTIOUS DISEASES: A HANDBOOK FOR PRACTITIONERS AND STUDENTS.**—By J. D. Rolleston, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), F.S.A., and G. W. Ronaldson, M.D. (Glas.), D.P.H. (Oxon.). Third Edition. 1940. William Heinemann (Medical Books), Limited, London. Pp. ix plus 477. Price, 17s. 6d.

THE third edition of this book has been revised and enlarged, the main additions being chapters on erysipelas and isolation methods. There are no illustrations as the senior author considers that 'the only satisfactory place to study the cutaneous lesions of the acute exanthemata... is at the bedside'. No doubt this is the correct attitude to adopt for students, but many doctors like to refresh their memories before going to the bedside.

Full descriptions of the acute infectious diseases commonly seen in Britain are to be found in this book, including a very small chapter on the fourth disease.

The chapters on typhoid and paratyphoid fevers are of particular interest to practitioners in India and are exceedingly informative. The chapter on typhus deals with the classical, louse type only and for that reason is of limited value to those who deal with this somewhat complex group of fevers in the tropics.

Tropical infectious diseases such as cholera and plague are not included.

The book is written in a very pleasant and interesting way, and one can readily find all the information one requires. The treatment advocated is up to date and yet conservative.

It is one of the best books of its size on the subject of infectious diseases and as such can be thoroughly recommended.

J. G.

**LANDMARKS AND SURFACE MARKINGS OF THE HUMAN BODY.**—By L. Bathe Rawling, M.B., B.Ch. (Cantab.), F.R.C.S. Eighth Edition (New Terminology). 1940. H. K. Lewis and Company, Limited, London. Pp. viii plus 98, with 36 illustrations. Price, 8s. 6d.

THE first edition of this book appeared in 1904 and since then it has been the accepted guide of each successive generation of medical students. The new edition is sure to receive a great welcome from past and present students alike. The author's adoption of the British Revision of B. N. A. Terminology, now generally in use, will meet with approval.

In the past this book was chiefly used by the young surgical dresser but, under the new regulations of the Calcutta University, it will be found to be of great use to the pre-clinical anatomy class. The printing, binding and illustrations are all excellent.

P. N. R.

**INJECTION TREATMENT OF HERNIA, HYDROCELE, GANGLION, HÆMORRHOIDS, PROSTATE GLAND, ANGIOMA, VARICOCELE, VARICOSE VEINS, BURSAE AND JOINTS.**—By P. Riddle, B.S., M.D., F.A.C.S. 1940. W. B. Saunders Company, London. Pp. ix plus 290, with 153 illustrations. Price, 27s. 6d.

INJECTION therapy is rapidly approaching a status which may confer upon it the dignity of a special subject. It is, however, necessary to emphasize that this method is not applicable in all cases and that in certain special cases it will not give as good results as surgery. The author has made an attempt here to include all those conditions to which injection therapy is applicable. This may be seen from the long list which is appended to the title of the book.

There are four parts in this book and at the end of each part there is an extensive bibliography. The first two parts deal with the injection treatment of hernia and varicose veins respectively, with adequate discussion of pathology, ætiology, complications and contraindications. In the third part there is a very good treatise on hæmorrhoids. The last chapter of part three, on the varicose theory of anal fissure, fistula and pruritus, will be found instructive. The final part is devoted to the consideration of an interesting medley including such subjects as hydrocele, varicocele, bursæ and joints, and the prostate gland.

We have no doubt that this book will be of use to the general medical practitioner and also to the general surgeon. The printing, get-up and illustrations are all very good but the price (27s. 6d.) will place the book out of reach of the man of moderate means.

P. N. R.

**ENDOCRINE GYNÆCOLOGY.**—Edited by E. C. Hamblen, B.S., M.D., F.A.C.S. 1939. Baillière, Tindall and Cox, London. Pp. xxviii plus 453. Illustrated. Price, £1 10s.

THIS book of 453 pages is concerned with the isolation and the synthetic preparation of endocrine glands, together with their therapeutic uses.

It is true that much of the subject-matter of the book has already appeared in various journals.

Dr. Hamblen has however collected and tabulated all this information into one volume, so that the reader may be enabled to find all information sought for, without having to search through various monographs.

There are numerous charts and graphs illustrative of the text.

The author must be congratulated upon the exhaustive study he has made into the early history and literature relative to the discovery of each of the endocrines and hormones.

The bibliography is very extensive and thorough. The book is well printed, and contains several good plates and many excellent photomicrographs.

## Five Ingredients with a Single Purpose

The five ingredients of Cal-Bis-Ma have but a single purpose—prompt, efficient and prolonged gastric neutralization. Sodium bicarbonate and magnesium carbonate are responsible for the quick effect; calcium carbonate, bismuth and colloidal kaolin prolong this effect. There is no secondary acid rise from this combination, and no distension, because gas is absorbed by the colloidal kaolin present. The irritated mucous membrane is soothed and protected by bismuth and kaolin. The therapeutic action is always the same because the ingredients are of matched density and are held together in a colloidal base. A trial supply is always at your disposal. Write for it on your letterhead.

**PHYSICAL TREATMENT BY MOVEMENT, MANIPULATION AND MASSAGE.**—By J. B. Mennell, M.A., M.D., B.C. (Cantab.), etc. Fourth Edition. 1940. J. and A. Churchill, Limited, London. Pp. xiv plus 669, with 281 illustrations including 32 plates, 8 in colour. Price, 25s.

Physical treatment in recent years has progressed in great strides owing to new additions to our knowledge of the physiology and biochemistry of living tissue. The first edition of this book was published in 1917, during the last Great War, but it was not intended to serve as a textbook for the massage student. The author's principal object was to place in the hands of his professional brethren a book to which they could refer when issuing instructions to their masseurs. The present edition fulfils the same object in greater measure.

There are altogether 32 chapters comprising 653 pages of reading matter, and the book deals with every condition for which physical treatment is indicated. Few will disagree with the statement that 'the masseur is born and not made'. Much has been written on the personal attributes desirable in those who undertake massage work; perhaps the first is that they should have suffered illness or injury themselves and have undergone a course of treatment. One eminent physician once said that he frequently ordered physical treatment to be carried out by a blind masseur but that if any one would introduce him to a dumb masseuse he would employ her all the time. It is the old story that 'the tongue is a smaller member but it is capable of inflicting unlimited harm'. So is tact a small word, but may well be the greatest asset to the masseuse. 'A smiling face oft masks a breaking heart' in the masseuse, but if it does so the patient should never be conscious of it. The choice of the masseuse, therefore, is of great importance in physical treatment. The chapters on medical gymnastics will be read with pleasure and profit, and those on backache are worthy of careful attention.

This book on physical treatment, now in its fourth edition, speaks for itself. We have much pleasure in recommending it to our colleagues. It will be useful to members of all branches of the medical profession. The printing and illustrations are of high quality and there is a useful index.

P. N. R.

**SURGERY OF THE HAND.**—By Marc Iselin, M.D. Translated by T. M. J. d'Offay, M.B., Ch.B. (Edn.), F.R.C.S. (Eng.), and T. B. Mouat, M.D., Ch.M. (Edn.), F.R.C.S. (Eng.). 1940. J. and A. Churchill, Limited, London. Pp. xiv plus 353, with 135 illustrations including 8 plates. Price, 21s.

This is a valuable monograph on wounds, infections and closed traumata of the hand by a well-known French surgeon. The translators deserve our best thanks for having made the book available to English-speaking people. In the author's preface to the English edition there is a poignant sentence which, in the light of recent history, makes tragic reading. 'The unhappy time of its publication prompts me to express the hope that it will help our British colleagues who are in the services to spend profitably those long hours of waiting that characterize this war.' It is dated March 1940, from the French Field Army.

This book consists of four parts, of which the first deals with wounds of the fingers and hand. The last chapter is devoted to the consideration of social problems arising out of such wounds. The author emphasizes the fact that the whole future of the patient is dependent on the first operation, which ought to be done as soon as possible. In part II there is a very instructive description of infections of the hand. The author does not exaggerate in stating 'that the great majority of complicated cases that we have had to treat have been incised elsewhere'. Closed traumata of hands and fingers are discussed in part III. The author's aphorism that 'the examination of closed

traumata of the hand and fingers is a radiographic examination' is worthy of note. The last part consisting of only six pages is a very important section, dealing as it does with assessment of incapacity.

This book has been described as a book for the practitioner and the surgeon. We strongly recommend it to our colleagues, who will certainly find it very useful in their everyday practice. The printing and illustrations are excellent, and a useful index is appended.

P. N. R.

**PROTOZOOLOGY.**—By Richard R. Kudo, D.Sc. (Enlarged and Completely Re-written Edition of 'Handbook of Protozoology'.) 1939. Baillière, Tindall and Cox, London. Pp. xi plus 689, with 291 illustrations. Price, 36s.

THIS is a book which deals with protozoology as a whole with the result that the comparatively few protozoa of interest to medical men and veterinarians tend to be rather submerged in a mass of protozoa of no medical or veterinary interest.

The book is only a handbook, so the descriptions of the various parasites are very short on account of limitations of space, and on this account the descriptions of the haemosporidia and trypanosoma pathogenic to man and animals are much too meagre for a medical man who has to deal with these parasites. One thing we were pleased to note, is the distinction between the genera *Entamoeba* and *Endamoeba* is recognized, a distinction not usually found in books of American origin.

Although of undoubted value for those who are undertaking the study of protozoology as a whole, it is felt that this book will not be of as much use to medical and veterinary students as one of the many books available that are devoted solely to the protozoa of importance as parasites of man and his domestic stock.

**OUTLINE OF PHYSIOLOGY.**—By William R. Amberson, Ph.D., and Dietrich C. Smith, Ph.D. 1939. The Williams and Wilkins Company, Baltimore. Pp. vii plus 412, with 177 figures. Obtainable from Messrs. Baillière, Tindall and Cox, London. Price, 22s.

THIS little volume has been written for students as an introduction to the study of physiology. In the early chapters the authors have dealt briefly with the modern physical and chemical concepts which the students of physiology are required to know. These ideas have been presented in a lucid style and will be of benefit to beginners. The inclusion of historical facts has made study of the book very interesting. The subject-matter in all the different sections has been written in a simple manner and as far as possible controversial points have been omitted. Details which are unnecessary for beginners have also been avoided and only the broad outlines and basic principles have been dealt with. The section on nervous integration of physiological function deserves special mention. The schematic diagrams are very helpful. Here also the fundamental points only have been presented, making the subject easily intelligible to a beginner.

P. D.

**NOTTER AND FIRTH'S HYGIENE.**—Revised by L. C. Adam, M.B., B.S., and E. J. Boome, M.B., Ch.B., M.R.C.P., D.P.H., T.D. Tenth Edition. 1940. Longmans, Green and Company, Limited, London. Pp. x plus 518. Illustrated. Price, 12s. 6d.

THIS is the tenth edition of a textbook originally published in 1894, the ninth edition of which came out in 1921. Consequently, as a well-known work, 'Notter and Firth's Hygiene' deserves due attention. However, the presentation of the subject conforms so much to the now outmoded approach to public health as a social welfare field that little can be said to recommend the

book for use in countries foreign to that of its publication. The factual material is relatively comprehensive and modern but so much of it is irrelevant to the daily routine of a Health Officer himself, particularly in India, that the book cannot be recommended for this country. In fact, textbooks on Public

Health Engineering and Microbiology, which to-day constitute the essential of every Health Officer's work-library, present most of the material in a more effective manner than the summary constituting the bulk of this text.

## Abstracts from Reports

### THE ROCKEFELLER FOUNDATION, NEW YORK: A REVIEW FOR 1939. BY RAYMOND B. FOSDICK, PRESIDENT OF THE FOUNDATION

THIS year, owing to the rapid and stupendous changes that the war has brought to the whole of Europe, it is not possible to give an adequate abstract of the work of the Rockefeller Foundation as it has been further so greatly interrupted and disorganized since the report was written that the greater part of the report as far as Europe is concerned is altogether out of date.

We accordingly give below a short section from this report which is a valuable essay on recent achievements in scientific advancement and the dark future ahead of the world should European civilization go under.

#### DIVIDED WE FALL

One occasionally hears the statement that the trend of intellectual leadership is westward across the Atlantic. In proof of the assertion specific fields are mentioned, such as neuro-surgery, astronomy, dentistry and perhaps orthopedics, in which America has won pre-eminent standing. But this argument overlooks the many fields in which leadership, certainly until the war began, was still in Europe and the many others in which genius and stimulation are as potent on one side of the ocean as on the other. In physiology, for example, it would be difficult to determine whether the leadership lies in Europe or in the United States. The same is true of anatomy and pathology. In fields like pharmacology, tropical medicine, ophthalmology, legal medicine, social medicine and dermatology—to mention only a few—leadership is unquestionably still in Europe, or was in 1939. In mathematics, the English are indisputably pre-eminent in analytic number theory; the Russians are making important contributions in topology and probability, the French in algebra. America cannot match the group of European scientists in the important fields of enzyme chemistry and the organic chemistry of natural products. Nowhere else in the world can one duplicate or even approach the co-ordinated and co-operating Scandinavian group which is focusing so many precise techniques of chemistry and physics on problems of biology.

If one is tempted to question the vitality of science in Europe, it is interesting to note that the most dramatic scientific development of the year 1939 originated there, i.e., the splitting of the atom of the heavy element uranium and its transmutation into barium and other light elements. This realization of the old dream of the alchemists was based upon results obtained in 1934 by the Italian physicist Fermi; but the disintegration products of uranium were first directly observed in 1939 by Hahn and Strassmann of Berlin.

America needs to be humble about this question of intellectual leadership. In spite of the anxiety and insecurity abroad during these recent years, of the six Nobel prizes awarded in science in 1939, five went to Europe and one to the United States. In countless ways we are dependent upon Europe for stimulation and leadership in relation to many segments of our intellectual and cultural activity.

If because of war-exhaustion or chaos the universities and laboratories of Europe should be forced to suspend their fundamental activities for even half a decade, the consequences to the intellectual life of America would be immediate and disastrous. For scientific

growth is almost invariably the result of cross-fertilization between laboratories and groups in widely separated parts of the world. Only rarely does one man or one group of men recite with clear, loud tones a whole important chapter, or even a whole important paragraph, in the epic of science. Much more often the start comes from some isolated and perhaps timid voice, making an inspired suggestion, raising a stimulating question. This first whisper echoes about the world of science, the reverberation from each laboratory purifying and strengthening the message, until presently the voice of science is decisive and authoritative. Thus, in the case of the break-down of uranium during the past year, the early tentative questionings came from Rome; they were caught up at Berlin, were eagerly heard at Paris and Copenhagen, and then spanned the Atlantic and were seized upon here so enthusiastically that literally within hours, rather than within days, the critical experiments had been checked and extended at Columbia University, at the Carnegie Institution of Washington and in Lawrence's laboratory at the University of California.

Similarly, the amazing development and application of sulfanilamide—that beneficent gift to mankind—has been the result of a collaboration in which flags and boundary lines have been non-existent. The first hint of it was discovered in Germany, oddly enough in connection with the commercial dye industry, and the drug was given the name prontosil. With this hint as a basis, in 1935 a German scientist—Dr. Gerhard Domagk—published the results of his experiments with mice under carefully controlled laboratory conditions, showing the extraordinary effect of prontosil on streptococcus. The Pasteur Institute in Paris then picked the matter up, and subjecting prontosil to organic analysis discovered that its activity was localized in one distinctive part of its molecular structure. This potent factor in prontosil, separated from the rest of the molecule, is what we now know as sulfanilamide. At this point Queen Charlotte's Hospital in London, with a grant from the Rockefeller Foundation, tried the drug on women suffering from streptococcal infection associated with puerperal or childbirth fever, immediately reducing the death rate from such infections by 25 per cent. The Johns Hopkins School of Medicine was the next institution to carry forward the experiments, and in the last three years research on this drug has been developed, with brilliant results, in laboratories and hospitals on both sides of the Atlantic.

Achievement in science, more often than not, is the result of the sustained thinking of many minds in many countries driving toward a common goal. The curative spirit of man cannot successfully be localized or nationalized. Ideas are starved when they are fenced in behind frontiers. The fundamental unity of modern civilization is the unity of its intellectual life, and that life cannot without disaster be broken up into separate parts. If, as a result of the present cataclysm on the other side of the Atlantic, Europe freezes into an Arctic night, we shall not easily keep the fires lit in the universities and laboratories of America.

### ANNUAL REPORT OF THE MALARIA INSTITUTE OF INDIA FOR THE YEAR 1939

THE activities of the Malaria Institute of India are many and varied. Its functions are to advise the

# Physiological action of **BOVRIL**

---

## **Restoring normal gastric secretion after illness**

In a recent series of tests on human beings,\* it was found that Bovril possessed exceptional power of stimulating gastric secretion, surpassing that shown by any other substance studied, and that the secretion was of normal hydrochloric acid content.

This is the physiological reason why Bovril should be considered an important adjunct to medical treatment.

Following most acute illnesses there is commonly a depression of gastric secretion, and the secretion is poor in hydrochloric acid. In such cases Bovril helps by stimulating the gastric mucosa and restoring the gastric juice to normal, both in volume and activity.

# HEPOL L.Y.H.

TRADE MARK

Hepol L.Y.H. is a preparation of which each fluid ounce contains the extract from four ounces of fresh liver, the equivalent of forty grains of dried yeast, and an ample amount of hæmoglobin.

Liver extracts are specific for various macrocytic anæmias. Our liver extract is rich in vitamin B<sub>12</sub>.

Yeast is a rich source of the B vitamins. A yeast extract has been found effective in tropical macrocytic anæmia and in moderately severe cases of ordinary pernicious anæmia.

Hæmoglobin, being an organic compound of iron, does not produce the gastro-intestinal symptoms that are sometimes produced by inorganic preparations of iron. Animal or vegetable sources of iron are recognized as desirable constituents of the diet in simple anæmias.

*Descriptive literature will be sent on request.*

and at 37 Lombard St., London E.C.2

## TORCH BRAND Glucose D

*Manufactured by Allen & Hanburys Ltd.*

Torch Brand Glucose D (with Orange and Calcium) is pure medicinal glucose to which have been added orange juice, calciferol (vitamin D) in the form of irradiated ergosterol and calcium glycerophosphate. The orange juice gives the preparation a pleasant flavour that is lacking in uncompounded glucose, which often needs flavouring with fruit juice to make it acceptable to the patient. Most foods contain more than one of the factors (calorific substances, vitamins, and salts) that are necessary for normal health; and lack of one such food in the diet may lead to a deficiency of more than one food factor. It is, therefore, not surprising that, in many cases of debility, symptoms suggestive of underfeeding and rickets are combined.

Milk contains sugar, calcium, phosphorus and vitamin D; so that, if a child refuses milk, he may not obtain enough of any of those food substances; but Torch Brand Glucose D contains them all.

**ALLEN & HANBURYS LTD.**  
(Incorporated in England)

CLIVE BUILDINGS, CALCUTTA  
And at 37, Lombard Street, London, E.C.3

Central Government and, where required, Provincial Governments and local bodies on all matters connected with malaria control, to carry out systematic research into the epidemiology and control of malaria and the bionomics of mosquitoes, to train medical officers in malariology, to act as a central bureau for the issue of publications dealing with malaria and mosquitoes and generally to advise and assist malaria workers throughout India. Close contact is maintained with malaria workers in other countries, both by correspondence and by the exchange of publications.

A six weeks' course in malariology for medical men is held annually at the field station, and many of the officers so trained are now doing valuable work in various parts of India. Nearly 300 students have undergone this training since the organization was first formed in 1927.

There are now thirteen publications produced by officers of the Institute in the Government of India Health Bulletin series. In addition to providing information for malaria workers throughout India, these publications are particularly valuable for teaching purposes, since they are kept continually up-to-date by the frequent issue of new editions.

An important function of the Institute is the testing of the various larvicides and insecticides which are used in malaria control work. Pyrethrum, which forms an essential ingredient of all insecticides, is now being grown successfully in this country, excellent results having been obtained with flowers grown in Kashmir, Kulu and the Nilgiri Hills. It is confidently expected that India will shortly be able to produce sufficient pyrethrum for her own needs and that an efficient insecticidal spray will eventually be made available at a comparatively low price. In this work, close contact has been maintained between the Malaria Institute and the Imperial Council of Agricultural Research.

The intensive anti-malaria campaign now in progress in Delhi urban area is being greatly facilitated by the recent transfer of the field station of the Institute from Karnal to Delhi.

The Delhi campaign is being carried out under the supervision and direction of the Malaria Institute. Three successive years of deficient rainfall render it impossible to assess with accuracy the value of the results achieved. Emphasis is laid on the fact that eradication of malaria from Delhi could only be achieved by converting the whole countryside into a barren desert but, states the report, it is confidently expected that as a result of this campaign the disease will no longer seriously affect the city's activities, as was formerly the case.

Officers of the Malaria Institute have been called upon to give advice regarding the rural anti-malaria schemes which have been initiated in various provinces as the result of a grant made by the Government of India. Field research units of the Institute have been working in the Wynaad, South India, and in the Terai district of the United Provinces in collaboration with two of the rural schemes. A third field research unit is carrying out investigations in Orissa in the vicinity of the Chilka Lake.

Laboratory researches include a number of important investigations on monkey malaria, of which several strains have been maintained. These have proved of great value for teaching purposes as well as affording abundant material for research work. Valuable results have also been achieved by the application of the precipitin test to mosquito blood meals. By this means it can be ascertained whether a particular species of mosquito feeds habitually on man or on cattle.

The report of the entomologist contains an account of a number of investigations regarding the life history and habits of various species of mosquitoes. Many collections of mosquitoes and other insects were received for identification during the year from all parts of India.

## ANNUAL REPORT OF THE PHYSIOLOGICAL SOCIETY OF INDIA, 1939

THE society is now 5 years old, being inaugurated in July 1934. It is said that the 5th and 6th years of the existence of a scientific institution of this type is the most critical period in its life. This period represents a time when the original enthusiasm and urge of the founders has largely subsided and its activities are at their lowest ebb. Unless this critical period is tided over, it is very difficult to anticipate the future growth and development of an organization. This is therefore the time when all those interested in the progress of physiological sciences in this country— young and old, senior and junior—should join together and find out ways and means through which the activities of such a highly useful scientific body as the Physiological Society of India may be properly co-ordinated and strengthened. Though our record of last year's work has not been imposing, we think we can at least congratulate ourselves that the Physiological Society has passed through the last few years with commendable zeal and vigour. If this enthusiasm, particularly on the part of the junior group of members, is kept alive, there seems to be every reason to hope that the society will maintain its career as a useful and active organization and will continue to provide a forum, as in the past, for the scientific deliberations of a wider fraternity of workers in general and applied physiology, pharmacology, biochemistry and other cognate sciences.

As provided for in the constitution, the Annual Science Congress Meeting of the Society was held this year at the physiological lecture theatre of the Madras Medical College. One of the Vice-Presidents of the Society, Colonel R. N. Chopra, presided. A number of delegates from various parts of India attended this meeting. This shows that interest has now been created amongst physiologists for an all-India organization and the time seems to be opportune for the society, if it has to justify its all-India character, to make a bold drive and increase its activities in all directions.

At this meeting at Madras, Prof. N. M. Basu and Dr. B. Mukerji explained to the members and guests the aims and objects of the society and asked for the co-operation of all workers engaged in the ever-widening field of physiological science in India to form branch societies in at least some of the bigger centres of academic work, so that a stimulus may be given to the younger generation of workers to present the results of their research work much more frequently than is possible now. Reviews of recent advances in knowledge of the various branches of physiology and cognate sciences may also be presented at these meetings. A system of close contact and active liaison could be easily maintained between the parent body and the newer branch organizations by correspondence and all the deliberations and lectures at the branch organizations could be printed in the Proceedings of the Society to be issued from Calcutta. The seeds for branch organizations have already been sown through our persistent advocacy of the cause of the society at the Lahore Session of the Science Congress in 1939, and at the Madras Session in 1940, and if one may judge from the responses received, it should be comparatively easy now to water them sufficiently so that they can sprout and come to full bloom. Only then will the society begin to fulfil its object of helping to develop physiological research and studies all over this country.

Our difficulties are varied and many but the possibilities are great and far-reaching. We can look back to the few years of our existence with pride and pleasure, but the society has not yet attained that status and prestige which all its promoters would like it to occupy in India. This is therefore not the time to sit idle and happily contemplate what we have already achieved, but all the members and office-bearers should put forward their best efforts to make the society a really all-India one in the true sense of the term. Only then will the aims and objects of the society come to be fulfilled and its existence

Our difficulties are varied and many but the possibilities are great and far-reaching. We can look back to the few years of our existence with pride and pleasure, but the society has not yet attained that status and prestige which all its promoters would like it to occupy in India. This is therefore not the time to sit idle and happily contemplate what we have already achieved, but all the members and office-bearers should put forward their best efforts to make the society a really all-India one in the true sense of the term. Only then will the aims and objects of the society come to be fulfilled and its existence

justified. We are optimists and believe that there are men in this society with foresight, ability and leadership who can make this an accomplished fact. The lamp that has been kindled at Calcutta must throw its light throughout India. This may be considered an ambitious project but can be accomplished if the members of the society, amongst whom there are many leaders in Indian scientific circles, have the will to do it, and if active co-operation amongst them can be ensured.

In conclusion, we wish to thank all those who helped the society with their co-operation by communicating their papers and attending the meetings, and to the authorities of the various institutions where our meetings were held.

#### REPORT ON THE WORKING OF THE PUNJAB MENTAL HOSPITAL, LAHORE, FOR THE YEAR 1939

THE total number of patients under treatment at the Punjab Mental Hospital during the year under report was 1,299 against 1,235 in the preceding year. The daily average attendance was 1,038 and the maximum number on any single day was 1,058, of whom 843 were men and 215 were women. In order to remove the congestion in the female section and to provide for the growing needs of the hospital it was decided to build a double-storeyed block to provide additional accommodation for 100 female patients. The work was taken in hand during the year under report and has now been completed.

The number of patients who died in the hospital during the year under report was 47, compared with 32 in the previous year. The larger number of deaths was due to the fact that several patients newly admitted to the hospital were in an extremely bad state of health and could not survive for more than a few days. There were no cases of suicide, of death by violence or accident. The number of patients who were discharged from the hospital as cured was 112 against 84 in the previous year; while the practice of handing over harmless and chronic patients to their guardians was also resorted to more freely than before.

Excluding a sum of Rs. 45,363 spent on 'original works' the expenditure by Government on the maintenance of the hospital was Rs. 3,10,727 compared with Rs. 3,08,054 in the previous year. A sum of Rs. 2,04,294 was recovered from local bodies and the receipts from paying patients and other miscellaneous receipts amounted to Rs. 27,342. The net cost to Government was, therefore, Rs. 79,091.

Lieutenant-Colonel C. J. Lodge-Patch, M.C., I.M.S., who was the Medical Superintendent of the Hospital proceeded on leave on the 20th July, 1939, and Dr. R. S. Sharma, P.C.M.S., Deputy Medical Superintendent, was appointed to officiate for him.

#### ANNUAL REPORT OF THE NATIONAL ASSOCIATION FOR SUPPLYING MEDICAL AID BY WOMEN TO THE WOMEN OF INDIA (COUNTESS OF DUFFERIN'S FUND INCLUDING THE WOMEN'S MEDICAL SERVICE) FOR THE YEAR 1939

##### THE COUNTESS OF DUFFERIN'S FUND AND WOMEN'S MEDICAL SERVICE

THIS year owing to unavoidable re-investment of funds at lower rates of interest, the recurring income of the Countess of Dufferin's Fund amounted only to Rs. 33,000 approximately, instead of the usual Rs. 40,000. It was spent as usual on grants to Provincial Dufferin branches and hospitals as well as scholarships to medical students, 15 of which are available at the Lady Hardinge Medical College, Delhi, four in Bombay, three in Calcutta, and two in Madras. Of these, 14 are awarded from association funds and the rest from trust

funds under the council. The Gilchrist Trustees gave their annual grant of £150 for six of the Lady Hardinge Medical College scholarships, for which the council desire to record their cordial thanks.

The great events of the year have been the opening of the new Dufferin Hospital in Calcutta in March by Lady Reid, and that at Amraoti in August. They are both very satisfactory buildings, but it is much to be regretted that the Calcutta Hospital Committee has not had funds at its disposal to meet the urgent need for an up-to-date nurses' home, and the nurses have had to be allotted part of the hospital itself as quarters, so lessening the accommodation available for patients and the income from rent and fees. The accommodation for medical staff has also proved inadequate, as the new hospital needs an increased staff and private wards have had to be set aside for their use, again to the detriment of hospital receipts. It is much to be hoped that public interest will be aroused sufficiently for funds to be collected to remedy these defects at an early date.

Amraoti on the other hand has provided very satisfactory accommodation for both its nursing and its medical staff, and is to be congratulated on its well-planned buildings.

Emphasis still needs to be laid on the great need for improvement in the nursing staff and the quarters provided for them in many of the hospitals. We can only repeat what has been said so many times before, that if the nursing profession is to take an honourable and leading place in the life of the country, then educated girls of good family must be willing to come forward in larger and larger numbers to train, and the local committees must see that the conditions of living are suitable for them, and they must not be expected to live in quarters grossly overcrowded or only fit for menials.

The financial condition of the Dufferin Hospitals as a whole is not satisfactory as so many are having a precarious existence owing to lack of endowments and local support, although their work is being more and more appreciated by the patients who come in increasing numbers and are willing to take any bed even on an open verandah rather than go on to whatever general hospital exists in the neighbourhood, this giving clear evidence that although the 'purdah' habit is breaking down in many districts, the demand for hospitals staffed only by women is stronger than ever and will remain even if 'purdah' should completely disappear.

It is to be regretted that the public still seem slow to realize the fact that medical relief, according to modern western methods, is expensive, and if they wish to obtain the services of highly qualified and experienced doctors such as the W. M. S. officers, and take the treatment required, they must be willing to contribute something towards the expenses in proportion to their resources. It is found that many middle and better class patients insist on occupying free beds in the general wards, though paying rooms are available, and at the most give a small donation to the poor box on leaving, even after confinements or operations, and so prevent the really poor from benefiting fully from the facilities offered. Most of the hospital committees are not willing to give the medical officer in charge authority to refuse admission to free beds to such patients and, in fact, often encourage the practice, with the result that the hospitals are in a chronic state of financial distress. Modern India, like other countries, needs to assimilate the fact that it can only afford free medical treatment to the really poor, and the general public must make a change in their attitude towards medical relief and be taught not to expect free advice and treatment unless they are really paupers. Only when this comes about will the hospitals be placed on a satisfactory basis.

The members of the Service maintained their reputation for efficiency during this year in spite of discouraging conditions, poor financial support and therefore limited staff, in many cases, and the fullness of their hospitals speaks well of their appreciation by those who so readily seek their aid.

## HEADACHE IS DISABLING

Headache may be as disabling as a grave illness. In migraine particularly, the headache is of all degrees of intensity, at times so severe as completely to incapacitate the sufferer. It is noteworthy how quickly the patient can obtain relief with Veganin. Composed of minimum doses of acetylsalicylic acid, phenacetin and codeine, Veganin affords striking proof of the superior analgesic potency of this synergistic alliance over that of its components administered separately. Recurrent painful conditions, such as migraine and dysmenorrhœa, yield with impressive promptness to the efficacy of Veganin.

# VEGANIN TABLETS

Supplied in tubes of 10 and 20. Veganin is not advertised to the public.

*A trial supply to Physicians on request.*

**MARTIN & HARRIS LTD.**, Mercantile Buildings, Lall Bazar, Calcutta.

Also at Bombay, Madras, Karachi and Rangoon.

Prepared by **WILLIAM R. WARNER & CO. LTD.**, LONDON, ENGLAND.

ber, 1939, of Captain J. G. Stonham, an officer the Indian Medical Service (Civil), lately in civil employment in Burma.

The Secretary of State for India has appointed Captain M. S. Zan to the Civil Branch of the Indian Medical Service, with effect from the 4th August, 1939, the date of his transfer to civil employment in Burma.

The services of Captain J. Guthrie, an officiating Surgeon, are replaced at the disposal of His Excellency the Commander-in-Chief, with effect from the 4th June, 1940.

On transfer to the Punjab, Captain H. H. Mahmood assumed charge of the office of Superintendent, Central Jail, Lahore, on the forenoon of the 10th July, 1940, relieving Lieutenant-Colonel G. A. Khan, Superintendent, Borstal Institute, and Medical Officer, Juvenile Jail and Female Jail, Lahore, of the additional charge.

#### PROMOTIONS

##### *Colonel to be Major-General*

#### RETIREMENTS

Captain S. P. Wauchoo. Dated 7th May, 1940.

Major G. J. Smith. Dated 3rd December, 1939.

## Notes

### CENTURIES OF USE

MEDICATION which has been in use for centuries—in fact since the earliest recorded periods of history—and still continues to have the most widespread use, must be looked upon, not so much as medication that has 'proved' itself, but as one of Nature's fundamental curative measures. Reference is made to the use of heat. Of the many forms of heat therapy available to the medical profession, physicians will find Antiphlogistine one of the most useful. It combines both prolonged moist heat and supporting medication.

### RUTONAL

RUTONAL has the same general therapeutic uses as phenobarbital and is employed as an anti-convulsant, anti-spasmodic and sedative in the treatment of epilepsy, petit mal and other conditions in which central nervous system sedation is required. Compared with phenobarbital it has been found in clinical practice that, weight for weight, Rutonal has an activity in the order of about half that of phenobarbital while it is less than half as toxic. It would appear that Rutonal, in therapeutically equivalent dosage, is a more potent anti-epileptic than phenobarbital, whether in epilepsy of the Jacksonian or of the idiopathic type. In the majority of patients Rutonal appears to be better tolerated than phenobarbital, being less liable to give rise to diurnal somnolence, lassitude and mental depression.

The booklet on Rutonal includes a selection of clinical reports on the use of this drug in a number of cases of epilepsy and copies may be obtained by members of the medical profession on request to Messrs. May and Baker (India), Limited, 11, Clive Street, Calcutta.

### 'HYPOLOID' MERSALYL

THE addition of 'Hypoloid' Mersalyl to the range of products issued by Burroughs Welleome and Co. provides the medical profession with a highly effective diuretic preparation for administration by intramuscular injection. The product consists of a 10 per cent solution of the sodium salt of salicyl-( $\gamma$ -hydroxymercuri- $\beta$ -methoxypropyl)-amide-O-acetic acid, with 5 per cent theophylline, which exercises a stabilizing influence on the mercurial complex and also tends to enhance its therapeutic effect. 'Hypoloid' Mersalyl is a valuable diuretic in oedema of cardiac or renal origin. It is particularly effective in the treatment of cardiac failure with oedema and diminished output of urine, and is frequently successful when digitalis and other diuretics fail. The product is issued in 'Hypoloid' ampoules of 1 c.cm. (in boxes of 10) and 2 c.cm. (in boxes of 5).

## Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

### A SCHEME OF CONTROL OF TUBERCULOSIS IN INDIA BY 'ORGANIZED' HOME TREATMENT

By C. FRIMODT-MÖLLER, C.B.E., M.B.,  
Ch.B. (Copenhagen),

*Medical Commissioner to the Tuberculosis Association  
of India*

EVERYONE who is acquainted with the conditions in India will probably admit that it is an extraordinarily difficult task to draw up a scheme for the control of tuberculosis in this vast country.

On the one side, there is a desire to introduce an ideal campaign, but against this have to be placed deplorably inadequate financial resources and other facilities for such a campaign, and nothing would handicap any campaign more than failure by an attempt to do the impossible. On the other side, there is often a surprising lack of understanding of how best to use such resources and facilities as are already available.

To have any real possibility of success, a scheme for combating tuberculosis in India must have duly balanced the object aimed at and the resources of money and personnel available, measures of prevention and measures of treatment, isolated anti-tuberculosis activities and a united front for tackling the whole tuberculosis problem.

The necessity for drawing up a balanced scheme is also brought home by a study of anti-tuberculosis activities in the West. There it will be seen that the tuberculosis policy has sometimes shown a swinging tendency and when it has swung out too far to one side by over-emphasis on certain aspects of the campaign then a set-back in that campaign has resulted. Naturally the campaign began with the attempt to treat all who suffered from tuberculosis in its manifest forms. When it was found that it was impossible to control the spread of the disease in this way, there came, in some responsible quarters, a period of disparaging institutional treatment as superfluous and too expensive, and all the emphasis was laid on raising the standard of living, improving hygienic conditions and educating the people about the nature of the disease by wholesale propaganda. But in spite of actual raising of the standard of living, of improving hygienic conditions and of wholesale propaganda in certain countries, the disease did not show the decline that was expected.

The result of this is that in some countries tuberculosis policy has swung back to treatment and isolation, but this policy goes now much further than it did before for two reasons: firstly, the discovery that there are many people suffering from tuberculosis with bacilli in the sputum who themselves do not know that they

are sick and therefore sources of infection to others, and, secondly, the technique of diagnosis has so improved that it is possible to find these preclinical sufferers from tuberculosis and to treat them. The finding of such 'carriers' is done through scientifically carried out tuberculosis surveys working from tuberculosis clinics equipped with all necessary facilities for this purpose.

Although the changes in the tuberculosis policy seemed at times to be even antagonistic, especially when there was overemphasis by their supporters, the general effect has, nevertheless, been not antagonistic but supplementary, and the present campaign in the West has drawn on all that was valuable in the various policies and has, in consequence, developed into a comprehensive, balanced and effective scheme. The war against tuberculosis utilizes every measure which can contribute its share to the defeat of the enemy. The tuberculosis policy is therefore now one of co-operation of state, local bodies, private bodies and the general public, with legislation, insurance measures and systems of more-or-less compulsory treatment and prevention.

#### *A balanced tuberculosis policy for India*

It is of no avail whatever to think that a balanced tuberculosis policy for India can be obtained by adopting that of the West. It is not only that the financial resources are so much smaller in India than in the West, but it is also that, even were considerable funds available, some of the other measures and facilities are lacking out of all proportion for a scheme on western lines to succeed in India.

What is the use, for example, of introducing compulsory notification of all tuberculous cases with compulsory modern treatment when the existing facilities for such treatment are completely negligible. In a country such as Scotland there is one bed for the treatment of tuberculous patients to each 900 of the population, which is almost enough for the treatment and isolation of all infectious cases. The lack of facilities for such treatment and isolation in India is fully borne out by the following figures. In Bombay presidency, where there is, proportionately to the population, the largest number of beds for tuberculous patients, there is one bed to about each 40,000 of the population; in the province of Assam with a population of more than 9,200,000 people there is not a single bed set aside for tuberculous patients, according to the *Indian Medical Review*, 1938.

Again, to take another example, even if sufficient beds and institutions could be made available, there is a great scarcity of doctors specially trained in modern methods of the treatment of tuberculosis and in dealing with the many aspects of the problems created by the disease.

In order to work out any tuberculosis policy for India it is therefore necessary to review not only the prevalence of the disease, but also the

existing anti-tuberculosis activities, and the resources available of both money and men. We have to keep in mind both the immediate campaign and the development of the campaign for the future, the creation of facilities for providing trained personnel, the place institutions are to have in the scheme, and the preventive measures which can and ought to be introduced with a reasonable prospect of adequate results.

In a country such as India where a raising of the general standard of living is likely to take generations and where, at the same time, the disease is on the increase, and the facilities for institutional treatment constitute the merest fraction of the enormous numbers of tuberculous patients, the emphasis in the control of tuberculosis must of necessity be on a campaign which concentrates all its efforts on striking at the real cause of the spread of the disease which is only one, namely, the source of infection.

The main object of the campaign must, therefore, be to search out the tuberculous patients in order to fight the disease where it exists and spreads. All efforts and resources must be directed to the anti-tuberculosis measures which will be particularly suitable for this object and which have already proved of value under Indian conditions. To these should be added only those other measures which can easily be adopted and developed and which can help to support the main campaign.

As it is beyond all possibility to construct even a small proportion of the tuberculosis hospitals and sanatoria necessary for institutional treatment of the two to five millions of tuberculous patients supposed to be suffering in India from active disease and needing treatment and care, there is no other way but to try to reach and help hundreds of thousands of the most dangerous sources of infection in their own homes by introducing organized home treatment and such other measures as would prevent them from spreading the disease to others.

#### *Organized tuberculosis home treatment*

Under the prevailing circumstances in India no tuberculosis policy which is balanced according to resources and measures available can be considered an ideal one. For a long time to come it will be useless to attempt such a scheme, but one must be content with the introduction of any scheme which from a practical point of view has a real prospect of success in reducing the death rate from tuberculosis and bringing substantial relief and cure to those who are suffering from this disease.

There is no reason to hide the fact that it has been clearly demonstrated in the West that institutional treatment and isolation of tuberculous patients bring far better results than any home treatment. But when institutional treatment on a large scale cannot be introduced, we need not stand idle or helpless when we can

concentrate our efforts on a scheme of control which will be immensely more effective than what is being done at present. If such a scheme could be successfully introduced it will be for the future to improve it when it becomes possible to do so, and to develop it along the lines which all would agree to be ideal.

It should be clearly understood from the very beginning that the scheme is not control by ordinary home treatment of the disease, but it is a scheme of control by 'organized' home treatment of tuberculosis which is quite a different thing. The word 'organized' implies the application of as much as possible of the modern specialized treatment and prevention to thousands of homes where at present patients are often left alone without any treatment whatever and without any preventive measures.

#### *Outline of the scheme*

There are five main measures or activities essential for a successful working of such organized home treatment, and the scheme as a whole, as well as its individual parts, will be considerably weakened even to the point of being useless, unless all the five measures are available and properly linked up as one chain of measures.

The five main activities are :—

- (a) The tuberculosis clinic.
- (b) Institutional treatment for a certain number of selected patients.
- (c) Close co-operation between the clinic and private practitioners.
- (d) Care and after-care committees to work in connection with the clinics and other tuberculosis institutions.
- (e) Colonies or settlements for tuberculous ex-patients.

#### *The place of institutions in the scheme*

It would be a great mistake to think that in the scheme of control of tuberculosis by organized home treatment there will be no place for tuberculosis institutions. Without such institutions the whole scheme would fail. They are the foundation for it and they form the basis from which the modern specialized treatment and prevention are to be carried into the homes.

On the other hand, the construction of a few more tuberculosis clinics, hospitals and sanatoria with a few thousand more beds is in fact, from a practical point of view, of no consequence whatever for an effective campaign, if the beds are to be used, as in the West, for the full course of treatment of pulmonary tuberculosis and for isolation of very infectious cases. But, if the institutions are established as a definite link in the chain of measures constituting organized home treatment, the increase of the number of beds now available even by only a few thousands is of the utmost importance to the whole campaign. The problem now to be tackled in

this connection is not the immediate construction of as many tuberculosis institutions as possible, but only as many as are absolutely necessary for the scheme in question without crippling the other measures equally essential for a successful working of a balanced scheme of organized home treatment and prevention. The necessity for the various kinds of tuberculosis institutions and their particular place in the scheme needs a brief explanation.

### *The tuberculosis clinic*

The tuberculosis clinic must have as its object prevention and, to a certain extent, treatment.

It is not necessary to go into detail about the various measures of prevention which the clinic should introduce in the homes of patients under the supervision of the doctors treating the patients, but two measures of prevention need to be mentioned.

One is the tuberculosis survey to be conducted by the clinic. Only by this is it possible to detect many persons carrying on their work and having tubercle bacilli in their sputum. The discovery of such carriers and the diagnosis of tuberculosis is a preventive measure of the greatest importance. In every large city in India there should be a tuberculosis clinic equipped with all modern facilities for diagnosis (a matter not always easy), which could be a consulting institution also for the doctors in the city.

The other measure of prevention needing mention is treatment which a clinic in India must give under the present circumstances. Artificial pneumothorax may be given as an example. By introducing this treatment, and in co-operation with the private practitioners controlling its effect, a great number of patients will be helped to get better in their homes, and approximately half of them will cease to have tubercle bacilli in their sputum and so cease to be sources of infection to others, while being treated in their own homes.

### *Hospital wards and sanatoria*

It is now possible by certain chest operations to cure many advanced patients in whom all other treatment has failed. These operations cannot be performed in a clinic but only in a fully-equipped tuberculosis hospital or sanatorium. The treatments referred to are, for instance, such operations as thoracoplasty, extra-pleural pneumothorax and other special operations, as well as treatment of spontaneous pneumothorax, certain forms of empyema, and other complications of various kinds. In the scheme of 'Control of Tuberculosis by Organized Home Treatment' these institutions therefore have their place.

In or near every large city there should be such a tuberculosis institution with 100 to 200 beds, but these beds should be reserved only for patients in need of the special treatment which cannot be given in their homes or in the

clinics, and after the special treatment the patients should return home for further treatment by the medical practitioners in consultation with the clinic doctor. In this way a small number of beds can become of the greatest value and play an indispensable part in the campaign.

These tuberculosis wards and sanatoria are also of great importance for the teaching and training of doctors. Without them the doctors in the city or province would have no opportunity of learning the modern methods of treatment and prevention for application in their practice. Teaching should, therefore, be given through post-graduate courses in these institutions and in the clinics.

### *Facilities for training of specialists*

For the training of tuberculosis specialists each province or larger state should have a well-equipped central sanatorium with at least 200 beds. Patients should be admitted to these institutions for their whole period of treatment and not just for the time of special treatment. Apart from the value to the patients themselves it is necessary that the doctors under training should follow the treatment from beginning to end. Only in such an institution will the doctors be able to get experience in all modern measures of treatment and prognosis of pulmonary tuberculosis.

It is, moreover, in such an institution that the best opportunity is found for research work on tuberculosis from the point of view of remedies against the disease, and such research work is indispensable in a place where specialists are trained.

Only doctors who have had long training and experience in such central institutions should be placed in charge of tuberculosis wards or sanatoria. These teaching sanatoria are best situated away from large cities in good climatic conditions.

### *Co-operation between clinic doctors and private practitioners*

No anti-tuberculosis campaign anywhere in the world has succeeded without close co-operation between the clinic and the private practitioners. The private practitioner must come to understand that the clinic is his best help and if this is to be so all competition between the two must be avoided. The clinic doctor should not be allowed private practice but should be compensated in this respect. Close co-operation with the clinic will increase the reputation of the private practitioner as the public will soon discover that his patients receive better and more specialized treatment.

Special arrangements will need to be made for poor patients who cannot afford to pay any fee to private practitioners. Unless these patients also are reached the campaign cannot succeed. The doctors who visit these patients, of whom there will be many, should have some

remuneration. This should be done through a care and after-care committee in connection with the clinic. This committee should pay a small fee to the doctor who visits and treats the poor patients, but only on the recommendation of the clinic doctor. He will assure the committee that the patient is really suffering from tuberculosis, that the patient is receiving the best treatment possible under the circumstances and that the proper preventive measures are being carried out in the home.

#### *Care and after-care committees*

Besides the work of a care and after-care committee in maintaining a close connection between the clinic and the private practitioner in caring for very poor patients already mentioned, it has other important functions. Among these are, helping the poor patient and his family either by food or by money, helping to isolate children from sick parents by placing them with relatives if possible or by caring for them in open-air shelters in day-time, and in finding suitable employment for patients restored sufficiently to work.

For expenditure connected with such work the care and after-care committee will need a fund. When it is seen that the most effective way of distribution of help to tuberculosis patients is through such a committee working in close co-operation with the clinic and other tuberculosis institutions, it will come to be realized that the committee should receive grants from Government and local bodies as well as subscriptions from the public. Support given to such a committee is not merely a charity but is also a self-defence against the disease.

#### *Colonies for tuberculous ex-patients*

There are always a number of patients who have very little hope of being able to maintain the good results of treatment when again exposed to the strain of their old conditions. They break down, and as tubercle bacilli usually reappear in their sputum, they become once more a source of danger to those among whom they live.

It is now more and more being recognized all over the world that in many patients the ultimate results of treatment depend to a great extent on the after-care, and that without this, much of the expenditure of skill, time and money in treatment is wasted. In the effort to help this class of patients various after-care schemes, such as colonies for ex-patients, have been brought into being. Experience has shown that a colony for ex-patients succeeds only when linked with a sanatorium and is justified only if it develops as a part of a combined institutional scheme.

The financing of an ex-patient's colony depends, of course, on the size of the scheme, but it is not impossible to introduce such colonies in India if adapted to existing conditions. There is already evidence to show that the beginning

of a colony in India can be made at a very low cost and that one may develop to be self-supporting, or nearly so, in maintenance expenditure. Such a colony should be constructed in simple village style with ordinary village houses only slightly altered to make them more open.

There are two great principles behind a colony, namely, medical help at hand for the colonists and work which give financial security for them.

A scheme of prevention would not become fully successful without such ex-patients' colonies. They should therefore be introduced gradually in connection with each large sanatorium.

#### *Propaganda*

In closing it is necessary to say a few words about propaganda in the campaign.

There are two kinds of propaganda which should be kept separate and which cannot be done at the same time.

The first and most important kind is the propaganda where the sick are found to be. It should concern only education of the patients and the persons in contact with them, with regard to the nature of the disease and the prevention of its spread among them. Such propaganda should, of course, stress the seriousness of the disease but it should not be overdone so as to frighten the people.

The second kind of propaganda is just as important for the whole campaign but is of a totally different type. This is the education of the general public through those sections of it which are able to understand it and benefit by it, such as colleges, schools and reading rooms and through activities such as the press and radio.

Such propaganda is very important in the beginning of the campaign. It will take a long time before it will be possible to see results of it, and there may be much disappointment and even many disappointing results. It is under these circumstances that a well-led propaganda campaign should set in and counterbalance any discouragement. It may be necessary to draw attention to that in the earlier stages of the campaign because the disease now hidden will come to light, it might seem that the disease is rather increasing than decreasing as the demand for treatment will be so much greater and more pressing than before. It should be explained that such a situation is really encouraging as it shows that the campaign is actually getting to grips with those problems which need solution first of all, and which need a general co-operation of all concerned to meet them satisfactorily.

#### *Co-operation*

The campaign in India will never succeed without something of that co-operation which in the West has brought so striking a decline of the death rate from tuberculosis. In the

(Continued at foot of opposite page)

## CHRONIC NON-TUBERCULOUS INFECTIONS OF THE LUNG

By A. C. UKIL

*Head of the Department of Chest Diseases, Medical College Hospitals, Calcutta*

### Introduction

CHRONIC non-tuberculous infections of the lung often simulate pulmonary tuberculosis in symptomatology, physical signs, clinical manifestations and even x-ray findings. Symptoms like cough, expectoration, dyspnoea, fever, pain in the chest, loss of weight, hæmoptysis, changes in the fingers and nails and signs arising from pathological changes, such as chronic catarrh, exudation, consolidation, excavation, fibrosis and the implication of pleural membranes, can be produced by non-tuberculous infections of the upper air passages, bronchial tubes and pulmonary parenchyma. There are cases in which pulmonary tuberculosis in an active or quiescent state and a non-tuberculous lesion due to other infections may be combined together.

The symptoms for which the patient approaches the doctor may be principally or entirely due to the non-tuberculous lesions. Wrong labelling in such cases may cause much inconvenience, mental worry and economic loss, by delaying or jeopardizing their recovery. To the general physician, as well as to the chest physician, a correct diagnosis, which can be obtained from a common-sense consideration of the history, physical examination, laboratory and x-ray investigation, is, therefore, of the greatest importance. To him, the first problem is to establish whether pulmonary tuberculosis exists or not; the next, in case pulmonary tuberculosis is present, whether it can explain the patient's symptoms and signs. In case he rules out pulmonary tuberculosis, he is confronted with the differential diagnosis of the pathological changes in the lung, and of the symptoms and other abnormal findings. The difficulties in diagnosis are increased when non-tuberculous lesions are unilateral and located in the upper lobe. In children giving a positive tuberculin test, the difficulties in diagnosis are further increased. Provided, however, a careful history

of the case is taken, clinical observations are carried out, x-ray and appropriate laboratory studies are made, a correct diagnosis can be established in most cases.

### Frequency

During the years 1938 and 1939, out of a total number of 14,052 new cases who attended the out-patients' section of the chest department of our hospital, only 3,111 or 22.1 per cent were labelled as pulmonary tuberculosis. 8.5 per cent of cases showed evidence of chronic bronchitis, 1.04 per cent of bronchial asthma, 0.5 per cent of bronchiectasis, and there was a small percentage that included pulmonary abscess, influenza, syphilis, pulmonary neoplasm, hydatid disease of the lung and pneumonocystosis. In 60 per cent of the cases, no lesions in the lungs could be demonstrated, which might interpret the symptoms. Some of these cases might have been due to foci of infection in the upper air passages or disease elsewhere than in the lung. It may be mentioned that all new cases attending the department are examined by fluoroscopy and that 88 per cent of the above cases were examined by radiography.

In a series of 1,877 non-tuberculous pulmonary disease cases admitted into the indoor medical wards of the Calcutta Medical College Hospital, where naturally serious cases are more commonly admitted, during the years 1937-39, the following incidence was noticed :—lobar pneumonia—647, bronchopneumonia—405, simple bronchitis—243, bronchial asthma—233, chronic bronchitis with emphysema—104, influenza—210, bronchiectasis—13, pulmonary abscess—18, pulmonary gangrene—1 and secondarily infected carcinoma of the lung—3.

In a series of 1,135 cases examined by me in my consultation chamber, where every case is examined under the x-ray screen and 95 per cent of the cases have been investigated by radiography, the following incidence was found :—pulmonary tuberculosis—50.5 per cent, chronic bronchitis, including bronchial asthma—11.8 per cent, bronchiectasis—3.4 per cent, pulmonary abscess—0.18 per cent, secondarily infected pulmonary neoplasm—0.15 per cent, cases in which no pulmonary lesions could be elicited—34 per cent.

In a series of 700 cases with chest manifestations and diagnosis reviewed by Dunham and Skavlem (1927), out of 574 cases admitted with a diagnosis of pulmonary tuberculosis, the diagnosis had to be changed in 166 (28.9 per cent) of the cases. Of these 166 cases, 72 were labelled as chronic bronchitis, 17 as bronchiectasis, 14 as heart disease and 6 as miscellaneous diseases outside the chest. Over 70 per cent of the cases of bronchitis and bronchiectasis were secondarily infected from infective foci in the upper air passages, indicating a close association between infection in the upper air passages and the lung.

*(Continued from previous page)*

West co-operation is a factor which now works automatically, co-operation between the tuberculosis institutions and the public as well as their doctors on the one hand, and on the other between the tuberculosis institutions and Government, local bodies, and voluntary tuberculosis associations.

In India such co-operation does not yet exist, but there is no reason not to work for it, and it is certain at least that it will never come into existence unless we work for it, determined to see it through. On this depends, ultimately, the success of all our efforts in fighting the disease on a nation-wide front.

In another series of 195 cases of pulmonary tuberculosis in America (Chapman, 1928), 57 per cent of whom consulted more than one physician, a wrong diagnosis was made in the following order (in patient's own words):—bronchitis—33, run down—19, influenza—17, non-tuberculous pleurisy—15, colds—8, pneumonia—5, nervous break-down—4, nervousness—4, spots on the lung—4, throat trouble—3, asthma—3, bad tonsils—3, tonsillitis—3, anaemia—3, catarrh—2, non-tuberculous laryngitis—2, intercostal neuralgia—2, ulcer of the stomach—2, overwork—2, weak lungs—2, no disease, cigarette cough, stomach cough, typhoid, intestinal 'flu', chronic (non-TB) ulcer of ear, chronic appendicitis, post-operative weakness, sinusitis, mastoiditis, thyroid trouble, elongated palate, weakness, rheumatism, whooping cough, (non-TB) rectal abscess, myocarditis, neurasthenia, hookworm, shell shock, spinal meningitis, catarrh of stomach and strained vocal cords—1 each.

#### SOME CHRONIC PULMONARY INFECTIONS WHICH MIGHT BE CONFUSED WITH PULMONARY TUBERCULOSIS

##### 1. *Unresolved lobar pneumonia and its sequelæ*

Acute caseous tuberculous pneumonia which is liable to be and sometimes is confused with lobar pneumonia, especially when the upper lobes are involved, need not be considered here, but some of the sequelæ of the latter, such as delayed resolution with prolonged convalescence, 'apical catarrh', abscess, bronchiectasis, chronic pulmonary fibrosis and empyema, may give rise to symptoms and signs which are likely to be confused with chronic pulmonary tuberculosis and pleural effusion of tuberculous origin.

True lobar pneumonia generally does not cause any actual destruction of tissue and leads to prompt resolution, but in caseous tuberculous pneumonia destruction of tissue is much more marked and cavity formation takes place. Not until the stage of destruction do tubercle bacilli appear in the sputum. In cases of delayed resolution of lobar pneumonia, the mottled x-ray appearance is not unlike that of tuberculous infiltration. But a carefully recorded history, clinical observation, x-ray investigation and blood and sputum tests help us to make an accurate diagnosis.

##### *An illustrative case*

H. S., Punjabi Hindu male, 43 years, transport worker.

*Clinical history.*—In February 1939, had pneumonia of right lung, followed by recovery. In May 1940, had again pneumonia of the right lung. Patient first attended the chest department on 11th June, 1940, with a history of cough, expectoration, fever 99°F. to 102°F., pain in right chest and dyspnoea on exertion for a month since the attack. Sputum was negative for tubercle bacilli thrice, even by concentration method. Sedimentation rate of red cells—88 mm. at end of first hour.

*Physical examination.*—Increased vocal fremitus, impaired resonance and râles over the upper and middle zones of the right lung. The appearances of the chest skiagram taken on 11th June, 1940, are shown in

figure 1, which shows extensive mottling, more marked in the lower zones, not unlike tuberculous infiltration but more homogeneous. This appearance and the negative sputum led us to label the case as delayed resolution in pneumonia and accordingly a course of M. & B. 693 was given. The patient became free from symptoms and signs within two weeks. The appearances of a skiagram taken on 5th July shows (figure 2) the clearing up of the mottled area. The diaphragm is also slightly raised owing to fibrosis.

The naso-pharyngeal investigation showed a deviated septum with spur, hypertrophy of the turbinates, septic tonsils and chronic pharyngitis.

##### 2. *Some sequelæ of broncho- or lobular pneumonia*

Although the acute condition is generally due to a mixed infection with pneumococcus, streptococcus, staphylococcus, bacillus influenzae, bacillus of Friedlander and *Micrococcus catarrhalis*, the cases due to streptococcus and influenza bacillus are more liable to become chronic, thus simulating changes more commonly met with in the bronchopneumonia of tuberculous origin.

In the more acute cases, one might have to differentiate between typhoid and paratyphoid fevers. In milder cases, where the duration extends beyond three or four weeks, one is required to differentiate between tuberculous and non-tuberculous cases. The age, location and distribution of the lesions, repeated sputum examination (stomach-wash sediment in infants and children), blood and x-ray examination, besides clinical observation, should be taken into consideration in arriving at the diagnosis.

##### 3. *Chronic bronchitis of infective origin*

Recurrent attacks of acute bronchitis, often due to secondary infection from the upper air passages (tonsils, adenoids, nasal sinuses), damage the bronchial mucosa and walls and make them more vulnerable to further attacks until the condition becomes chronic. Climate and season seem to have some influence in precipitating or perpetuating attacks, winter and the rainy season being considered unfavourable. The relationship of atmospheric conditions to the production of these physical abnormalities is not well understood but recent work done in France indicates that alterations in ionization of the atmosphere may create an imbalance in the neuro-vegetative system and may aggravate the effects of infection already present.

In a large majority of cases of chronic bronchitis (93 per cent in our series), septic conditions have been found in the naso-pharynx, and/or nasal sinuses. In Dunham and Skavlem's series (*loc. cit.*) 72 per cent showed infection in the upper respiratory tract. In most of these cases of chronic nasal infection, there is postnasal discharge. From the way tracheally introduced lipiodol travels down the bronchi into the bronchioles and pulmonary tissues, there is no doubt that in these cases septic material trickles down the tracheo-bronchial passages and keeps up the bronchial catarrh. The routine examination of the nose and throat

and x-ray examination of the nasal sinuses are, therefore, important in investigating a case of chronic bronchitis.

The infective material in the bronchial tubes produces a chronic cough with a variable amount of expectoration, occasional fever during acute exacerbations or a long-continued low type of afternoon fever, occasional streaks of blood, a substandard state of health and some degree of dyspnoea in cases of bronchospasm and emphysema. The damaged bronchial walls may lead to dilatation of the tubes and peribronchial changes, producing various types of bronchiectasis. Usually most cases follow an incompletely recovered acute bronchitis but there are many in whom the course has been chronic from the commencement. In children with enlarged tonsils and adenoids, along with cough, an under-developed condition is presented. These symptoms should be enough to induce the patients to suspect pulmonary tuberculosis and promptly to seek medical aid but actually the delay is much longer than is anticipated. In a series of 1,200 cases that attended the chest department of our hospital and in 134 of my private cases, the following figures have been obtained:—

Duration	Hospital series	Personal series
Below 1 year ..	877	76
Between 1-3 years ..	134	31
" 3-5 " ..	73	12
" 5-10 " ..	78	8
Above 10 " ..	38	7

#### Age and sex distribution

**Age.**—Out of 1,200 hospital cases, 72 were below 10 years, 200 between 10 to 20 years, 441 between 20 to 30 years, 275 between 30 to 40 years, and 212 above 40 years. Among 134 cases in my personal series, 13 cases were below 10 years, 20 between 10 to 20 years, 49 between 20 to 30 years, 26 between 30 to 40 years and 16 above 40 years.

**Sex.**—More males attended the department with chronic bronchitis than females. Thus, in the hospital series, 957 males and 243 females were diagnosed, while in my personal series, 99 males and 35 females were diagnosed as chronic bronchitis.

Five to ten per cent of the bronchitis cases came with complaints of bronchospasm or bronchial asthma. It has already been pointed out that quite a large percentage of these cases showed the existence of septic conditions in the upper respiratory tract. How far the infective element was responsible in the production of the condition it is difficult to say, but in a fair number of cases the attacks begin with 'colds' or influenza-like onset, with or without some fever. The question of genesis and pathology of these cases in this country is far from settled,

but a few laboratory investigations carried out may be of interest.

Nine out of the 1,200 cases in the hospital series showed evidence of some degree of bronchiectasis by lipiodol bronchography. Only one case showed tubercle bacilli in the sputum without any evidence of parenchymal infiltration. Two cases had a syphilitic origin, both being relieved by anti-syphilitic treatment. In investigating the cases of chronic bronchitis, radiography was utilized in 30 per cent of the hospital cases and 97 per cent of my private cases.

**Sputum.**—The sputum is usually muco-purulent and in cases of putrid bronchitis it may have an offensive odour. The sputum may be intimately mixed or streaked with blood. The bacterial flora present shows mainly streptococcus, *Micrococcus catarrhalis*, some diphtheroid bacilli, staphylococcus, Friedlander's bacillus, bacillus influenzae and pneumococcus. In ulcerative and putrid bronchitis, a specific group of anaerobic micro-organisms, of which spirochaetae (*T. microdentium*, *T. macrodentium*, *S. vincenti*, *S. bronchialis*), fusiform bacilli, vibrios and cocci are the most important, are often present.

**Blood changes.**—A variable degree of eosinophilia is present in a large percentage of cases. Out of 366 cases in which a diagnosis of chronic bronchitis was made at the out-patients' section of the chest department, the percentage of eosinophile cells and the incidence of eosinophilia is shown in the following table:—

TABLE

Percentage of eosinophiles	PERCENTAGE INCIDENCE	
	Hospital cases	Private cases
Under 5 ..	55	11
5 and under 15 ..	24	40
15 " " 25 ..	6	9
25 " " 40 ..	6	11
Over 40 " ..	9	29

Eosinophilia was more pronounced in cases with less than three years' duration than in more chronic cases and particularly marked in cases with a duration of less than one year. Acton and Dharmendra (1933) noticed a high blood eosinophilia in bronchitis cases infected with a group of Gram-negative bacilli allied to Friedlander's bacillus or *Eberthella phaffi*. They (Acton and Dharmendra, 1933a) also noticed a shift to the left in Arneth count and a high Arneth index in cases of infective bronchitis. Napier and Dharmendra (1936) observed that, in these cases, auto-vaccine therapy brought about a reduction of the shift to the left in Arneth count.

It may be pointed out, in this connection, that there is a large group of cases in which the blood eosinophilia is not marked but in which

## PULMONARY TUBERCULOSIS AND DIABETES MELLITUS

By P. V. BENJAMIN, M.B., B.S. (Mad.), T.D.D. (Wales)

*Medical Superintendent*

and

M. C. VERGHESE, M.B., B.S. (Andhra)

*First Assistant, Union Mission Tuberculosis Sanatorium,  
Arogyavaram, near Madanapalle, South India*

It is generally recognized that the incidence of tuberculosis in diabetics is higher than in the general population. Root and Bloor (1939) found that in a series of 1,659 diabetic patients in a Boston (U. S. A.) hospital, 2.5 per cent showed also active pulmonary tuberculosis, which was probably about five times as great as would be expected in the non-diabetic population.

It is also recognized that when pulmonary tuberculosis develops in a diabetic, it is of a serious type, and some workers have estimated that when diabetics develop pulmonary tuberculosis, 70 per cent die of the tuberculosis.

In this paper we shall review a series of 157 patients with both diabetes and pulmonary tuberculosis, who were found among 7,205 patients treated in the Union Mission Tuberculosis Sanatorium, Arogyavaram, between 1918 and May 1940.

### *Sex and age incidence*

Of the 157 cases, 133 were men, and 24 women, but no deductions can be drawn from the wide difference in these figures, although the difference is considerably greater than that in the number of men and women patients in the institution.

The age incidence among the 157 patients with both diabetes and tuberculosis is shown in table I.

(Continued from previous page)

Dr. I. Ellias, medical registrar, Medical College Hospital, Calcutta, for kindly compiling the figures of cases in the medical wards for me.

It will be seen from the table that only 34 or 21.7 per cent of the diabetic patients were below 35 years of age and that comparatively few cases of diabetes were found among the tuberculous patients in the same age group—namely, only 34 out of 5,707 (0.59 per cent). Above the age of 35, there are 123 diabetics out of 1,175 tuberculous patients (10.46 per cent). According to our experience, therefore, diabetes is frequently associated with tuberculosis after the age of 35, and should always be looked for in the older tuberculous patients.

### *Relationship between the onset of pulmonary tuberculosis and diabetes*

It has been found in our series of 157 cases that 115 (73.2 per cent) gave a definite history of diabetes prior to the onset of pulmonary tuberculosis. In 38 (24.2 per cent) cases their diabetic condition was not known, and no investigation for diabetes was done prior to admission into the sanatorium for the treatment of pulmonary tuberculosis. In two cases diabetes was recognized only six months after the onset of pulmonary tuberculosis, and in two cases diabetes and pulmonary tuberculosis were diagnosed simultaneously. These findings support the view held by many that, where both diseases co-exist, in the majority of cases diabetes antedates the onset of pulmonary tuberculosis. In the 115 cases where diabetes was recognized before the onset of pulmonary tuberculosis, the period of diabetic life before tuberculous affection was recognized was as follows:—

TABLE II

*The period of onset of diabetes before that of tuberculosis*

Length of period	Number	Percentage
Four years and below ..	73	63.5
Above four years ..	42	36.5

PLATE XIV  
CHRONIC NON-TUBERCULOUS INFECTIONS OF THE LUNG

Fig 1

Fig 2.

Fig 3

Fig 4

Fig. 8.

Fig. 9.

*Descriptions—*

Figs 1 and 2—Delayed resolution in pneumonia.  
Fig 3 and 4—Chronic pulmonary abscess.  
Figs 5, 6 and 7—Bronchial carcinoma.  
Figs 8 and 9.—Pulmonary sarcoma.

Figs. 5, 6 and 7.

PLATE XV  
PULMONARY TUBERCULOSIS AND DIABETES MELLITUS

Fig. 1.

Fig. 2.

From table II it will be seen that in these patients the tuberculosis developed before four years in 73 (63.5 per cent).

#### *Type of tuberculosis as studied by x-ray*

It has been possible to study the x-ray films in 112 of the 157 cases, films not being available for some of the earlier cases. With a view to determining the type and severity of the tuberculous disease, the following points were observed, namely, the amount of fibrosis, tendency to dissemination, whether one or both lungs were involved, and the amount of cavitation. This is shown in table III.

TABLE III  
*Type of disease as judged by x-ray study in 112 cases*

Type	Number	Percentage
Exudative .. ..	83	74.1
Fibrotic .. ..	3	2.6
Mixed .. ..	20	17.8
Caseo-pneumonic .. ..	6	5.3
Unilateral .. ..	44	39.2
Bilateral .. ..	68	60.7
Localized .. ..	26	23.2
Disseminated .. ..	86	76.8
Cavities { Single .. ..	42	37.5
{ Multiple .. ..	58	48.2
Thick perihilar involvement ..	35	31.3

The findings in the above series are not materially different from those found by Benjamin (1938) for a series of 2,021 Indian patients suffering from tuberculosis. On the other hand, although in general there is not any appreciable difference in type, the character of the exudative reaction in diabetics tends to be more severe, and the lung shows a thick shadow similar to that in lobar pneumonia. This usually covers the entire middle zone, including the perihilar region. The two illustrations (plate XV) show a typical tuberculous process in diabetic patients.

#### *Treatment*

In the earlier years, the combination of diabetes and tuberculosis was considered to present an almost hopeless prognosis. The advent of insulin and artificial pneumothorax and other measures of collapse therapy have completely altered the outlook.

To get good results both the tuberculosis and the diabetes have to be treated simultaneously. If the diabetes cannot be controlled by diet alone, insulin has to be given. The diet, however, has to be more generous than in diabetes uncomplicated with tuberculosis.

If the lung indicates some form of collapse therapy, this should be instituted irrespective of the presence of diabetes, provided the diabetes is treated at the same time. If the diabetes is carefully regulated, surgery is no more dangerous than in the average non-diabetic case.

In 145 patients treated for more than one month, unilateral pneumothorax was done in 69, simultaneous bilateral pneumothorax in 6, phrenico-exsaisis in 9, thoracoscopy and cauterization in 11, and rib resection for empyema in 1. No thoracoplastics have been done in this series, but this is not because the patients were diabetic, but because the types of lesion in the lungs were not suitable for this operation.

Diabetes is not a contra-indication to gold therapy. In our series sanoerysin has been given in 21 cases.

#### *Complications during treatment*

The following complications were found during treatment of the 145 cases with tuberculosis and diabetes :—

Laryngeal tuberculosis .. ..	8
Intestinal tuberculosis .. ..	1
Glandular tuberculosis .. ..	1
Spontaneous pneumothorax .. ..	4
Pleurisy with effusion .. ..	5
Dry pleurisy .. ..	3
Effusion in artificial pneumothorax ..	50
Empyema .. ..	7
Hæmoptysis .. ..	60
Fistula-in-ano .. ..	10

In addition, there was the diabetic complication of ketosis as a terminal symptom in two patients.

The above tuberculous complications are what are usually found in non-diabetic tuberculous patients: the only points of significance are that effusion in artificial pneumothorax is slightly higher, 66.7 per cent as against 54.2 per cent in the non-diabetic patients, and bleeding from the lungs occurred in 60 (41.4 per cent) as against 34.3 per cent for the whole number of patients. Of the patients with hæmoptysis, in eight the hæmorrhage was the immediate cause of death.

#### *Stage of disease and immediate results of treatment*

Of the 157 patients, 12 are excluded in the analysis of results of treatment, as their period of observation was less than one month.

Of the remaining 145 patients, one was in stage I, 14 in stage II, and 130 (or 89.7 per cent) were in stage III. In the classification of the stage of disease, it is accepted as a general principle that pulmonary tuberculosis complicated with diabetes is classified one stage worse than it would have been without diabetes unless there are other serious complications. In the present series of patients, however, this has not had much effect, as the majority were already in stage III, apart from the question of diabetes.

The results of treatment are shown in table IV :—

between one year and two years, and 1 after between two years and three years.

TABLE IV

*Classification of 145 cases according to the stage and immediate results of treatment*

Stage	Number	Arrested	Much improved	Improved	Percentage of positive results	Stationary	Worse	Died
I	1	..	1	..	..	..	..	..
II	14	1	7	2	..	1	3	..
III	130	..	28	32	46.1	23	22	25
TOTAL	145	1	36	34	..	24	25	25

Of the 130 cases in stage III, positive results were obtained in 60, or 46.1 per cent, as against 55.5 per cent of positive results in 3,130 stage III cases without diabetes.

Of the 145 patients, 25 (17.2 per cent) died during treatment; the immediate cause of death was in 16 progressive tuberculosis, in 8 severe hæmoptysis, and in 2 diabetic coma.

If the results are classified according to the severity of the diabetes, we find that we can analyse the results in 112 patients; in 33 patients who belonged to the earlier part of the period reviewed, the blood sugar estimation was not done. The results are shown in table V.

It will be seen from table V that positive results were obtained in 3 (30 per cent) of the cases of mild diabetes, in 24 (44.4 per

If we group together the patients who died in the sanatorium and those known to have died after discharge, we find that 63 out of 76 patients, whose fate is known, have died within three years. This means that so far the ultimate results of treatment are not good. The explanation of the discrepancy between the immediate results and after results is that probably the patients were unable to maintain the improvement, because they could not continue the strict treatment necessary for both diabetes and the tuberculosis, as in only one case was the tuberculous disease completely arrested.

#### Summary

(1) A review is made of 157 patients suffering from both diabetes and tuberculosis.

TABLE V

*Classification according to severity of diabetes and immediate results of treatment*

Severity of diabetes	Number	Arrested + much improved + improved	Percentage of positive results	Stationary and worse	Died
Mild (blood sugar below 200 mg. per cent)	10	3	30.0	5	2
Moderate (between 200 and 300 mg. per cent).	54	24	44.4	18	12
Severe (above 300 mg. per cent) ..	48	21	43.7	16	11
GRAND TOTAL ..	112	48	..	39	25

cent) of moderate diabetes, and in 21 (43.7 per cent) of severe diabetes. The severity of diabetes does not seem to affect the results of the treatment when the diabetes is controlled.

#### After results of discharged patients

In assessing the value of treatment it is necessary to follow up the cases after discharge.

Of the 120 patients who were discharged from the sanatorium, it has been possible to trace 51. An analysis of the 51 cases shows that 38 (74.5 per cent) have died. Of the 38 dead, 28 (73.7 per cent) died within six months of discharge. 5 between six months and one year, 4

(2) Figures are given of sex and age incidence.

(3) The relationship of onset of diabetes and tuberculosis is discussed.

(4) The type of tuberculosis in diabetics is not materially different from that in non-diabetics in India, except that the exudative reaction seems more severe.

(5) Diabetes is not a contra-indication to any of the usual forms of treatment of tuberculosis, including surgery.

(6) Hæmoptysis was seen more frequently in the diabetic group than in the non-diabetic.

## SPONTANEOUS PNEUMOTHORAX

By W. G. JONES, B.Sc., M.D.

Wanless Tuberculosis Sanatorium, Wanlesswadi,  
District Satara

SPONTANEOUS pneumothorax is a subject about which we all know something but do not know enough. In this article, no attempt is made to cover the subject exhaustively, but with the purpose of gathering together current views and interesting information that should profit those of us who are learning how to treat conditions in that heretofore rather unknown continent, the chest.

There are three kinds of pneumothorax: induced (artificial) or therapeutic; spontaneous or that produced without external influence; and traumatic, caused by external influences. It is better to apply the term spontaneous pneumothorax to all cases whether primary or secondary to some known pathological change, and to reserve the term idiopathic spontaneous pneumothorax for those cases when there is no evident cause for this condition. A superimposed spontaneous pneumothorax is the term used when it occurs in the course of an artificial pneumothorax.

It used to be thought that spontaneous pneumothorax was due to tuberculosis only but this is far from correct. Post-mortem studies reveal a large number of causes, although tuberculosis is certainly the most common one. Of 918 autopsied cases (Goldberg, 1935)

		Per cent
Tuberculosis was found in ..	715	77.8
Gangrene and empyema ..	110	12.0
Wounds ..	32	3.5
Bronchiectasis, abscess, emphysema, infarct and paracentesis	34	3.7
Caries or abscess of chest wall, perforation of viscus or gland, etc. ....	11	
Cause undetermined ..	16	3.0
	918	

Thus we see that spontaneous pneumothorax is caused by all types of pulmonary diseases, especially those associated with a focus of necrosis situated close to the visceral pleura. In children it may occur more commonly in

(Continued from previous page)

(7) The immediate results of treatment of tuberculosis in diabetics is good, but slightly below the average for non-diabetics.

(8) The after results have been discouraging so far and point to the necessity of very careful control of both diabetes and tuberculosis, if the improvement gained during treatment is to be maintained after discharge.

## REFERENCES

- Benjamin, P. V. (1938). *Indian Med. Gaz.*, Vol. LXXIII, p. 540.  
Root, H. F., and Bloor, W. R. (1939) *Amer. Rev. Tuberc.*, Vol. XXXIX, p. 714.

association with a streptococcal or staphylococcal bronchopneumonia, or in those diseases producing a violent cough, such as pertussis or asthma.

But spontaneous pneumothorax is by no means found only at the post-mortem table. Laennec in 1819 recognized an 'idiopathic' variety without obvious pathology which was found in apparently healthy people. Until 1932, however, the literature contained only scattered reports of such cases, and the first series (51 cases) was reported in that year by Kjaergaard (1932) of Copenhagen. Since then many such series have been published. This increase in idiopathic cases reported in the past 10 years is due to the more widespread diagnostic use of the x-ray in all types of chest condition. Negative tuberculin reactions were reported in about half of all cases classed as spontaneous pneumothorax without other 'evident pulmonary pathology. Without the use of x-rays the failure of diagnosis is due to the transient nature of the subjective complaints in the majority of instances, and the rapid complete recovery on simple rest treatment.

The cause of simple idiopathic spontaneous pneumothorax in an apparently healthy person is not very clear. Laennec (Kirshner, 1939) thought it arose from the rupture during coughing, sneezing, straining, or other spasmodic effort of an emphysematous bleb on the surface of the pleura. Some claim to have actually seen such blebs at autopsy, but 'idiopathic' cases seldom come to the autopsy table. It is thought that these blebs represent air which has come from the rupture of an alveolus or terminal bronchiole and which has then 'dissected' along the interstitial tissue to the pleura. In rare cases the air proceeds centrally and is then found subcutaneous, having reached the skin of the neck *via* the mediastinum. Others incline to attribute the rupture to a weak 'congenital defect' or to a weak spot at a scar.

At all events the majority of these cases present transient symptoms, and there is as a rule no pleural reaction or exudate. Many cases of recurrent spontaneous pneumothorax on one or both sides are reported in the literature. The symptoms depend on the extent of the pneumothorax and the suddenness of its onset. This depends on the size of the pleural tear and its type—closed, open or valvular. In the simple cases the tear soon closes and the air is absorbed without complications. The open types, producing a persistent pneumothorax fortunately are rare, in this group. A small tear may become closed with the onset of exudate (spontaneous or induced) or by further collapse of the lung.

The valvular type produces a 'tension pneumothorax' which can give alarming symptoms very suddenly. The mechanism of these valves has been studied by Zavod (1939) who describes three types:—(1) the flap valve, produced by an incomplete tear at the pulmonary insertion

of an adhesion; (2) the slit valve, as made by a stab wound of the lung, or a longitudinal laceration of the lung by the point of a needle; and (3) the purse-string valve, an ulcerative opening from a peripheral cavity.

We have ourselves seen recently a patient of thoracoplasty with a contralateral pneumothorax who developed alarming symptoms of spontaneous pneumothorax on three successive occasions when an increased amount of air was given on the pneumothorax side. He must have had a valve type of laceration that opened up with greater lung collapse.

The chief symptoms of spontaneous pneumothorax are pain in the chest, dyspnoea and shock; or there may be few or no symptoms at all. Much depends on the suddenness of onset and extent of collapse. This diagnosis should be kept in mind in all kinds of pulmonary disease, and in pulmonary tuberculosis at all times. Joress (1936) has called attention to the fact that severe abdominal pain, often with persistent nausea and vomiting, is a not uncommon symptom of spontaneous pneumothorax, and may be very misleading. In some cases the onset is sudden, at other times it is gradual. The abdominal pain may be accompanied with local signs (muscular rigidity, etc.) and when dyspnoea and other chest signs are absent the diagnosis is easy to miss. The production of pleural fluid (as the evidence of the pleuritis which is the basis of the referred pain to the abdomen) may be delayed for days or weeks and hence this diagnosis should not be dismissed too quickly.

Spontaneous pneumothorax is of course most common and often a serious complication in pulmonary tuberculosis. Its incidence is given by Young (1936) as 10 to 14 per cent. It is especially common in bilateral pneumothorax. Mattill and Jennings (1940) report it in 21 per cent of 144 bilateral pneumothorax cases, in which the limited respiratory reserve makes a spontaneous pneumothorax readily detected. In the presence of advanced pulmonary tuberculosis death may occur early from shock, exhaustion or heart failure. The rupture of a pleural tubercle is a frequent cause in many cases.

For the practising physician who is treating tuberculosis by artificial pneumothorax it is well to realize that a potent and preventable cause of superimposed spontaneous pneumothorax is unphysiological pressure in the pleural cavity, by air, fluid or oil; too much air, too much oil, or neglected hydro-pneumothorax; and also that adhesions are a source of danger from tearing or giving away of a necrotic area at the base of an adhesion (McCloskey, 1937). Particular attention needs to be drawn to the fact that unphysiological pressure applies not only to excessive positive pressures, but also to excessive negative pressures. This is the reason why fluid or pus (from the development of a superimposed spontaneous pneumothorax) often develops in

an *abandoned* artificial pneumothorax. Those who permit an empyema to develop through neglect are as culpable as those who cause it through ignorance or carelessness. Once a physician has induced an artificial pneumothorax he is responsible for its proper maintenance or abandonment until complete re-expansion has taken place.

The complications of spontaneous pneumothorax are often serious in the course of pulmonary tuberculosis. The mortality is estimated at 16 to 25 per cent or more (Myers, Levine, and Leggett, 1937). While simple cases cause no undue concern, any case, even an early one, may prove to be a serious problem with a greatly altered prognosis, should spontaneous pneumothorax occur. Empyema, patent bronchopleural fistula, and congestive heart failure are most to be feared; mediastinal displacement may seriously embarrass a weakened heart or an already overburdened good lung; mediastinal hernia may make ineffective an hitherto effective pneumothorax; existing disease may be exaggerated.

The diagnosis of spontaneous pneumothorax is usually easy, but sometimes it is difficult. In the fluoroscope or the x-ray one looks for undue lung compression or mediastinal shift. The finding of a positive pressure in a previously negative-pressure pneumothorax denotes a closed spontaneous type (McCloskey, 1937). In the open valve type the manometric fluctuation (from a certain negative to a certain positive pressure) is constant even after removal of air. In the valvular type there is an increasing positive pressure not relieved by a deflation. The Coryllos school advocates examinations of the air of the pleural space (for percentage of oxygen and carbon dioxide) to diagnose small perforations, but this is usually not possible in India. Simpler, and quite sufficiently effective, methods to find a pleural perforation, in addition to those just mentioned, are: (1) injection of dye (2 c.cm. of 1 per cent watery solution of methylene blue) or a few drops of some aromatic oil (eucalyptus or peppermint) into the pleural space; or (2) putting a drop of the oil into the pneumothorax apparatus delivery tube: the odour is apparent very soon after introduction of scented air into the pleural space. (This method may not work when the perforation is submerged under fluid.)

*Physical examination.*—Dyspnoea may be quite evident—even when not complained of—and must always be explained. The signs in the chest are those of pneumothorax or of a hydro-pneumothorax. In tension pneumothorax there may be a lag in the movement of the involved side, obliteration of intercostal spaces, hyper-resonant percussion note, shifting in the position of the heart towards the normal lung, often to an extensive degree when the mediastinum is flexible. When the tear is patent and sufficiently large, amphoric breathing may be heard, or an amphoric echo with cough, or when fluid acts as

a valve over the rent (metallic tinkle). In severe collapse of the lung, producing bronchial closure, the breath sounds may be absent. As the lung re-expands amphoric breathing and other signs disappear.

*Treatment.*—In idiopathic spontaneous pneumothorax the chief treatment is rest in bed, with morphia for the pain and the dyspnoea. Deflation is necessary when the intra-pleural pressure is positive. For recurrences, it is wise to attempt a sealing of the pulmonary tear by intra-pleural injection of 25 to 50 c.cm. of 30 to 50 per cent dextrose to produce a sterile reaction (Brown, 1936; Young, 1936).

In tuberculous cases the first treatment is the immediate removal of sufficient air to relieve the dyspnoea or to save life. Oxygen will relieve the anoxemia if it is available. Collapse must be treated by the usual appropriate measures (heat, fluids, etc.), except that the Fowler head-up position is preferable to the head-down one on account of the dyspnoea. Morphia (in small doses) will help to calm the patient but large ones may obscure the anoxemia and permit relapse. It is absolutely essential to know whether the pneumothorax is increasing or not. In the continuous (open or valvular) types repeated or continuous aspiration of air must be arranged for. In less violent cases when the tear is apparently small it is wise to induce an effusion, if one has not already formed, by injection into the pleural space of dextrose (*see above*), or of oil (5 to 10 c.cm. of sterile olive or paraffin oil). An effusion should not be aspirated as it will aid in blocking the pulmonary tear; or if aspiration is indicated, as when the effusion is very large, only a small amount should be removed at one time, to relieve pressure.

It may be emphasized here that the onset of superimposed spontaneous pneumothorax by no means indicates that the pneumothorax is 'spoiled' and needs to be abandoned. Many cases recover and are none the worse for the accident, and may continue taking the treatment as before. On the other hand, in a larger number of cases the pneumothorax fails from this point of view, as the production of a pulmonary perforation sooner or later brings on empyema—tuberculous or mixed. Empyema so produced is a 'self-reinfecting empyema' and is the basic reason why simple aspiration, or aspiration *plus* antiseptic lavage so often fails. In these cases it is much wiser to abandon the pneumothorax treatment and accomplish both pulmonary collapse and empyema obliteration by thoracoplasty before the general condition of the patient worsens or a cross-spread into the good lung occurs. At the Wanless Sanatorium during the past two years this treatment (thoracoplasty) has saved every case in which it was possible to use it, while previously by 'medical treatment and aspirations' we lost every case.

We should not forget that certain cases of spontaneous pneumothorax respond favourably

to a phrenic interruption (a crushing is sufficient) when other measures fail.

An important item in the management of spontaneous pneumothorax is to have available at all times a suitable deflator. The books say 'insert a catheter into the pleural space' when the pulmonary tear is a large one, and let the end 'open slightly below the level of the patient into a weak antiseptic solution'. We have never done this. In tension pneumothorax it is necessary to relieve the positive pressure in the chest, and this can be accomplished by a simple automatic deflator as shown in figure 1. A needle is strapped to the chest wall under strict aseptic conditions, sealed in with benzoin and connected to this deflator. The illustration shows how the end of the tube is under water and the depth of the under-water exit can be adjusted to suit the need. This tube is also joined to the water manometer. This apparatus

Fig. 1.

works well for a tension pneumothorax, but in our experience is not entirely satisfactory for routine use as it does not provide suction.

Hence we developed the continuous deflator shown in figure 2 several years ago, and it has proved its worth many times. While it appears rather complicated it is really a simple mechanism. We were given a pneumothorax apparatus now on sale in the U.S.A., consisting of a motor geared at right angles to a slow moving wheel on the periphery of which are six small rubber wheels. These rubber wheels run in a groove, compressing a rubber tube, thereby giving suction at the left end of the tube as indicated at 1. Suction is carried to the needle at 2, or *via* the bottle—for aspirating fluids—at 3. The degree of suction desired is regulated by a mercury escape valve 4. (The mechanism is simply that suction remains constant according to the depth of the hollow tube

under the mercury. A higher degree of suction draws in air from the outside through the hollow tube.) 5 is a safety valve in case of positive pressure, as from coughing, etc. The electric current from wall plug, 6, is carried through several electric light bulbs to supply resistance, as our motor is for 110 volts and our current 230 volts. Spare bulbs of varying wattage are carried in the box, 8, so that motor speed can be varied by changing the resistance. 9 is the off-and-on switch. 10 is the water manometer, made with an extra tube (a pipette) in the middle so that cough merely blows fluid from the left manometer arm into the pipette (as shown by the arrow), and the manometer arms are refilled to zero from this reservoir. The capacity of this aspirator is limited only by the excessive heating of the motor (due to improper voltages used) and by the motor speed which can be adjusted as described. Once in operation the patient or his attendants work the switch as needed. This saves the attending

Fig. 2.—Electric decompressor (Wanless Sanatorium)

physician many an hour. Bottle 5 in this apparatus acts as a positive decompressor just like the one shown in figure 1.

#### Summary and conclusions

1. Spontaneous pneumothorax is a not uncommon accident in apparently healthy people, and these cases are found by using the x-ray freely in every kind of chest complaint. It is usually easy to treat, and complete recovery is the rule.

2. Spontaneous pneumothorax may also result from any kind of pulmonary disease that produces local necrosis of tissue. In tuberculosis it is quite common. It may be a serious complication and result in the death of the patient. It may come from extension of disease to the pleura; but in many instances it results from conditions which are under the control of the physician, and to this degree is preventable.

3. The treatment of spontaneous pneumothorax is often difficult and requires very prompt attention. A deflator and a continuous

## TREATMENT OF TUBERCULOUS EMPYEMA

ILLUSTRATED REPORT ON 17 CASES TREATED IN THE  
WANLESS TUBERCULOSIS SANATORIUM,  
WANLESSWADI, DISTRICT SATARA

By G. SAMUEL, M.B., B.S. (Madras)  
Acting Medical Superintendent

A PURE tuberculous empyema is caused by the tubercle bacillus and a mixed tuberculous empyema is caused by the tubercle bacillus and pyogenic organisms. The latter is always due to superimposed infection either from within, i.e., from the blood stream, or from without, through bad technique during aspiration or from contiguous infection from the neighbouring organs. A broncho-pleural fistula or sometimes a spontaneous pneumothorax give rise to mixed infection.

A pure tuberculous empyema is caused by pleural tuberculosis or is secondary to a tuberculous lung infection. This is caused by discharge of infected material into the pleural cavity from any caseating sub-pleural tubercle on the surface of the lung, which commonly infects the benign effusion.

The inflammatory exudate or pus consists mainly of a dense network of fibrin in the meshes of which are serum and very large numbers of polymorphonuclear leucocytes. In the course of time, especially in long-standing empyema, the exudate is invaded by fibroblasts which lay down bundles of collagen fibres so that the affected portion of the lung is covered by a layer of exceedingly dense fibrous tissue: as the lung is encapsuled by a dense fibrous tissue wall the subsequent expansion of the lung is prevented, even after evacuating the pleural cavity. The parietal pleura becomes thicker by the same process and prevents the collapse of the chest wall after the thoracoplasty operation. This

(Continued from previous column)

aspirator have been described. The treatment of the resulting bronchial fistula or empyema usually requires a thoracoplasty which gives excellent results in suitable cases.

Case 6.

process affects the mediastinum also which is made stiff—a rigid wall is now interposed between the two pleural cavities. The effect on the lung of the purulent exudate is much more deleterious than on the visceral or parietal pleura. There may be necrosis and destruction of the lung tissue at the seat of pressure together with interstitial inflammation, which results in fibrosis and contraction and still further interferes with subsequent expansion.

About 4 to 5 per cent of all pneumothorax fluids terminate in tuberculous empyema, according to some authors, but much higher figures are sometimes given. The fluid in these cases becomes very thick and creamy and the smear often shows numerous tubercle bacilli.

If the empyema is left alone it may be recovered from spontaneously, provided it is of limited extent. It may kill the patient from septicaemia or amyloid disease, or the empyema may rupture externally or into neighbouring cavities such as a bronchus, the œsophagus or the peritoneal cavity.

#### *Classification of tuberculous empyema*

Hedblom's classification of tuberculous empyema into four groups is, in my opinion, the best one :

Group I.—Pure tuberculous empyema without pulmonary tuberculosis.

Group II.—Mixed tuberculous and pyogenic empyema without pulmonary tuberculosis.

Group III.—Pure tuberculous empyema with active pulmonary tuberculosis.

Group IV.—Mixed tuberculous and pyogenic empyema with active pulmonary tuberculosis.

#### *Indications for the treatment of tuberculous empyema*

1. If the underlying lung is tuberculous and requires thoracoplasty for itself, then the empyema (and the lung) should be treated by thoracoplasty.

2. If the underlying lung is not diseased or if it is tuberculous and for itself does not require thoracoplasty, the tuberculous empyema should not be treated by thoracoplasty unless aspiration treatment fails.

3. Thoracotomy should be used only when mixed infection exists and high toxæmia therefrom. It should then be done immediately.

#### *Aspiration treatment*

Aspiration once or twice weekly, with air replacement under negative pressure controlled by x-ray examination twice monthly, is advisable. Should any four consecutive films show no appreciable decrease in the pleural cavity, thoracoplasty should be done immediately.

Where thoracotomy and thoracoplasty are both indicated the thoracotomy should be done first, since the patient is thereby put in a much better condition to tolerate the thoracoplasty.

Thoracoplasty for tuberculous empyema is different from that done for pulmonary tuberculosis because :—

- (i) The patients are frequently much poorer risks for surgical shock,
- (ii) The collapse must be much more complete and calls for much more extensive decorticalization.

We divide the operation into 5 or 6 stages if necessary. We remove the full length of all ribs including the seventh; also in many cases the posterior half or two-thirds of the remaining ribs, exclusive of the twelfth rib. Ribs are removed extra-pleurally, beginning from above downwards. The periosteum of each rib is thoroughly treated with 10 per cent formalin throughout the entire length (instead of only in the posterior part, which is our custom in pulmonary tuberculosis). Sometimes extra-pleural thoracoplasty alone does not entirely obliterate the cavity, then Schade thoracoplasty has to be used for the treatment of the remaining cavity.

The records of the sanatorium contain 17 case reports of tuberculous empyema. Of these, 4 were treated with aspiration alone, 10 with thoracoplasty and 3 are still under treatment. It is too soon to report the results in the former; in the latter 8 cases (80 per cent) have obliterated cavities and completely healed wounds. The oldest cure has now been well for two years. One death occurred among the thoracoplasty group making a mortality of 20 per cent. The aspiration group shows no mortality.

Seven case reports with accompanying skiagrams are given as typical examples :—

*Case 1.*—Female, aged 30, was admitted on 3rd March, 1939—had a history of hæmoptysis in May 1930. Patient was apparently well but sputum-positive—x-ray showed a small cavity in the sub-clavicular region on the left side. She fell ill off and on during the period of six years. Artificial pneumothorax was started in December 1936. Sputum became negative for some time. Lung expanded owing to effusion—cavity re-opened; sputum became positive again. Had fever. Was aspirated off and on in a hospital in North India. Came here with tuberculous empyema with mixed infection and underlying lung disease. Thoracoplasty operation was undertaken on 7th March, 1939—four stages were done and the patient was discharged, with the empyema cavity obliterated, in a very good state of health.

(This case belongs to group IV.)

*Case 2.*—Female, aged 35, admitted here on 7th April, 1939—for tuberculous empyema with mixed infection due to underlying tuberculous lung disease—she developed pulmo-pleural fistula six years ago and was treated in other hospitals without effect. Productive cough—5 to 10 oz. of sputum every day; temperature up to 99.5°—anæmic—postural treatment and other medical and symptomatic treatment had no effect. Thoracoplasty operation was undertaken on 20th April, 1939—four stages were done. She is quite well with the empyema cavity obliterated.

(This case belongs to group IV.)

*Case 3.*—Male, aged 32, was admitted on 7th March, 1935, suffering from tuberculosis—left lung with a sub-clavicular cavity and caseo-pneumonic infiltration—sputum positive. Artificial pneumothorax treatment

was started and kept up for four months, when he developed effusion. Collapse was contra-selective because of apical adhesion. Internal pneumolysis was done—did well for two months with good collapse and sputum negative. Some time later the patient developed tuberculous empyema, several aspirations and irrigations of the pleural cavity were done but with no effect. Thoracoplasty operation was undertaken on 27th March, 1936. Two stages were done as the pocket was a small one. Patient was discharged quite well with the empyema cavity obliterated.

(This case belongs to group III.)

*Case 4.*—Female, aged 31, was admitted on 1st December, 1937, with caseo-pneumonic infiltration on the left side and multiple cavities—sputum positive. Artificial pneumothorax was started on 4th December. She had contra-selective collapse with some apical adhesions for which internal pneumolysis was done on 5th January, 1938. She had good collapse and was discharged with negative sputum on 14th October, 1938. Artificial pneumothorax was continued, but after some time she developed tuberculous empyema. She was readmitted in February 1939—several aspirations were done with no effect. Thoracoplasty operation was undertaken on 28th March, 1939—three stages were done—the pleural cavity was obliterated and the patient was discharged quite well.

(This case belongs to group III.)

obliterated. Patient was discharged on 14th October, 1937.

(This case belongs to group III.)

*Case 7.*—Male, aged 40, was admitted on 28th November, 1937, with caseo-pneumonic affection on the right side. Artificial pneumothorax was done and kept up for ten months with good collapse. Patient developed fluid on 19th May, 1938—fluid became turbid and became positive for tubercle bacilli—aspiration was started from 19th May, 1938, and kept up till 2nd December, 1938—twice weekly to begin with and once weekly later. The lung slowly expanded. The patient was discharged on 6th December, 1938, with sputum negative—the pleural cavity obliterated and the underlying lung disease controlled.

(This case belongs to group III.)

### Discussion

*Mortality.*—Our mortality figure, 20 per cent for treatment with thoracoplasty, is happily low. For example, recently Mattill and Jennings gave a mortality of 33½ per cent which is about the rate usually given. We ascribe our high survival rate to the early use of thoracoplasty and more especially to the use of many small

Case 7.

*Case 5.*—Male, aged 36, admitted on 31st May, 1938, with caseo-pneumonic infiltration on the left side with two sub-clavicular cavities—sputum positive. Artificial pneumothorax started on 3rd June, 1938—sputum became negative. As there was an adhesion, internal pneumolysis was done on 11th July with good collapse—sputum remained negative. After two months, in September 1938 effusion developed which became positive for tubercle bacilli. Aspirations were done for several months—the pus-pocket in the pleural cavity remained the same. Thoracoplasty operation was undertaken on 29th March, 1939—three stages were done and the pocket was closed. The patient was discharged quite well with pleural cavity obliterated.

(This case belongs to group III.)

*Case 6.*—Male, aged 20, was admitted for tuberculous empyema with underlying lung disease on 20th June, 1937. He had high fever and hacking cough—only two months' history. Heart was displaced and there was dyspnoea. Aspiration was done twice weekly and air put in under negative pressure. This treatment was continued from 23rd July to September 1937. The lung expanded and the underlying acute pneumonic infiltration disappeared and the pleural cavity became

stages in the operation. Delay and procrastination in applying radical measures cost human life, especially in mixed infection when the toxæmia rapidly lowers resistance (to surgical shock) by producing amyloid degenerative changes in the liver, kidneys and adrenal glands.

## TUBERCULOSIS IN WOMEN: PREGNANCY AND TUBERCULOSIS

By L. S. GHOSH

*Professor of Maternity and Child Welfare, All-India Institute of Hygiene and Public Health, Calcutta*

IN Europe and North America, the problem of the tuberculous woman has been studied with increasing depth and scope continuously since the end of the great war, and it seems that any national programme of attack upon the disease must indisputably include among its major projects the sifting of data relating to tuberculosis as it bears upon the woman and her special physiology and domestic status.

The object of this paper is to trace some aspects of the problem, chiefly those relating to involvement of the female genital organs by the tuberculous process, the relationship to fertility, and the influence of pregnancy upon the course of the disease.

In India, the subject has already received attention in certain aspects. Muir (1926) reports that in 1922 in Calcutta, the death rate among women due to tuberculosis was 7.2 per thousand and mentions the drastic influences of early marriage and the purdah system upon the spread of tuberculosis among women in Bengal. These effects were deplored also by Shrikhande (1935) in relationship to pulmonary tuberculosis among women. Cases of uterine tuberculosis have been reported by Gupta (1928) and by Krishnaswamy, Goyle and Vasudevan (1936). Ukil (1930) puts the death rate of women between 15 to 20 years in Calcutta as six times greater than that of men. In a later paper, the same author (1933) presents the problem of the undiagnosed cases of tuberculosis among children under ten years and invites maternity and child-welfare clinics to utilize, for such cases coming to their notice, the facilities offered by tuberculosis dispensaries and clinics. Pai (1932) stresses the necessity of birth control and late marriage in tuberculous women. Riste (1938) in a review of deaths from tuberculosis occurring during a seven years' period in Ludhiana, Punjab, reports the female death rate as 2.7 times higher than that of males and attributes this high figure to early marriage, early child-bearing and purdah.

### *The effect of tuberculosis upon fertility in women*

In considering the influence of tuberculosis upon fertility in women, one is led to distinguish between actual attack upon the essential organs of reproduction—the uterus, ovaries and Fallopian tubes—and the effects upon them of the intoxication associated with attack upon other systems of the body (with which may be included vulvo-vaginal lesions).

#### *Group I*

*Attack upon the essential organs of reproduction.*—In this group two types of involvement may be envisaged: (1) mechanical interference

with the continuity of passages and destruction of the tissues by the tuberculous process, such as occur in salpingitis, oöphoritis, cervicitis and endometritis; and (2) pathological changes of non-specific character such as sclero-cystic disease of the ovaries (the *tuberculoase inflammatoire* of Poncet and Leriche, 1910), a condition almost invariably detected in animals dead of tuberculosis, and probably a reactive rather than tuberculous manifestation.

#### *Group II*

*Ovarian dysfunction arising from tuberculous intoxication.*—The second group is composed of conditions or symptoms suggestive of, or referable to, ovarian dysfunction, or upset of the sex hormone system—symptoms such as dysmenorrhœa, amenorrhœa and other disturbances of menstruation including delayed puberty.

It is generally accepted, although one must admit that few studies on really assessable lines have been recorded, that where the organs of reproduction are not the site of attack, in the earlier age groups at least, the fertility of tuberculous women is little, if any, less than that of their non-affected sisters.

Jameson (1935) states that at Saranac one or more pregnancies among tuberculous married women was twice as common as sterility.

Skillen and Bogen (1938) in connection with a review of 10,000 patients of the Olive View Sanatorium, California, state that one-fifth of the married women patients had never been pregnant, 718 out of 2,633 had not been delivered of a live child, while one-third of those who had had pregnancies, had only one child. The average number of children in this group was 2.2.

Gow (1940) refers to the greater fertility of tuberculous women in Bengal when compared to the non-tuberculous.

All such statements and figures have, however, to be considered in the light of many factors—the degree to which contraceptive measures are employed, the age groups in question, the activity and nature of the tuberculous disease, the presence of co-existing venereal infections of the genital tract likely to affect fertility, the fertility of the non-tuberculous ascertained on strictly comparable lines and finally, and not least important, the attitude towards pregnancy in the tuberculous, maintained by eminent local phthisiologists and obstetricians. In the United States, for example, Trembley's (1909) views were responsible for widely held medical opinion in favour of termination of pregnancy.

*Extent of genital involvement.*—Although in the majority of cases genital lesions are secondary to infection elsewhere in the body, primary genital attack of every type occurs. Regarding Indian cases, Gupta describes two cervical out of six genital cases as primary, while in none was pulmonary involvement present when the genital lesions were investigated. On the other

hand, in five out of eight cases recorded by Krishnaswamy, Goyle and Vasudevan, the pelvic lesions appear to have been secondary to pulmonary lesions.

With regard to secondary genital attack, the figures of Merletti (1901) are of interest. At autopsy upon 1,350 women dead of pulmonary tuberculosis, this author detected genital lesions in 172 cases (12.6 per cent). Jameson, after careful examination of the pelvic organs at autopsy upon 17 women dead of tuberculosis, detected genital involvement in six (35 per cent). Bouilly advises extirpation of the tubes and ovaries in all instances of laparotomy performed for abdominal tuberculosis, as he is convinced that the abdominal condition is secondary to invasion of the tubes.

The attack upon the pelvic organs in generalized disease must of course be considered separately. Hirsch and Hoffmann (1933) report that during an immunization programme at Lübeck, in the case of 11 infants accidentally infected through food, all of whom died of generalized tuberculosis, nine showed genital lesions of which five, only, were tubal.

*Age in relationship to genital tuberculosis.*—It must be borne in mind that although genital attack may be manifest at any age (in Askanasy's case, cited by Daniels, uterine tuberculosis occurred in a child of 2½ years) the greatest incidence occurs during the early child-bearing period.

The ages of Gupta's six patients are given as 21 years, 34 years in three cases, 30 years, and 40 years, while the ages of Krishnaswamy, Goyle and Vasudevan's cases are given as 20 years in two cases, 23 years, 25 years in three cases, 26 years, and 32 years.

### Group I

#### *Tuberculous genital involvement*

*Tuberculous salpingitis.*—In considering the first group one has to admit that the most frank evidence in favour of sterility must be related to the proportionate number of tubal infections. In at least 75 per cent of cases of tuberculous salpingitis, the attack is bilateral, commonly with early involvement of the ampulla. Conception in such cases is almost precluded, although ectopic gestation in a tuberculous tube has been reported by Wetterdal (1924) and 17 cases collected by him from the literature.

Excluding cases of involvement other than pelvoperitoneal, Jameson in an analysis of 73 cases of salpingitis, from the literature, obtained the following figures:—sterile 17 per cent, pregnancies 16 per cent; for 37 cases seen by himself, however, the returns were 85.6 per cent sterile and 14.2 per cent in whom pregnancy occurred. Greenberg (1921) gives 63.5 per cent as the sterility rate and Bush (1933) 61 per cent. The figures in all cases refer to married women only and are not discussed with reference to sterility in non-tuberculous women.

*Frequency of occurrence.*—The figures cited by various authors vary from 50 per cent or less to over 90 per cent, but microscopic examination of the tissues has usually been omitted by those authors giving low percentages. As regards Indian records, although Gupta states that, if the uterus is attacked, the tubes are always involved, and that salpingitis is the commonest genital lesion, in only one case out of six reported by him, and that one in which the uterus also was attacked, is tubal infection mentioned as present. In three out of eight cases reported by Krishnaswamy, Goyle and Vasudevan, salpingitis was present. One must, however, bear in mind that microscopic section requires to be resorted to before infection of the tubes can be eliminated.

It is a significant fact also that the peak incidence of tuberculosis of the Fallopian tubes appears to lie between the second and third decades, the richest reproductive period.

*Tuberculous oöphoritis.*—Ovarian involvement offers a less well-defined and probably underestimated relationship to sterility in the tuberculous woman. Although in approximately 25 per cent of all cases of tuberculous salpingitis the ovaries are involved by direct extension, forming a tubo-ovarian mass, destructive lesions of the ovary are rare, and even then may be unilateral, the other ovary proving unaffected or showing a reactive change only. Primary lesions of the ovary although very rare do occur, but even assuming, somewhat exaggeratedly, that tuberculous salpingitis forms 90 per cent of genital tuberculous lesions, the occurrence of frank disease in the ovary probably would not be met with in excess of 25 per cent of all genital cases.

In the investigation of fertility, weight is being given increasingly to the non-specific changes in the ovary met with in tuberculous women, changes such as sclero-cystic disease resulting in ovarian dysfunction. Poncet and Leriche believe that this condition is an inflammatory form of tuberculosis which may be lit up at any time by strain (as may occur during delivery or the puerperium), a view which has not received general support.

*Tuberculous cervicitis and endometritis.*—Although authors variously assess uterine involvement at 12 per cent—76 per cent, Norris (1921) and others state that in about 50 per cent of all cases of genital tuberculosis in women, the uterus is attacked. There is some evidence that cervicitis is commoner than is usually stated, and occurs earlier than infection of the endometrium. In the case reported by Gipel, salpingitis, endometritis and cervicitis occurred in an infant of six months. Gow, referring to Bengal, puts the incidence of tuberculosis of the cervix uteri at 1 in 605 and asserts that young girls are more frequently the victims of this manifestation. Of the six cases of uterine involvement discussed by Gupta, four were cervical

and in one more the cervix fundus and tubes were all infected. Krishnaswamy, Goyle and Vasudevan's eight cases included five in which the disease was located in the cervix.

Tuberculous endometritis arises as a rule in the functionalis layer and can be diagnosed by premenstrual curetting only, as the diseased endometrium is at first shed with the menstrual flow. Vogt (1928) doing diagnostic curettage for sterility found tuberculous endometritis existed in only 7.2 per cent of 212 cases.

It would appear therefore that the relationship of uterine tuberculosis to sterility is not a highly significant one. Deymel (1927) and Gupta each report a case of multiple pregnancy in a woman with long-standing uterine infection. Of the five additional cases reported by Gupta one patient is described as sterile, two were multiparæ and in two instances pregnancy is not mentioned. Regarding Krishnaswamy, Goyle and Vasudevan's eight patients, no mention is made of children in three cases, one is described as a nullipara, two had had one child, one had had five, and one three children.

*Non-specific lesions of the ovary.*—Jameson describing studies related to the examination (post-mortem) of the internal genital organs of 14 women between the ages of 30 to 40 years, in all of whom pulmonary tuberculosis had been the cause of death and none of whom had exhibited gross evidence of genital invasion, states that the ovaries were normal in size, cystic changes were present in nine, while in all the tunica albuginea showed definite thickening.

Such tunical thickening, although not pathognomonic of tuberculosis, is bound to affect ovulation adversely. This author further remarks that on the analogy that deficiency of follicular hormone is indicated by atrophic endometrium a study of uterine curettings of tuberculous women pointed to a deficiency of ovarian secretion in the majority.

There is no doubt that sclero-cystic changes in the ovaries are very much commoner in tuberculous than in non-tuberculous women. Jameson states that this change is almost invariably present with or without the presence of other genital lesions.

The microscopic appearance of the organ in this condition—thickened and adherent tunica, a considerable increase of the stromal substance at the expense of the epithelium, and the preponderance of cystic and atresic follicles—suggests that although probably in the early years fertility is little interfered with, even in the tuberculous women in whom no specific genital lesion occurs, the period of fertility may conceivably be shortened.

#### Group II

*Ovarian dysfunction resulting from tuberculous intoxication.*—Amenorrhœa, with which is also classified scanty menses, is taken as direct evidence of interference with the full functioning

of the ovaries, while menorrhagia and hypermenorrhœa are considered the effect of dysfunction *plus* the result of loss of capillary tension which is the normal accompaniment of menstruation.

Nomogram comparing the gynecological complaints of 122 tuberculous and 139 non-tuberculous women (studied by Jameson).

[Figures taken from *Gynecological and Obstetrical Tuberculosis*, Jameson, 1935.]

The nomogram is compiled from the figures given by Jameson relating to the gynecological complaints of a group of 122 tuberculous women, compared with those of 139 non-infected. It will be seen that menstrual disturbances attain a slightly higher figure, 29.2 per cent in the former group, as against 24.6 per cent in the non-tuberculous group. The chief forms of disturbance are dysmenorrhœa, metrorrhagia, menorrhagia and scanty flow.

Stanitch (1923) emphasizes that the ovaries are among the first organs to be affected by the intoxication of acute generalized tuberculosis, the signal of such attack being either amenorrhœa of abrupt onset or menorrhagia with increased flow and a shortened intermenstrual interval. It is well known that compromise of the defence mechanism in tuberculosis in women is frequently indicated by marked menstrual disturbance, either in the form of amenorrhœa or of menorrhagia of a severe type. Stanitch regards amenorrhœa as a valuable guide to the allergic condition of the patient. Certainly in fibroid phthisis the menses are seldom abnormal. Macht (1910), classifying scanty menses with complete amenorrhœa, found that in 27.3 per cent of all tuberculous women patients seen such disturbance occurred, and that 71.5 per cent of these patients were under 30 years of age. Morris gives the high figure of 77 per cent of women patients as having suffered from menstrual disturbance of some type. In none

of these patients were clinical manifestations of pelvic infection present.

*Delayed puberty.*—The more chronic forms of tuberculosis in the young, *e.g.*, Pott's disease, recurrent pleurisy, scrofula, etc., are often associated with delayed puberty. Stanitch reports puberty occurring at 16 to 20 years in such cases and points out that menstruation, when established, has no apparent deleterious effect upon the lesions.

*Menstrual irregularities.*—Haese (1927) upon analysis of 469 patients with a normal menstrual cycle states that ultimately irregularity of amenorrhœa occurred in 17.4 per cent. This author found that using the N. T. A. (U. S. A.) standards, irregularity of menstruation was twice as common in the second stage of infection as in the first, although the proportion of amenorrhœa was slightly less. In the third stage, with cavitation, irregularity occurred twice as frequently as in the second stage, while the proportion of patients with amenorrhœa was nearly four times as high as in stage 1 (11.1 per cent). Haese does not consider that dysmenorrhœa bears any significant relationship to tuberculosis. Jameson's figures also are of interest: in 20 per cent of 200 cases, a history of irregularity or amenorrhœa prior to diagnosis of the disease was elicited. Subsequent to diagnosis this figure rose to 26 per cent, although the extent of the disease process seemed to have little influence on menstruation.

Friedrich (1913) cites the highest figures of all. This author records 45 per cent amenorrhœa in stage 1, 64 per cent in stage 2, and 85 per cent in stage 3.

There seems little doubt that menstrual irregularity is manifest in a considerable proportion of women patients, irrespective of the site of lesion. Its significance as an indication of the progress of the disease and the extent of ovarian disturbance is not clear. Certainly under treatment some patients resort to a regular cycle. That menstrual disturbance has an evil effect upon the course of the tuberculous condition is however generally accepted; probably both are simultaneous manifestations of a failure of defence. In India figures are not forthcoming relating to the frequency and clinical significance of menstrual disturbance in tuberculous women, although much valuable data must be recorded in women's hospitals and in the gynaecological departments of the large teaching hospitals.

#### *Pregnancy and tuberculosis*

Subsequent to 1918, with the establishment of improved methods of diagnosis of tuberculosis, clearer light has been thrown upon the inter-related factors, which bear upon this common combination of a physiological and pathological disturbance of metabolism and much has been added to the literature on the subject in recent years.

In assessing the effect of pregnancy upon the tuberculous, one must distinguish between the

effects of the pregnant state, the strain of delivery and the significance of the puerperium.

Although several authors have written of the influence of pregnancy upon the higher incidence of tuberculosis among women, the figures of Brindeau (1931) and Bridgman and Norwood (1926) dealing with 32,667 and 14,000 pregnant women, respectively, show no evidence of a higher incidence among parturients.

It is true that in India certain factors peculiar to the country's social structure require to be assessed in this regard, before the figures of France and the U. S. A. can be deemed applicable here, but this very social structure, producing as it does groups distinct ideologically, may offer thereby the greatest facility for the elucidation of special problems, if opportunities were forthcoming.

It is obvious that if the strain of early puberty is shortly followed by the strain of a first pregnancy, capacity to resist infection is bound to be reduced. Thus in India it is necessary to estimate the several effects upon the incidence of tuberculosis in women, of pregnancy at an early age (*e.g.*, delivery before the age of 16 years), of repeated pregnancies at short intervals, and of such factors favourable to infection as lack of sunlight, unsuitable or poor diet, inadequate rest and medical care.

Although it has not been possible to trace any study made in this country designed to elicit, by reference to strictly comparable control groups, information regarding the influence of such factors, certain authors such as Pai, Shrikhande and Riste have referred to the subject. Pai mentions the value of birth control and late marriage in the control of tuberculosis, while Shrikhande also stresses the evil effects of purdah and early marriage upon pulmonary tuberculosis. Riste, taking the mortality rates of seven consecutive years in Ludhiana, Punjab, ascribes the higher rate among women (2.7 times the mortality rate of males) to early marriage, early child-bearing and purdah.

It is clear that much more requires to be known about the influence of these factors under Indian conditions.

Certain conclusions reached at the Obstetrical and Gynaecological Congress held in Geneva in 1923 (Morisson-Lacombe, 1924) are of interest as indicating the first swing away from the two divergent, largely uncompromising schools of thought then existing, the one regarding pregnancy as favourable, the other as disastrous, to the course of the disease in the tuberculous woman. Aggravation of the lesions, to the extent of about 60 per cent, was held to occur, by predominant opinion at the congress, such aggravation increasing as term approaches. It was emphasized that each case should be observed by an obstetrician and phthisiologist, *while greater weight should be given to the opinion of the latter*. Although it was considered better for the tuberculous woman to avoid pregnancy, the necessity to distinguish the patient

with the long healed fibrous lesion from that with active disease was stressed, provided always that strict medical supervision could be maintained throughout pregnancy and afterwards.

Induction of abortion later than at the third month was deemed dangerous, and in this regard the congress elicited certain facts upon which decision might be taken regarding the advisability of induction when pregnancy is detected before the end of the third month. These were termed 'signs of gravity' and 'signs of alarm'.

Briefly, in regard to the 'signs of gravity' the congress found that benign fibrous lesions and pleurisies are little affected by pregnancy, serious results being unlikely to occur in more than 5 per cent of cases. Progressive fibro-caseous lesions on the other hand were held to be aggravated in almost all cases, afebrile patients with active non-progressive disease or chronic cavities being excepted.

Tuberculosis becoming manifest clinically for the first time during pregnancy was held to deserve special consideration, as being more dangerous owing to the possibility of tuberculous pneumonia supervening. Special significance, it was noted, should be ascribed to the development of complications peculiar to pregnancy.

'Signs of alarm' referred to clinical and other evidence of aggravation of the disease, including changes in allergy as demonstrable by cutaneous reactions.

Since 1923, investigation of the problem both experimentally in animals and by observation of patients has tended to strengthen the position of those who maintain that after certain data (similar to those suggested at the Geneva Congress) have been collected and weighed, any decision for or against artificial termination of pregnancy must take into account personal factors, and conditions in India demand that personal factors should include the economic status, the domestic responsibilities and the capacity for co-operation of the patient. The available facilities for adequate observation and treatment must finally influence the decision. In spite of this there are authors who believe with Bourne (1931) that artificial abortion has no place generally in the treatment of tuberculosis. Gow (1940), on the other hand, with regard to Bengali women considers interference advisable as late as the 28th week of pregnancy. It seems highly important that obstetricians and phthisiologists in this country should combine to elicit data on which procedure might to some extent be standardized, all the more as in the majority of the smaller hospitals and to many practitioners by whom such decisions are being taken, the opinion of a specialist in tuberculosis is seldom available. It is true that we do not face a falling birth rate, as Germany did when her obstetricians were being influenced in favour of conservation of pregnancy but if, as many authors state, to bring about termination of pregnancy after the third month has a more

deleterious effect upon the patient than continuation of pregnancy to term, should we not know whether or not, conditions as they exist socially in India to-day, cancel in effect the balance in favour of conservation?

Of the few statistical studies made upon this subject that of Hill (1928), comparing the condition of 160 women (in whom pregnancy accompanied or immediately preceded the disease) with their state one year and two years after diagnosis of the disease or of conception or parturition (according to the group), yielded most interesting evidence.

No appreciable effect of pregnancy upon the progress of the disease was elicited. It was found that the earlier the diagnosis of pregnancy, the safer was the pregnancy, for the women: less than one-twelfth only of the women diagnosed before gestation were dead a year after termination of pregnancy: of those diagnosed during pregnancy, one-fifth, and in the case of those diagnosed after delivery, the high figure of one-third. Hill states that as in the case of primiparae in general, among the tuberculous the highest mortality rate was suffered by those pregnant for the first time.

The importance of this problem to the phthisiologist is reflected in the fact that Hill found that the maternal mortality rates of tuberculous mothers correspond with the deaths at different ages of all tuberculous women.

*Effects of pregnancy.*—The work of Abruzzese (1929) has shown that probably in the tuberculous patient the change most to be feared in pregnancy is that increased capillary permeability, which attains a maximum about the seventh month, after which time it decreases to rise again for a few days in the early post-partum period. The part played in the exacerbation of lesions by decalcification, hyper-cholestræmia and endocrine readjustment in pregnancy is not clear. In regard to hormones, the work of Steinbach and Klein (1937) has shown that antuitrin S has a favourable effect upon the tuberculous lesions in animals; Skillen and Bogen, on the other hand, report that neither follicular nor corpus luteum hormones appeared to influence the course of the disease in animals.

The question of pregnancy in tuberculosis cannot be considered apart from the facilities for adequate and efficient amelioration of the disease during the period of pregnancy and for at least six months subsequent to delivery; the value of artificial pneumothorax, etc., in suitable cases need not be stressed here. Such operative aids must also have the buttress of willing and intelligent co-operation of patient and relatives alike, while for those for whom the tedium of enforced rest of minimal activity must be the prescribed course how enormous must be the contribution in patience and faith made by the patient.

*Spontaneous abortion in tuberculous women.*—Russi (1926), reviewing 75 patients of whom three-quarters were sick enough to require

hospitalization before delivery, found that 41 per cent had premature labours, 50 per cent went to term, 9 per cent had abortions. In the case of patients with the disease first diagnosed or appearing during pregnancy, 29 per cent only went to term, while 35 per cent had premature labour. As regards obstetrical intervention, the amount resorted to corresponded to that in non-tuberculous patients. Jameson reports that in his experience of a few cases, all women went to term.

#### *Conduction of labour in the tuberculous woman*

There is one point which seems to have been overlooked in the consideration given to the question of the delivery of the tuberculous woman in this country, namely, the presence of an obstetrician at delivery and facilities for the application of anæsthesia.

Sodium amytal, morphine, even forceps in the second stage of labour, skilful nitrous oxide and oxygen anæsthesia are favoured by modern workers. In fact any method of delivery designed to reduce shock, limit muscular strain, and control hæmorrhage is necessarily that most favourable to the tuberculous patient. Care during pregnancy may be largely countered by labour unskilfully conducted, followed by exhaustion.

In India even in large towns there is often the greatest difficulty in obtaining an ante-natal bed for the tuberculous woman in our overcrowded hospitals and maternity institutions, because of the natural fear of spread of infection in general wards. Sanatoria are few and often too far distant.

Admission during labour and discharge after ten days is all that in most cases can be achieved. Under such conditions pregnancy is bound to take a heavy toll. Ante-natal beds for tuberculous patients are an imperative need in any maternity hospital. The services of an honorary phthisiologist for all such institutions is also highly desirable.

One would again suggest that it is to the phthisiologist that the problem must be presented, and with him must be aligned, as Ukil has suggested, the maternity and child-welfare clinics and facilities for institutionalization for ante-natal care and delivery. The pregnant woman who is infected with tuberculosis, once she has made a contact with any part of the system, should be able to obtain treatment for the disease throughout the pregnancy, and be ensured delivery conducted under the most favourable conditions, with her child and herself coming under care from the puerperium onwards. If the units in the system are dissociated, the result is not only disastrous to the woman and discouraging to the clinician, but dangerous also to the child, who has not therefore been isolated from the mother.

The present social conditions in this country make it difficult for the system of treatment in sanatoria to be linked closely with maternity hospitals and institutions and it may be that in

order to achieve reliable data on a subject of really vital importance at least one sanatorium project in India should make provision for the tuberculous pregnant woman throughout pregnancy, during delivery and from the puerperium onwards.

The control of such patients in the home can only be tackled with hope of success when the functions of the generalized health visitor have been realized and the problem of her training and her linking to institutions which serve the pregnant and the tuberculous woman has been adequately achieved.

Further, the co-operation of the general practitioner requires to be enlisted in order to effect some attempt at standardization. The issue of uniform record forms to be filled in by him for each tuberculous married woman coming under his care may well be undertaken by the Tuberculosis Association, the completed card being returned to the Association, for record of data.

Such measures have been undertaken in the United States and have proved most useful.

#### *Summary*

Two forms of tuberculous attack seem likely to affect appreciably the fertility of women of child-bearing age, tuberculous salpingitis and secondary, toxic (sclero-cystic) changes in the ovaries, the latter met with frequently in tuberculous disease although not pathognomic of such.

It is not clear to what extent the menstrual irregularity, which features in a considerable proportion of tuberculous women, is significant as an indication of the progress of the disease and the extent of ovarian disturbance.

The importance of considering separately the effects of pregnancy, delivery, and the puerperium upon the course of the disease is stressed.

A study to assess the influence of pregnancy and parturition upon the tuberculous woman with special reference to factors such as early puberty, early and frequent child-bearing, unsatisfactory diet, inadequate rest and medical care, is urgently needed. A sanatorium project, with this aim, improved control of patients in the homes by development of the system of care by the generalized health visitor, and standardized reports by private practitioners are suggested as possible approaches to the problem.

As a tuberculous pregnant woman should be under the care of a phthisiologist throughout pregnancy and for six months after delivery, the provision of ante-natal beds for tuberculous women in maternity hospitals and the appointment of honorary phthisiologists to such institutions is suggested. It is pointed out that delivery in every case should be undertaken by an obstetrician having at his disposal efficient medical resources to reduce muscular strain, shock and hæmorrhage, and to arrange for the protection of the infant from infection by the mother.

regarded as one of the predisposing causes of tuberculosis and the disease itself is characterized by considerable wasting of the tissues. Proper feeding, therefore, plays an important rôle both in prophylaxis and treatment of tuberculosis. 'Good food' is one of the fundamental items of our present-day sanatorium regime. But although the need of supplying proper nourishment is generally accepted, there has been much controversy in recent times as to the quantity and nature of foodstuffs required. Hippocrates about 400 B.C. advocated a milk diet when there was no high fever and barley water and honey for febrile states, whereas John Mirfield in A.D. 1400 put forward the claims of 'river crab and sugar of roses'.

*Overfeeding :—Old and modern views*

In the earlier period of sanatorium treatment Otto Walther of Nordach preached and practised 'stuffing' of his patients with as much food as they could be made to take. He taught his patients to eat whatever was put before them irrespective of their appetite, taste and state of digestion. If the patients vomited, they had to start all over again. One of the enthusiasts (Debove) went so far as to introduce food through the stomach tube. In other words, overfeeding was regarded as a 'cure' and the patients were made to swallow food like medicine.

The idea of 'food cure' which held sway for a considerable time was gradually given up. It was later found that the rapid and excessive gain in weight which followed forced feeding did not help in increasing resistance or combating tuberculous toxemia; nor did it enhance the process of cicatrization of lesions. On the other hand, the overload of useless fat and water greatly undermines the general health. The patient is weak, flabby and breathless with rapid pulse; his appetite and digestion are impaired and in some cases the digestive mechanism is so upset that the patient loses in a few days what he had gained in several months.

It is now customary to take a more rational view. We now recognize that the progressive increase of weight is not an index of improvement unless it is also accompanied by amelioration of symptoms and unless physical signs and x-ray examinations show evidence of healing. Consistent with these improvements, we aim at a slow and persistent gain finally reaching 10 to 15 lbs. higher than the patient's normal weight in health.

*Adequate and balanced dietary*

(a) *Caloric value.*—What is required is not overfeeding but an adequate and balanced diet. Bardswell and Chapman (1908) after a thorough experimental study of the subject concluded that 3,000 calories per day are quite sufficient. The figures published by the League of Nations and the British Medical Association corroborate Bardswell and Chapman's standard. The

average Indian patient will require a little less but a patient who will not improve with 3,000 calories will not do so with any amount of stuffing.

(b) *Proteins*.—Besides the requisite caloric value, the food must contain all the proximate principles—protein, fat, carbohydrate and vitamins in proper proportions. As tuberculosis is associated with considerable wasting of protein elements, the natural tendency was to make good this loss by feeding on excess of protein food. Some advocated animal proteins while others preferred vegetable proteins. In France, eating of raw meat (zomotherapy) was in vogue. Proteins, however, are said to increase the respiratory activity, and, as fats and carbohydrates are known to be protein-sparers, this has been used as an argument against excessive meat eating.

In India where the people are mainly vegetarian, milk is the chief source of protein. Non-vegetarians may make a wide choice from goat, mutton, game and poultry. In Bengal, fish supplies a cheap source of easily assimilable proteins.

(c) *Fats*.—The one advantage of fat is that, unlike protein and carbohydrate, it does not materially increase the volume of respiration or metabolism. But an excess of fat inhibits gastric secretion and is not well borne by most patients. Apart from its inherent vitamin content, fat by itself does not possess any specific healing power. Feeding on excess of fat should therefore be discouraged. Of all fats, butter is most liked by patients and is easily digested. Ghee and vegetable oils, which are used for cooking, are good vehicles for supplying fat, besides making the food more appetizing.

(d) *Carbohydrates*.—As for carbohydrates, we take more rather than less of it. Patients on high-carbohydrate and low-fat diet put on more weight than those on high-fat diet. As carbohydrates spare both protein and fats, they play an important part in body building.

(e) *Vitamins*.—Vitamins A and D are credited with having the power of increasing resistance against tuberculous infection. They are derived from the fatty food contained in a balanced dietary, and it is customary to prescribe these in excess in the shape of cod-liver oil, adexolin, haliverol, etc. Recently Abbasy, Harris and Ellman (1937) have shown that patients with active tuberculosis must take much more anti-scorbutic vitamin (vitamin C) than normal individuals before it can be detected in their urine.

Two oranges a day or their equivalent amount of dry ascorbic acid (vitamin C) are worth while adding to the dietaries.

(f) *Minerals*.—Cereals combined with green vegetables and fruits supply all the mineral salts required.

*Condiments*.—These are best left to individual taste. In institutions, however, where diverse tastes are to be catered for, they

should be sparingly used. What is appetizing and palatable to one will be too hot and rich for another. Besides, an excess of condiments is apt to upset digestion.

(h) *Milk and eggs*.—We take the opportunity of saying a few words on these two articles of food because of the advice freely given to the consumptives 'drink plenty of milk', 'eat plenty of eggs'.

Milk is certainly a perfect food in the sense that in addition to containing all the proximate principles in proper proportions it is rich in mineral salts and vitamins. A quart of milk is equivalent in food value to a pound of lean meat or 8 eggs. It appears to be the ideal food for growing infants in dilutions suited to their relatively large stomachs. But for adults its bulk is too much for the digestive organs to handle easily. In our experience many patients, who drink a lot of milk for a quick cure, develop flatulent dyspepsia and diarrhoea. We must, therefore, prescribe just as much milk as they can easily digest. In our hospital we used to give 1 seer of milk daily. By cutting it down to  $\frac{3}{4}$  seer of milk and  $\frac{1}{2}$  pow of *dahi*, indigestion of our patients has been diminished.

Eggs are very hard to digest specially when they are taken raw. They should always be taken fried, scrambled or boiled. As eggs do not stimulate gastric juice and resist tryptic digestion, they should never be prescribed for patients with weak digestion. For Indian patients, not more than 2 eggs a day should be prescribed. Many cases of colicky pains and diarrhoea may be traced to eggs.

(h) *Variety*.—From what I have said, it is apparent that a good diet should be a mixed diet containing a variety of all elements and not a preponderance of one element or the other. It should be changed from meal to meal and day to day to prevent monotony. What is even more important is to see that the food is properly cooked and artistically served. The dishes should be spotlessly clean, and the food should look appetizing and attractive. Dettweiler who made a great success with his sanatorium used to say that his kitchen was his pharmacy.

#### *The daily menu*

A fixed weekly menu in an institution is better avoided, although it has many advantages from the administrative point of view. Patients will in such cases forecast the next day's menu and they will be anything but pleased when their forecast comes true.

As regards the number of meals, some experts recommend 5 to 7 meals or more a day which means that the patients would be eating and drinking almost throughout the day. Small frequent meals will not give the stomach and intestines the required rest and is sure to spoil the appetite. We prefer to give 4 meals a day—two principal meals at 11 a.m. and 7 p.m.—

one good meal at 7 a.m. and a light meal at 4 p.m.

At least half an hour's rest before each meal is of great importance. This improves the appetite. Smoking before meals causes temporary hyperglycæmia and spoils the appetite. If allowed, it should be advised after meals.

Fluids should be taken in between the meals and not with them; lemonade makes a good stimulating beverage.

The following is our daily menu for full diet for Indian patients :—

7 a.m.—Buttered toast; half-boiled, scrambled or poached egg; dalia or oatmeal porridge; milk.

11 a.m.—Rice, vegetables curried or boiled; dāl; meat curry or stew; chutney; *dahi*; lemon.

4 p.m.—Milk; fruit; sweets.

7 p.m.—Rice, chapati or luchi; vegetables fried or curried; dāl; fish curry; milk.

The following list shows the quantity of raw foodstuffs supplied per patient per day :—

Rice and atta .. 12 oz.	<i>Dahi</i> .. 4 oz.	Potatoes .. 6 oz.
Dāl .. 2 "	Egg .. One	Green vegetables 8 "
Meat .. 4 "	Fruit .. One	Sugar .. 2 "
Fish .. 2 "	item	Lemon .. One
Bread .. 3 "	Butter .. $\frac{1}{2}$ oz.	Salt and condi- ments as required.
Milk .. 24 "	Ghee .. 1 "	
	Mustard oil 2 "	

The diet, as set forth above, contains approximately 125 gm. of protein, 130 gm. of fat and 470 gm. of carbohydrate and yields about 3,500 calories. The above calculations are based on the quantities of crude foodstuffs and, allowing 500 calories for preparation and cooking, the diet gives about 3,000 calories which is the standard requirement. The cost, excluding the pay of the cook, comes to about 12 annas per head per day.

#### *Personal and economic factors*

Unlike many Indian sanatoria, we supply food to all our patients. The advantage is that the patient's diet is entirely under our supervision and control and the patients are saved a lot of worry and bother. Whereas there is much to recommend in this system, we must not forget that there is nothing like a standard diet in this country which will suit the needs of all individuals. The nature of foods and the modes of cooking are as diverse as are the habits and customs of the people. They vary from province to province, district to district and no two households are alike in this respect. A patient who has been brought up on a particular kind of dietary and has developed his likes and dislikes will find it difficult to adapt himself to the standard menu and if he is sentimental, as many tuberculous patients are, he is sure to react by anorexia and digestive disturbances. In Bengal the diet is more homogeneous than in other provinces, and still we find it impossible to

cater for all tastes. In view of this difficulty, we are now building a few cottages with attached kitchens, where the patients will have facilities to cook for themselves.

Economic factors should also be taken into consideration. Tuberculosis is more prevalent among the poor, who are underfed in the normal circumstances of life. It is a disease which inflicts prolonged suffering and the unfortunate patients who, deprived of earning capacity, has often to depend, with his family, on the charity of others. To give him an impression that only 'plenty of eggs and milk' can cure him is to make him pessimistic about his future and drive him to desperation.

The question of prescribing a diet is, therefore, more or less an individual problem. The diet must be designed so as to suit the individual palate, the purse and the needs of the patients, remembering that tuberculosis requires just a little more food than is required for a healthy person. In private houses such individualization of diet is quite easy but in institutions it is more difficult. Here we have to think of the community which the institution mainly serves. For example, Frimley Sanatorium, which is under control of the Brompton Hospital, London, is principally meant for working-class people and their diet consists of the ordinary food that the people of this class can provide for themselves. The diet of Jadabpur is quite suitable for middle class Bengalees from whom the majority of our patients are derived. A common labourer placed on this diet will gain in weight rapidly, only to lose as rapidly when he returns to his home conditions.

#### *Diet in other Indian sanatoria*

With a view to ascertaining how the problem of diet is met in other Indian sanatoria and special hospitals, we sent out a questionnaire to the heads of 23 tuberculosis institutions. Unfortunately, only 5 replies were received. We give below in tabular form a summary of the relevant portions of the information received, including our own.

#### *Special forms of diet*

Although there is no specific diet for tuberculosis, experts have from time to time put forward special dietetic formulæ claiming for these remarkable therapeutic properties. We shall only mention two of these :—

(a) *Gerson's salt-free diet*.—Gerson of Germany, supported by Sauerbruch, has devised a new diet the principles of which are based on the 're-mineralization' theory and consist in—

(i) Elimination of 'common salt and addition of 'mineralogen' which is a mixture of many mineral salts, except chlorides.

(ii) Limitation of carbohydrates.

(iii) Diminution of animal proteins.

(iv) Use of vegetables and fruits in excess.

The majority of observers have failed to reproduce the good results claimed by its sponsors and at present the consensus of opinion is that the cost and the trouble are not worth undertaking, at least for pulmonary tuberculosis.

(b) *High caloric diet with insulin*.—Recently Vere Pearson and Day (Rolleston and Moncrieff, 1939) have advocated what they call 'high

8-15 p.m. followed in half an hour each time by 6 ounces of fruit drink (made of orange, lemon juice and sugar). During treatment the patients should have lumps of sugar or glucose drink handy so that on the slightest manifestation of hypoglycæmia (cold sweat, tremor, sinking feeling) they may help themselves and avert alarming symptoms.

Name of the institution	Percentage of patients who are supplied food from the Sanatorium kitchen	Number of meals per day	Nature of diet	Caloric value	Cost per patient per month	Opinion as to whether food should be supplied from the institution
Hill-side Sanatorium, Vengurla, Bombay.	50	5	Mixed diet suitable for rice eaters.	3,000	Rs. 15	Not necessarily. Cooking according to patients' liking but under medical supervision.
Royapetta Hospital, Madras City, and Tambaran Sanatorium, Madras.	100	6	Mixed diet specially suitable for South India.	..	15 to 20	The patients should be encouraged to have their own diet. Only milk, eggs and cunji to be supplied from the sanatorium.
Visrantipuram Sanatorium, Rajahmundry, Madras.	85	5	Do.	3,000	10	Sanatorium diet for those who cannot afford their own. Others to arrange according to their liking but under medical supervision.
S. J., T. B. Hospital, Delhi.	100	4	Mixed diet suitable for Indians.	..	30	The food should always be supplied by the sanatorium except in special cases.
Bel-air Sanatorium, Panchgani.	100	6	Mixed diet mainly European.	..	30	The food should be supplied from the sanatorium although the task is difficult. There are different cooks to cater for different communities.
Jadabpur T. B. Hospital.	98	4	(a) Indian diet specially suitable for Bengalees. (b) Mixed diet cooked differently for Anglo-Indian patients.	3,500	23 27	Yes, but the patients who cannot adapt themselves to hospital diet should be given facilities to cater for themselves under supervision.

caloric diet' combined with insulin. The underlying principle is to give carbohydrate in excess which helps in body building and in the language of the authors 'seems to coincide with a decreased destructiveness of the diseased process as witnessed by the decline of the sedimentation rate'. Insulin is combined 'to give the victim a real famished feeling' and to increase his carbohydrate intake.

The diet gives 4,000 calories and consists in giving extra dishes of carbohydrate preparations with the usual English lunch, tea and supper into the details of which I need not enter. Sixty units of insulin are given in 24 hours in 6 injections of 10 units. Three of the injections are given 20 to 30 minutes before the principal meals (8-30 a.m., 1-15 p.m., and 7 p.m.). The other 3 are given at 11 a.m., 1-45 p.m., and

The method is worth giving a trial in selected cases where the patients can afford it and are not putting on weight or gaining strength under the usual regimen. Half a dozen injections daily with risks of hypoglycæmia and insulin-sensitization render this method unsuitable for use in a mass scale.

#### *Diet in complications*

(i) *In hæmoptysis*.—Where the sputum is only streaked with blood or the hæmoptysis is slight, a little curtailment of the diet is all that is necessary. When the bleeding is active and severe, all solids should be withheld and all feeds should be served cold. Milk diet (2 to 3 pints a day) is usually recommended, but as pure milk does not agree with most patients it may

## A PSEUDO-TUBERCULOUS CONDITION ASSOCIATED WITH EOSINOPHILIA

By C. FRIMODT-MÖLLER, C.B.E., M.B.,  
Ch.B. (Copenhagen)

Medical Commissioner to the Tuberculosis Association  
of India  
and

R. M. BARTON, M.A. (Oxon.)

Pathologist, Union Mission Tuberculosis Sanatorium,  
Arogyavaram, near Madanapalle, South India

### Introduction

AMONG many patients sent to the Union Mission Tuberculosis Sanatorium, Arogyavaram, diagnosed as having tuberculosis on account of

(Continued from previous page)

conveniently be mixed with barley water or fruit juice, or served as ice cream. Gelatin given in the form of jelly is supposed to increase the coagulability of the blood and will be welcomed by many fastidious patients. Twenty-four hours after the bleeding has stopped pudding and porridge may be given even if the patient is bringing up clots. Resumption of ordinary diet should not be too long delayed, as absence of proper nourishment will only help in the spread of the disease.

(ii) *In tuberculous enteritis*.—A pure milk diet is recommended by some, but as milk does not agree with most of these patients it is better avoided. Dry milk preparations are, however, digested by many. Milk may also be given as *dahi* beaten up with water into a drink. Sometimes proprietary milk foods like Horlick's malted milk are better tolerated.

To avoid irritation of the ulcers, roughage should be reduced to a minimum. Strained vegetable soup and mashed potatoes serve the purpose well. We combine this with soft rice and lean fish. In no case should vegetable or fruit pips be allowed to be swallowed.

All experts agree in giving a high calcium and high vitamin diet. Food calcium is supplemented by calcium injections. Two ounces of orange juice with  $\frac{1}{2}$  ounce of cod-liver oil or a few drops of adexolin or haliverol should be given 3 or 4 times daily. When oranges are not available tomatoes may be substituted.

(iii) *Laryngeal tuberculosis*.—Special dieting is called for only when there is dysphagia. When this condition develops, the throat should be anaesthetized with cocaine or orthoform before giving foods. When dysphagia is at all severe, pasty, semi-solid foods like porridge or pudding are swallowed with greater ease than either solids or liquids.

the usual clinical symptoms associated with the disease, we find an increasing number who, after a thorough examination, we are convinced have no tuberculosis at all. In many of these patients a skiagram taken when the patient has first consulted his doctor has apparently confirmed the diagnosis even to the point of signifying advanced disease.

In this paper we wish to call attention to a group of these patients where we think an error of diagnosis has been made chiefly on the interpretation of the *x*-ray picture. With the more frequent use of *x*-rays in the diagnosis of chest conditions, there is the possibility of a greater number of these people being wrongly condemned as tuberculous, a mistake we ourselves made in the earlier years of our work.

The first indication that we were facing what may be called a pseudo-tuberculous condition arose out of routine blood examinations of all our patients. Some of these showed a very high eosinophile count, even to over 90 per cent in the differential count. Very few of these had tubercle bacilli in the sputum, even when in more recent years we have used culture methods and stomach-wash examinations for the isolation of tubercle bacilli. These patients had almost all the usual symptoms of tuberculosis including fever, cough, sputum, loss of weight, chest pain and sometimes hæmoptysis, and by physical examination showed the signs usually taken as indicating tuberculosis. At the same time we began to notice that in many of these patients the skiagrams showed a fairly constant similarity. The condition is so typical that in the common parlance of our *x*-ray room it is called 'eosinophile lung'. This is characterized generally by an extensive mottling over both lung fields, usually evenly distributed; the size of the shadows is about 2 mm. and there is usually a certain amount of increased striation. In some patients the *x*-ray findings are more marked than in others. The general appearance is something similar to miliary tuberculosis or to silicosis.

Since we began to think these cases might not be tuberculous, we have done tuberculin reactions, and the majority of these have been negative. We have also studied changes in the differential count after subcutaneous injections of 'old tuberculin', and in most there was no increase in the *stabkernige* cells, a strong indication of the absence of an active tuberculous condition.

A further study of this condition showed that these patients had a good prognosis as judged by the discharge results and after-histories, beyond what could have been expected had the condition been tuberculous.

It has also been possible to check up some of these patients several years later, and they have still shown the same condition, especially in the *x*-ray picture and the blood picture, and sometimes also the clinical symptoms were unchanged.

*Material selected for study*

In selecting material for this study we went through our records since 1925, when routine blood studies were first begun in the institution and about which time also the x-rays began to be used, and we selected all patients, who on admission had an eosinophilia higher than 20 per cent. We also included 179 patients since 1930, (when routine monthly blood studies began) who, although coming with less than 20 per cent eosinophiles, had above that figure during their stay in the sanatorium. This made a total of 533 patients, out of about 5,500 admitted during the period reviewed. Besides these, we have also included 67 patients who came for consultation without being admitted, and who had above 20 per cent eosinophiles or more, making a total of 600 altogether for review.

The figure of 20 per cent eosinophiles was chosen as the lower limit, partly because it was indisputably a high eosinophilia, even though eosinophilia is common in India where helminthiasis and skin infection are frequently found, partly because we have not found those with below 20 per cent eosinophiles showing the x-ray picture referred to above.

*General review of material*

The records of the 600 patients were first analysed according to eosinophile count, sputum

possible, about the aetiology of the condition which we are studying.

The arrangement in the tables is according to absolute eosinophile count as being more accurate than the percentage of eosinophiles in the differential count, although in practical work we find this percentage gives sufficient information. There are included in the tables those patients, 179 in number, who were admitted with less than 20 per cent eosinophiles, but who had an eosinophile count above that figure during their treatment, all with less than 1,000 eosinophiles, and the majority of those with between 1,000 and 2,000 eosinophiles were admitted with less than 20 per cent. In the majority of these there was a transient eosinophilia which could be explained without reference to any lung condition. An increase in eosinophiles is fairly frequently seen during or soon after treatment with sanocrysin, an observation of Houghton (1932) and others. Attacks of unexplained pruritis, eczematous skin conditions, scabies, exacerbation of filarial infection also caused eosinophilia during treatment.

The highest eosinophile counts met with were 85,000, 48,160, 47,880, and 42,390 per c. mm. The highest eosinophile percentage was 92 per cent.

From table I it will be seen that 194 (32.3 per cent) of the patients had tubercle bacilli and so were definitely tuberculous. With the increase

\* The stools of patients coming for consultation were not examined.

examination for tubercle bacilli, stool examination for ova and for cysts.

These findings are given in table I.

In a number of patients with sputum negative for tubercle bacilli, tuberculin tests were done and the results are shown in table II.

The classifications in tables I and II were selected with a view to obtaining information, if

of the eosinophile percentage, the percentage of positive sputum findings rapidly decreases; e.g., below 2,000 eosinophiles, 126 out of 206 (61.2 per cent) have tubercle bacilli; above 5,000 eosinophiles, only 11 out of 164 (6.7 per cent) have tubercle bacilli.

The number of patients with ova is high, namely 308 out of 509 examined (60.5 per cent).

TABLE II

Reaction to tuberculin of tubercle bacilli negative patients with an eosinophile percentage of 20 or more on admission or during treatment

Eosinophile count on admission (per c.mm.)	Number showing no tubercle bacilli	Number examined with tuberculin	PIRQUET OR MANTOUX		OLD TUBERCULIN AND SCHILLING		NEGATIVE TO TUBERCULIN	
			-	+	-	+	Number	Per cent
0-500 ..	5	4	1	3	0	2	0	0.0
500-1,000 ..	14	13	5	6	2	2	5	38.5
1,000-2,000 ..	61	31	13	13	13	8	15	48.4

Above 20,000 ..	16	3	3	0	1	0	3	100.0
No absolute count	103	23	14	4	9	1	18	78.3
TOTAL ..	406	188	100	64	92	30	112	59.6

Of these patients we found that 250 (49.1 per cent) had hookworm infection, and 58 other helminth infections without hookworm, mostly *Ascaris lumbricoides* and *Trichuris trichiura*. The helminthiasis is higher than the general average, for another examination of 3,000 patients showed only 28 per cent infected with hookworm.

From table II it may be seen that of 406 patients who showed no tubercle bacilli, 188 were examined with tuberculin, 164 with von Pirquet or Mantoux, and 122 with old tuberculin followed by the Schilling count. As stated earlier, tuberculin was not used much in the earlier part of the period under review.

The von Pirquet test was done with undiluted old tuberculin and the Mantoux generally with a standard dilution of 0.1 c.cm. of 1/1,000, but, in a few patients 0.1 c.cm. of 1/10,000 was used, and in some the standard dilution, if negative, was followed by 0.1 c.cm. of 1/100. In the old tuberculin test with the Schilling count, 0.3 c.cm. of 1/100 old tuberculin was given subcutaneously, with Schilling counts on each of two days

before, and 24 hours and 48 hours after the injection. The technique is described by Benjamin and Barton (1937).

It will be noted that of the 188 patients examined with tuberculin, 112 (59.6 per cent) were negative. As there was no reason to suppose these patients were in an anergic condition, this is strong evidence of the absence of tuberculous infection. Although the figures are small, there is indication that, the higher the eosinophile count is, the more numerous are tuberculin-negatives.

#### Study of the x-ray

The next part of the investigation was a study of the skiagrams. This was possible in 430 of the 600 patients with high eosinophilia. In 170 no x-ray film was available for study, because in some of the earliest of the series of patients no skiagram was taken, in some patients coming for consultation screening only was done, in earlier years some films were sent away with the patients, and some of the early films were not satisfactory for the present study.

TABLE III

Examination of x-ray films of patients with high eosinophilia

Eosinophile count on admission (per c.mm.)	Number of patient-	TB-positive patients with 'non-eosinophile lungs'	TB-NEGATIVE PATIENTS	
			'Non-eosinophile lungs'	'Eosinophile lungs'
0-500 ..	41	39	2	0
500-1,000 ..	58	43	8	7
1,000-2,000 ..	89	39	33	17
2,000-3,000 ..	49	24	15	10
3,000-5,000 ..	37	9	10	18
5,000-10,000 ..	52	4	12	36
10,000-20,000 ..	45	0	4	41
Above 20,000 ..	7	0	0	7
No absolute count	52	2	11	39
TOTAL ..	430	160	95	175

Out of the 430 patients, 175 gave an 'eosinophile lung' x-ray picture, as described earlier. All had a negative sputum. In none of the bacilli-positive cases was there a typical 'eosinophile lung' picture; 95 patients were negative for tubercle bacilli in the sputum and had no 'eosinophile lung' picture (table III).

From table III it will be seen that the 'eosinophile lung' picture was more often found in patients with the higher eosinophile counts; of 102 patients with a count of over 5,000 eosinophiles, 84 had the characteristic x-ray findings, while of 266 patients with below 5,000 eosinophiles, only 52 had the characteristic x-ray. The positive sputum findings decrease with the increase of eosinophiles.

The 'eosinophile lung' picture varied considerably in degree, being very marked in some individuals and only of slight degree in others, the variation not always connected with the number of eosinophiles.

Consideration of 175 'eosinophile lung' patients

If we consider the 175 patients whose x-ray showed the characteristic picture, we find the following :—

(a) Sex and age distribution

Age	Men	Women
Below 10 .. ..	6	2
11-15 .. ..	13	6
16-20 .. ..	30	9
21-25 .. ..	35	9
26-30 .. ..	31	4
31-35 .. ..	12	3
36-40 .. ..	9	3
41-50 .. ..	3	..
TOTAL .. ..	139	36

The proportion of men to women is slightly higher than that for all patients admitted to the sanatorium, being about 4.1 against the average of about 5.2.

The age distribution is largely the same as that found for all patients admitted to the sanatorium, the only point being that there are

rather more in the youngest age group and no old people are found.

(b) Symptoms and physical findings

If we consider the symptoms as given in the patients' histories, or on examination in the sanatorium, we find the following the most common :—

Cough .. ..	153
Fever (history) .. ..	144
Sputum .. ..	110
Loss of weight .. ..	86
Pain in chest .. ..	84
Coloured sputum or hæmoptysis .. ..	45
Asthma or bronchitis .. ..	35
Loss of strength .. ..	31

A history of influenza or pneumonia was given by 28 patients.

On physical examination, 91 patients had râles or rhonchi; 63 of 146 patients admitted had fever, mostly low, for a very short time after admission.

From the above figures, it will be seen that it was quite natural that the patients were sent here with a diagnosis of tuberculosis.

(c) Stools

The stool findings are shown in table IV.

From table IV it will be seen that there is a lower incidence of intestinal infection than is found for the whole group of 600 patients as shown in table I, 48.2 per cent as against 64.6 per cent in the large group. Also the percentage of patients with the eosinophile count over 5,000 is less than those with a count of under 5,000, namely 40.2 per cent, as compared with 56.9 per cent.

Tuberculin tests

Of the 175 'eosinophile lung' patients, 106 were tested with tuberculin, and the reactions are shown in table V.

In table V it will be seen that 74 (69.8 per cent) were negative to tuberculin; there being no appreciable difference between those with above 5,000 eosinophiles and those with below 5,000. The percentage of negative reactors is

TABLE IV  
Stool examinations of tubercle bacilli negative patients and 'eosinophile lung' x-ray findings

Eosinophile count on admission (per c.mm.)	Number of patients	STOOL EXAMINATIONS				
		Number examined	Ova found	<i>E. histolytica</i> and/or <i>Giardia</i>	Number with intestinal infection	Per cent with intestinal infection

*Illustrative case histories*

(i) K. S., 13 year old boy.  
*First admission* from 18th September, 1932, to 6th December, 1932.  
*Family history.*—An older brother, a patient in the sanatorium in 1927, diagnosed non-tuberculous, with high eosinophilia.  
*Previous history.*—Cough on and off for five years; last four months increased cough with much sputum.  
*Physical examination.*—General condition fairly good. Auscultation showed râles and rhonchi all over both lungs. Other organs nothing special. Temperature normal.  
*X-ray.*—Over whole of both lung fields an evenly distributed mottling of small shadows, non-confluent, about milary size, with increased striation all over (figure 1).  
*Sputum.*—Twelve direct smears and one concentration negative for tubercle bacilli.  
*Blood.*—Hæmoglobin 95 per cent; red cells 4,376,000; leucocytes 19,000; neutrophils 29 per cent (*Stabkernige* 1.5); eosinophiles 52 per cent; basophile 1 per cent; lymphocytes 17 per cent; monocytes 1 per cent; sedimentation rate 39 mm. (Westergren 1 hour); Kahn +; malaria parasites not found.  
*Stools.*—No ova or cysts found.  
*Weight.*—66 lb., increasing to 80.  
The patient improved well under symptomatic treatment.  
*Second admission* from 29th May, 1936, to 3rd August, 1936.  
*History.*—For 2½ years after discharge remained well, then again cough and little sputum, with short period of fever; a local hospital reported a few acid-fast bacilli in antiformin smear.

*X-ray.*—As previously, extensive mottling over both lungs, a little more intense on right side, but of same type as reported above. No changes suggesting exudative lesion (figures 2 and 3).  
*Sputum.*—Twelve direct smears, three concentration tests and one culture, all negative for tubercle bacilli.  
*Blood.*—Hæmoglobin 85 per cent; red cells 4,584,000; leucocytes 16,000; neutrophils 17 per cent (*Stabkernige* 1.0 per cent); eosinophiles 63.5 per cent; basophiles 0 per cent; lymphocytes 13.5 per cent; monocytes 6 per cent; sedimentation rate 58 mm. (Westergren 1 hour); Kahn ++ (no clinical symptoms of syphilis).  
*Stools.*—Hookworm ova present; no amœbæ or cysts found. No bacilli found (three direct smears).  
*Tuberculin.*—von Pirquet—positive.  
*Weight.*—Increased from 97 to 101 lb.  
The patient improved again under symptomatic treatment.  
(ii) Male, age 27. Admitted 21st May, 1936; discharged 9th June, 1936.  
*Family history.*—Nil.  
*Previous history.*—1934 high fever for two months; last three months cough, fever, little sputum.  
*Physical examination.*—General condition good; auscultation showed some fine râles over right lung only. Temperature 99.8°F. (evening, rectal).  
*X-ray.*—Both lung fields show extensive mottling of numerous small non-confluent nodules, not very sharply outlined, about milary size, evenly distributed over whole field; increased fine linear markings, some striations leading upward to apices from hilus (figures 4 and 5).  
*Sputum.*—Four direct smears and one concentration negative for tubercle bacilli.  
*Blood.*—Hæmoglobin 85 per cent; red cells 4,944,000; no malaria parasites; Kahn negative.

\* Old tuberculin 3 mg. given subcutaneously on 2nd June, 1936.

*Stools.*—No ova or cysts found; no tubercle bacilli found (four direct smears).

*Tuberculin.*—von Pirquet negative; old tuberculin and Schilling count negative (*see above table*) with no local or general reaction to 3 mg. of old tuberculin subcutaneously.

*Weight.*—Increased from 108 to 110 lb.

(iii) Male, age 18. Admitted 21st November, 1936; discharged 13th February, 1937.

*Family history.*—Nil.

*Previous history.*—Many attacks of fever in 1935. thought to be malaria; dry cough and low fever last four months with little sputum; loss of weight 12 lb.

*Physical examination.*—General condition good; auscultation showed no râles or rhonchi; later few rhonchi found. Temperature 100°F. (evening, rectal).

*X-ray.*—Both lung fields show more than normal lung markings, mostly due to increase of linear striations, and also numerous miliary-sized opacities, not confluent (figures 6 and 7).

*Sputum.*—Thirteen direct smears and two concentrations and one culture (six tubes) negative for tubercle bacilli.

*Blood.*—Hæmoglobin 116 per cent; red cells 5,664,000; no malaria parasites found; Kahn negative.

demonstrate tubercle bacilli, and a high percentage of the cases are tuberculin negative.

In 113 of the 175 patients, a Kahn test was done, and was positive in 15, which is a higher percentage, being nearly double that found in the routine examination of our patients. None of the patients, however, showed clinical manifestations of syphilis, and the x-ray picture is not that usually associated with a syphilitic lung, nor is eosinophilia a characteristic finding in syphilis.

Pneumoconiosis is another possibility that has to be considered. The usual industrial pneumoconiosis, such as silicosis, anthracosis and asbestiosis, can be ruled out in our series of patients as they were not engaged in such dusty occupations. If the lung condition were due to the ordinary dust of a dusty country, the condition should be extremely common in many parts of

\* Old tuberculin 3 mg. given subcutaneously on 1st December, 1936.

*Stools.*—Trichuris ova found; no cysts.

*Urine.*—Occasionally albumin +, with few casts and pus cells. No tubercle bacilli found.

*Tuberculin.*—von Pirquet negative; old tuberculin and Schilling count negative (*see above table*), with no local or general reaction to 3 mg. of old tuberculin subcutaneously.

*Weight.*—Increased from 105 to 118 lb.

### Discussion

The above three case histories make it clear that we have to deal with a lung condition which cannot easily be classified under the most common chronic lung affections.

In none of the x-ray films of the special group of 175 were typical tuberculous changes manifest, such as early or advanced infiltrations, of either exudative or more productive character and which, if found, are mostly confined to certain areas of the lung. The only form of tuberculosis with which this appearance could be compared would be that with either a hæmatogenous or bronchogenic dissemination of tubercles all over the lungs. But in these 'eosinophile lung' cases the elements in the lung condition have a smaller appearance than is generally found in the different forms of miliary tuberculosis, and linear markings are more increased than even in chronic miliary tuberculosis. Besides the nature of the x-ray findings not being quite typical, we have shown that in none of the cases have we been able to

India, but there is no evidence of this. Normally eosinophilia is not noted as being associated with pneumoconiosis. Also the usual x-ray picture found in persons affected by dusts normally shows much more linear marking than in our cases. However, further studies are needed before ordinary dust can be ruled out as an agent.

Chronic changes in the lungs due to long-standing heart disease can be ruled out as a cause, because in only one patient was valvular disease noted.

Another lung condition associated with eosinophilia is Löffler's syndrome (Löffler, 1932). But this is a fleeting infiltration with eosinophilia, which appears suddenly and disappears within a fortnight. It appears in certain localized areas of the lung and leaves no trace on resolution. In none of our cases have we found any changes of this nature and in most of them the lesions have shown no marked changes in the time we have observed them, and in several we have even found the same change after several years.

In connection with Löffler's syndrome it has been suggested, for example by Wild and Loertscher (1934) and Müller (1938), that the x-ray changes in the lung are caused by the passage of ascaris larvæ through the lungs. Müller was able to produce in himself fleeting multiple infiltrates in the lung with eosinophilia, by eating

material containing ascaris ova. This leads us to wonder whether the condition described by us might be a chronic condition caused by the repeated passage of hookworm or ascaris larvæ through the lungs. But if this were so, the eosinophilic condition, being generally believed to be an acute reaction of allergic type, should disappear even if the chronic lung changes remained. We have also observed patients over periods of several months when it was most unlikely that re-infection of any size either with hookworms or with ascaris could take place and x-ray and eosinophilia remained unchanged.

Apart from the question of lesions in the lungs being caused by direct passage of helminth larvæ through them, these intestinal infections are thought by Acton and Dharmendra (1933) and Dharmendra and Napier (1935) to be responsible for a number of cases of bronchial asthma. In the total number of our high eosinophile series there is a high infection with hookworms and other parasites, and a moderate number with *Entamoeba histolytica* and *Giardia intestinalis*, but in the patients who show the 'eosinophile lung' picture, the intestinal infection is less, namely 48.2 per cent, against 64.6 per cent for the whole group, or 71 per cent for the whole group less the selected group of 175. In the highest eosinophile group the intestinal infection is even less than in groups with lower (but still high) eosinophile counts. It seems most unlikely, therefore, that intestinal infection can be the sole explanation.

As regards asthma, the majority of the patients in our series have had cough and other chest symptoms over a long period, but only a few, namely 35, have reported symptoms of asthma or bronchitis, and in only a few of these have we observed typical attacks of bronchial asthma. In any case we can say that typical asthma is not characteristic of this disease.

In conclusion, it may be said that much in this clinical entity points to allergic origin, chiefly because the eosinophilia dominates the syndrome described. But it is possible that there may not be a single agent which causes such a condition, but several.

#### Summary and conclusions

Out of a series of 600 patients with 20 per cent of eosinophiles or more, 175 were found to show an x-ray picture characterized by an evenly distributed extensive mottling of small nodular shadows over both lung fields, with increased linear markings.

Of the 175 patients, 106 had more than 5,000 eosinophiles per c.mm. on admission; 48 per cent had intestinal infection with helminths, *E. histolytica*, or *Giardia*; 69 per cent were tuberculin-negative. The significance of these figures is discussed, and they are compared with the findings for the whole group of 600 patients.

The lung condition found cannot be explained as due to tuberculosis, syphilis or heart disease.

## A NOTE ON TUBERCULOSIS SURVEYS

By R. B. LAL, M.B., B.S., D.P.H., D.T.M. & H., D.B., F.N.I.

From the Department of Vital Statistics and Epidemiology (All-India Institute of Hygiene and Public Health, Calcutta)

CONSIDERABLE interest has recently been evinced by tuberculosis workers in tuberculosis surveys. As to the objects and scope of these surveys, however, there appears to be no clear understanding and the notions about the subject seem to be rather vague. Whilst some are satisfied with carrying out tuberculosis tests amongst a group of school children, others consider a survey incomplete without the determination of the so-called causative factors. In many instances little thought is given to a clear definition of the objects of the survey. They are merely taken for granted and it is believed that the purposes of the survey, whatever they may be, will be amply served by collecting from the patients attending tuberculosis clinics a large mass of information, the larger the better. It will be obvious to anyone who has considered the matter carefully that such an outlook can lead to no results.

Speaking generally, a survey, be it that of a piece of territory or of a section of a community, may be conducted with two objects in view, namely: (1) exploratory or (2) with a set purpose of acquisition of the knowledge of the relevant conditions existing at the time, or likely to develop in the near future, which might help and guide the planning and execution of some proposed constructive work or the putting into effect of some desirable improvements.

(Continued from previous column)

The possibility of its being caused by dust inhalation is considered. The condition is different from Löffler's syndrome. It has some similarity to certain types of bronchial asthma found in India and thought to be connected with intestinal infection. The condition is believed to be allergic in origin.

The importance of blood differential counts in the diagnosis of doubtful cases of tuberculosis is evident.

#### Acknowledgment

We wish to acknowledge the help of Dr. P. V. Benjamin, the present Medical Superintendent, who has been associated with us in this work.

Very often there is a temptation to wander away from the set object and this must be resisted. Thus if the survey is to serve a useful purpose its objects and scope must be clearly defined, and in the planning and execution these must be constantly borne in mind.

A tuberculosis survey may be conducted with the objects of : (1) Estimation of the extent of the tuberculosis problem in a community, or (2) Determination of what may be conveniently called, the 'herd structure' in regard to tuberculosis. Herd structure in a wide sense would include the state of the community with regard to the extent and nature of sources of infection, the type of the prevalent organisms, the immunity status, and the accessory factors, including climatological, socio-economic and others, favouring or otherwise the spread of infection and disease from the sources to new victims. Besides, one must determine the forces inducing changes in these factors as well as the rates of change. Among these will be included the community effort, both official and non-official, which might be or could be directed towards an anti-tuberculosis campaign.

A third object which a survey might serve is to provide data for purposes of comparison before and after the institution of certain measures relating to prevention or treatment or both. Besides, an investigation into a particular problem, *e.g.*, the effect of a certain industry on the incidence of tuberculosis, may be considered as a special type of survey because the general principles and methods applicable to such an investigation are the same as those of the surveys.

The exact scope of a particular survey will be determined mostly by three factors, namely :—

1. The object,
2. The means available, and
3. The amount of co-operation that can be enlisted, etc.

The question of the objects and scope of tuberculosis surveys has been more specifically discussed in the Report of the Tuberculosis Survey Committee of the Indian Research Fund Association in 1937 to which reference might be made. The committee has envisaged five different types of surveys according to the object in view and have commented upon the circumstances under which they might be carried out and the organization and funds required in each case.

The few tuberculosis surveys which have so far been carried out in this country have been sponsored by clinicians who have specialized in tuberculosis with the result that undue emphasis has been placed on the patient, his diagnosis and treatment, rather than on the communal aspect of the problem. The data have been mostly collected in the dispensaries rather than in the homes of patients. The danger inherent in such a procedure is that the impressions, or even facts, collected regarding those attending

the clinics may be projected to the whole population. Even when precaution is taken to steer clear of this error, it has in most instances been found difficult to draw useful conclusions from the available data, with regard to the population under consideration. It is, therefore, desirable that the survey should be planned properly so that after the data are collected they may be capable of proper analysis and be sufficient in quantity and quality to provide satisfactory information on the main questions. In respect of many items, information will be required for both tuberculous and non-tuberculous families and individuals for purposes of comparison.

To meet these two requirements it is necessary clearly and exactly to set out the nature of the information which will be collected, how it will be classified and how it will be analysed for purposes of instituting comparisons and contrasts, and how the whole scheme will be organized. Proper planning requires considerable critical ability, judgment, experience and expert knowledge of the subject, and it is here that mistakes are often made. Mistakes committed at this stage cannot be corrected later on, with the result that much valuable data go to waste on account of facts vaguely recorded or for lack of information on vital matters, the inferences that can be justifiably made from the available data remain inconclusive. On the other hand, one of the most common failings is to overburden the schedule with a great many unnecessary items which are only vaguely and very indirectly concerned with the points under consideration. Such extra items of information not only cause unnecessary waste of time of the investigators but complicate matters and confuse the issues. No definite rules can be laid down as to how the items of information should be selected or how they should be classified. But speaking generally the following considerations should be kept in mind in drawing up a schedule :—

(1) Each person should bear a serial number, which should in no circumstances be duplicated to designate another individual, nor should one person bear more than one serial number. This rule applies equally to other units of observation such as a village, a house, or a family.

(2) Sufficient information should be included to identify the person who made the inquiry and the date when such inquiry was made. This is necessary for reference. It will facilitate checking and will be found essential in case a correction has to be made.

(3) Necessary information for identifying the individual to whom the particulars in the schedule relate should be included.

(4) Personal information relating to age, sex, etc., should be recorded, so as to work out the usual distributions of population in relation to various problems.

(5) The results of any tests which it is intended to carry out should be noted on standard forms, so that they are comparable.

(6) What other items are included will depend upon the decision as to what hypotheses are to be tested. For this reason definite hypotheses bearing on the problem must be formulated. Thus, for instance, the hypothesis that urban residence tends to immunize the population, and thus modify the course and nature of the disease, may be a matter for investigation. For this purpose it will be necessary to have for comparison groups of individuals who have been subjected to varying degrees of city life ranging from *nil* to complete. The types of lesion in the two groups will then be compared. However, since it is known or suspected that the type of lesion is subject to variation owing to factors other than the one under investigation (e.g., primary or secondary infection, quantum of infection, age, etc.), it is obviously necessary to remove the effects of these disturbing factors or, in other words, to restrict comparison to such groups of urban and non-urban people as are the same in all other material respects. Thus it will be necessary to have a knowledge of the operation of these other factors on each individual under study. This is by no means an easy matter. In many instances either this important point is altogether missed, or, on account of lack of technical knowledge of the subject or methods, it is not properly accomplished. Nevertheless, it is a necessary condition for making valid comparison.

(7) The basis of classification may also present considerable difficulties. Care should be taken to define precisely each class and the basis of classification should be related to the tuberculosis problem. Moreover, the classes should be readily determinable with the means provided. The class intervals should be reasonable in number, neither too many so as to become difficult of defining, nor too few so as to lose significance. A key of instructions should be provided to ensure uniformity of records and intelligent co-operation.

(8) In designing the schedules attention should be paid to the size of paper, print, etc., so that they can be easily manipulated. The same applies to the arrangement of items so that interrogation or recording of observations proceeds in a logical order. Much time and trouble can be saved by appropriately numbering the items of information and the various classes according to the method of sorting which it is intended to apply.

For the convenience of workers and for purposes of securing uniformity, some authoritative body such as the Tuberculosis Survey Committee might prepare schedules for two types of surveys. Those who wish to carry out other types of survey may find the above points helpful in preparing the schedules, and the keys to the schedules. In the absence of previous experience they will probably do well to enlist the collaboration of an experienced epidemiologist in planning the inquiry.

A matter of considerable importance to which only a passing reference has so far been made requires further consideration. While we actually investigate units of population such as individuals, families, houses, or villages our real interest lies beyond them. We are not so much concerned with the particular members or units which are subjected to examination, but our aim is to outline the picture of the community or population of an area in relation to the tuberculosis problem. We wish to see the woods rather than the trees. We should bear this in mind when we proceed to examine the constituents of the community or group for which the picture is required.

It would appear that the most satisfactory picture will be obtained if every member constituting the community is subjected to investigation. This is impracticable when, as is invariably the case, the community is large or many particulars about each individual are to be investigated. Besides for most purposes the desired information can be obtained by examining a sample of the population provided the sample is properly taken. A constituent member of a sample is not there in his personal capacity but in his capacity as a representative of a certain group. Hence care has to be exercised that (a) the various groups or classes of the population, made in reference to the characteristic studied or having a bearing on it, are all represented in the sample, (b) that the relative number of the individuals representing various group are included in the sample in the proportion in which they are met with in the community as a whole, and (c) that the representatives from each group are drawn in a random manner so that there is no conscious selection. Any bias introduced in the selection of representative numbers of a group will vitiate the results on account of intra-group variation. This source of error is not always apparent and must be carefully guarded against. In order that the sample satisfies these criteria it is necessary to know into what classes the population is divisible in relation to the problem under investigation and what is the approximate strength of each class. To settle this point a preliminary survey of the whole community is required. When preliminary data have been collected a good sample may be selected by a man possessing the necessary technical knowledge and experience. Naturally, the more homogeneous a population is, the smaller will be the number of classes, and hence a smaller number of representatives will constitute a good sample. Similarly the intra-group homogeneity will determine the size of the contingent required to represent it adequately. A general rule, to satisfy adequacy of size, can be applied in suitable cases. A sample will be of adequate size if its mean in respect of the characteristics under investigation does not significantly differ from the mean of the population from which it

has been drawn. The deviation of the sample mean from the mean of the population varies inversely as the square root of the size of the sample. In practice this rule does not help because the mean of the population is not known. All that is possible is to take samples of increasing sizes, till a sample size is reached when any further addition will not significantly reduce the difference between the means.

Having secured a representative and adequate sample of the population, the procedure of survey becomes one of technical and administrative organization. The activities of the survey staff may, for convenience, be divided into the following classes:—

1. Securing public co-operation by educating public opinion.

2. Application and interpretation of tuberculin test, clinical laboratory and x-rays examinations of persons suspected of the disease and their treatment. The circumstances under which the open cases are placed with regard to chances of conveying infection to susceptibles should be noted and the results communicated to health authorities.

3. Routine collection, analysis and interpretation of epidemiological and clinical data.

4. Presenting the report.

The success or otherwise of the survey will largely depend upon the administrative and technical capabilities and energy of the officer in direct charge of the survey and the assistance and co-operation obtained from the staff and the public. The money spent upon the survey will be largely wasted if the services of a properly trained officer and other personnel cannot be secured. It is a mistake to assume that a successful clinician with experience of tuberculosis work in a clinic or a hospital will, without epidemiological training and experience, be able to handle a survey efficiently. Unfortunately this mistake has been committed in more than one instance with disastrous results. Apart from other considerations, therefore, it is a sound policy not to undertake complicated surveys, such for example as those designed to elucidate causal factors, unless properly trained and experienced personnel is available.

To obtain the maximum results in the minimum period it is necessary to prescribe the duties and responsibilities of the various members of the staff and the amount of work which on an average is expected of them. The officer in direct charge of the inquiry is the proper person to undertake this task with the consultation of a more experienced worker if necessary. While local circumstances and capabilities of the junior personnel will largely determine the exact distribution of duties, it is necessary to point out that the tendency to devote too much time to the clinic and the office work rather than to the patient's houses must be strongly resisted. The place of work of the surveyors is essentially in the homes and work places. The clinic is

only an auxiliary organization put up for purposes of studying the type of disease in suspected cases. It also subserves a minor function in enlisting the co-operation of public by offering free treatment facilities. Undue emphasis on the clinic work, to the extent of even making it a treatment centre for all diseases, on the plea that thereby public co-operation is secured, has wrecked some survey schemes. It is, for instance, within the knowledge of the author that in a particular survey, in which the officer in charge spent the greater part of his time in the clinic, the perfunctory nature of the home visits was demonstrated by the fact that many a patient in the third stage of the disease was recorded for the first time at the clinic even though the house had been visited a few days previously. It is obvious that in such circumstances little reliance could be placed on the results of home visits. The argument is sometimes advanced that, in the initial stages of the inquiry, contact with the public can be best made through the clinic and later on the routine can be changed to increase home visits. This is a mistaken policy. It may be true that the contact is made more easily through the clinic but it is not the proper kind of contact. It is a wrong approach and as such it does not lead to the right type of public co-operation. Once the public has been taught to expect free treatment, it naturally becomes a demand, and when this is denied or restricted, it stiffens rather than softens resistance. Besides it becomes unintelligible to the lay public why the investigators should interfere with them and undertake the examination of their person and homes when they either have no need for it or do not desire consultation. In drawing up the time-table of the various members of the staff, therefore, the clinic should appropriate the minimum time required for essential service.

In enlisting public co-operation the key position is held by the lady health visitor. It is she that prepares the way for the doctor. Given good personality, tact and a certain amount of leisure she can secure the wholehearted co-operation of the housewife. The visit breaks the monotony of her domestic life and conjures up new hopes of betterment of the family. A man is as a rule more argumentative. He believes that the sacred responsibility of preventing outsiders from crossing the doorstep rests heavily on him and he looks upon any outside intrusion with suspicion. He thinks of all kinds of improbable implications which might adversely affect the welfare of the family. With an ignorant man it is only the outside pressure, be it official or that of public opinion, that breaks the resistance. This method of approach is not very desirable. When, however, the previous consent of the housewife has been obtained he resigns himself to the view that after all it is a domestic affair in which his interference is not really needed. The doctor's visit is now awaited with eagerness, and once

his initial coolness is got over by a tactful remark on the part of the doctor, he is converted into an enthusiast. The confidence in the survey party displayed by the parents is infectious. The children see a lot of fun in their work and they not only willingly submit to the prick of the needle but also wish to participate actively in it by offering their services for odd jobs. The lady health visitor becomes a friend and is followed by a crowd of children from house to house.

With this method of approach the services offered by the clinic are gratefully accepted and not claimed as a matter of right.

To obtain information of maximum value and correctly to appreciate the position in the community is both science and art. The uninitiated will do well to consult an experienced worker, preferably the one who helped him in planning the survey.

These general remarks are offered in the hope that workers undertaking surveys for the first time may avoid some of the pitfalls into which the writer has seen people falling. Details of the procedure for carrying out the survey work have been purposely avoided. For these the report of the survey committee should be consulted. A suggestion which may be finally made is that it will be more profitable if the surveys are systematically made according to a plan rather than in a haphazard manner. If for instance it is desired to frame one anti-tuberculosis policy for the whole province and for that purpose a comprehensive knowledge of the position is required, it will be desirable to select the areas to be surveyed according to the principles of sampling mentioned above. Relatively large samples should be taken for preliminary surveys whose object would be to ascertain the extent and intensity of tuberculosis reaction in various groups of the population and also the incidence of obvious cases, especially those most unfavourably placed as regards treatment and transmission of disease. This type of survey should be followed to determine the morbidity and mortality rates, as well as the type of disease. For this more detailed type of survey smaller units may be selected, particularly from those sections of the community to which the preliminary survey had drawn attention on account of high incidence, or for other reasons.

Surveys for ascertaining the causal factors have been conducted by certain workers in foreign countries. Of these the Tyneside inquiry conducted by Bradbury (1933) is a good sample. It should, however, be realized that such inquiries, if they are to be made properly, require a considerable amount of time and money. Besides, unless a properly trained staff is available these undertakings are not likely to yield results commensurate with the time and money spent on them. Another point which should be taken into consideration is whether the available resources would provide

## MODERN MEASURES IN THE MASS CONTROL OF TUBERCULOSIS IN THE UNITED STATES OF AMERICA

By S. R. A. SHAH, K.S., M.B., B.S. (Punjab),  
D.P.H. (England), D.T.M. (Liverpool)  
Public Health Department, Punjab

### Introduction

RECENTLY I had an opportunity, as the holder of a Fellowship from the International Health Division of the Rockefeller Foundation of New York, of spending a year in the United States of America studying tuberculosis, and I visited most of the important centres and institutions where anti-tuberculosis work is being carried on. A few of the institutions visited by me were: Henry Phipps Institute for the study, treatment and prevention of tuberculosis, Philadelphia; Saranac Laboratory for the study of tuberculosis and Trudeau Sanatorium, Saranac Lake; Bellevue and New York Hospitals, New York City; Herman-Kiefer Hospital, Detroit; Tuberculosis Department of the University Hospital, Ann Arbor; Pottenger Sanatorium, California; Fairview Sanatorium for the Negroes, Michigan; Sanatoria for American Indians at

(Continued from previous column)

sufficient funds for instituting collective measures according to the indications obtained by the survey. Thus, for instance, if it is found that overcrowding is the principal factor operating in the spread of tuberculosis, in a certain area, would it be possible to rectify this defect with the funds that could be made available? It may also be argued that in case funds could be made available for such a desirable object, it is not necessary to await the verdict of a tuberculosis survey to proceed with a scheme of removing over-crowding. However, it must be remembered that the results of a properly conducted survey may provide a convincing argument for educating public opinion and strengthen the hands of the health authority to overcome the inertia and hesitancy on the part of those that hold the purse. In any case, if such a survey is to be made the greatest possible care should be exercised in selecting the area. Unfortunately, statistical data which might guide and help in the selection of the area are practically non-existent in this country. Under the circumstances it is highly desirable not to undertake the survey of causal factors unless the tuberculin survey and survey of morbidity and mortality have been carried out and their results are known. Besides providing the necessary information required for the more detailed survey the preliminary surveys will help in training the personnel and in creating public support.

Besides gaining clinical experience, my studies were arranged in such a manner as to enable me to gain first-hand knowledge of the methods of mass control of tuberculosis which is the subject of this article.

#### *Evolution of modern concepts of tuberculosis control*

Soon after the discovery of the tubercle bacillus the view gained ground that adult tuberculosis was endogenous, that is, the lodgement of the infecting agent took place during childhood and manifested itself in later life on account of certain vague reasons such as the strains and stresses of life which might break open the old, not quite healed, foci, and liberate tubercle bacilli. While it was admitted that in an adult with a positive tuberculin reaction, indicating childhood infection, a massive dose of infection might break down the acquired immunity, it was believed that ordinarily he had no further danger of contracting a fresh infection from outside sources. A little infection during childhood was supposed to protect against a big infection during later life.

For these reasons the anti-tuberculosis campaign was directed mainly along two channels:—

- (a) against the vaguely understood strains and stresses of adult life to guard against the flare-up of dormant childhood infection.
- (b) to protect children in the nebulous hope that they would acquire just enough tuberculosis as would protect them against future infection and no more.

Hardly fifteen years ago these were the prevailing views. The element of direct infection of the adult was either not clearly understood or just ignored.

At this stage two extraordinary developments were taking place in the United States that were destined later to form the basis for the modern, also known as the newer, methods of tuberculosis control.

Ghon and others had drawn attention to the 'primary complex'. First infection or childhood type of tuberculosis, and superinfection or adult type of tuberculosis were studied and understood more and more clearly. Opie (1924) and Opie and McPhedran (1926) of the Henry Phipps Institute of Philadelphia in their pioneer investigations on latent tuberculosis of the lungs brought out clearly that adult lesions represented new infections from without. Simultaneous and subsequent studies by McPhedran, Chadwick, Rathbom (Myers, 1930) and others confirmed these views. With more general use of the x-rays it became a common experience to find apparently perfectly healthy people with grave

progressive lesions of the lungs. The pathology of onset of tuberculosis was understood in a much better fashion. All this helped to bring the contagious nature of tuberculosis into prominence.

The other development of far-reaching consequence was a country-wide programme to wipe out tuberculosis in cattle by slaughtering every animal that showed evidence of infection. In the beginning it met with great opposition on the part of cattle owners because it involved the destruction of a large number of cattle and sometimes of whole herds. Some compensation was paid for the animals killed but it fell far short of their actual value. Later, however, with better understanding of the owners that it was being done for the protection of the rest of their cattle, the campaign proved a complete success. Within a few years the infection among cattle was reduced to a minimal point. In many areas the rate of tuberculous cattle is less than 0.5 per cent to-day (*J. A. M. A.*, 1934). This achievement has proved an eye-opener to physicians. What can be accomplished in bovine tuberculosis can also be achieved in human tuberculosis. Of course the drastic method of sending every tuberculin-positive animal off to the slaughter house cannot be applied to human beings but there are other means of achieving the desired end. Human beings with tuberculosis can also be prevented from infecting healthy people, and this can be brought about by intelligent management of patients either in their homes or in an institution until they improve to a stage when they are no longer dangerous for others, or failing that, until they die.

Thus, the discovery of exogenous infection of adults supplemented by the dramatic results of the direct attack on bovine tuberculosis in the United States gave shape to the modern campaign against tuberculosis which, to quote Long (1935), 'centres around the patient with open tuberculosis expectorating bacilli. Reduced to its simplest terms the object must be to find the open case, and bar it as a source of contagion to others'.

It is generally admitted that environmental factors and resistance-lowering influences such as poverty, over-crowding, poor housing, malnutrition, inadequate medical care and lack of education play a considerable part in the drama of tuberculosis, but these are considered as contributory causes facilitating the spread of infection. The prime object of a modern campaign is to find the spreaders of infection, and once they are found, to keep them from being the source of contagion to others.

#### **TUBERCULOSIS CONTROL MEASURES**

The modern programme of tuberculosis control in the United States can be divided into two broad categories, case-finding and case-supervision. Every effort is made to maintain a proper and constant correlation between the

two. This is facilitated by having a unified direction of effort towards case-finding and case-supervision. So far as governmental agency goes, the entire programme, right from the organization of hospitals down to the education of the public at large, which is a necessary adjunct to a successful case-finding programme, is the concern of one department only, the Department of Health. In the various States the responsibility for the programme is usually placed in the Division of Tuberculosis of the State Department of Health. A Director of Tuberculosis responsible to the State Commission of Health is in charge of this division.

In view of the communicability of the disease the following procedures are considered essential in the administration of control measures :—

- (i) Reporting and registration of cases of tuberculosis.
- (ii) Active and progressive case-finding.
- (iii) Provision of modern hospital care and treatment for tuberculosis cases.
- (iv) Domiciliary supervision of families in which tuberculosis is or has been a problem.
- (v) Follow up of all cases and contacts.
- (vi) Rehabilitation of cases.
- (vii) Financial assistance to needy families.
- (viii) An educational programme for the medical and nursing professions and public through institutes, demonstrations, lectures, exhibits, motion pictures and literature.

In addition to the above-mentioned programme, the department of health carries out periodic appraisal and evaluation of procedures and services from the point of view of administrative economy and of expansion of our knowledge of the epidemiology and pathogenesis of the disease. It regulates, stimulates and assists research work.

It is impossible in this brief article to describe in detail the various procedures just mentioned. An attempt may however be made to mention a few important factors. It may be noted that in the different states the procedures may vary in some detail according to the conditions prevailing there, but the fundamental problems are the same for all communities.

#### *Case-finding*

It is of prime importance in any communicable disease that the sources of infection be found.

Since tuberculosis in cattle has been so well controlled in the United States there remains only one important source of tubercle bacilli and that is the person who has tuberculosis. Forms of tuberculosis other than pulmonary are comparatively rare and therefore are not so important as sources of infection, but occasionally they also can disperse bacilli and are not altogether ignored.

It is important to find persons who have tuberculosis before they have become 'open'

eases because, at this stage, not only can they be treated with far greater chances of recovery, but also they cannot have done any harm to others. However, it is common experience in the United States even to-day to find 80 per cent of cases reported to be in the moderately and far advanced stages of the disease.

Tuberculosis is such an insidious disease that a person suffering from it does not generally seek advice until it is well advanced. It is therefore of great importance in the successful conduct of the control programme to go out into the field and find him. This is the primary function of the tuberculosis clinic. The clinics are usually permanent, and the tendency to-day is to have them either as a part of a tuberculosis hospital or to run them under close supervision of one.

Formerly, tuberculosis clinics, and for that matter all tuberculosis institutions, were largely organized by private philanthropic bodies such as the National Tuberculosis Association and Charities Aid Association of New York State. Their policy was to demonstrate to the government as well as to the people the practical methods of tuberculosis control. The great value of the institutions was soon recognized and state, county and municipal sanatoria and clinics followed so that to-day most of these institutions are state-controlled.

The ideal in view now is to expand the network of clinics and sanatoria and to cheapen the methods of diagnosis to such an extent that the entire population has a periodic health examination sufficiently complete to rule out tuberculosis, but as yet this is not practicable. It is practicable, however, to find out special groups in the population where tuberculosis is more prevalent than others and to concentrate our efforts on them. Examples of such groups are contacts of open cases, men in hazardous occupations like those exposed to silica dust, inhabitants of congested areas and adults.

In the recent past, school surveys have been very popular. School children form a group that can be easily regimented, and some believe that such surveys have great educational value. Moreover, anything done for the children appeals to the public fancy. But now, through experience, it has been realized that for case-finding it is not a fruitful procedure. Children of school age have very little clinical tuberculosis and almost never have it in a communicable state. If these children are really to be protected we should direct our efforts towards older groups where the spreaders of infection are to be found.

This has been most strikingly brought out by Plunkett in reporting the experience of New York State Tuberculosis Clinics. He states (quoted by Douglas, 1939) that because of the large number of persons that must be examined to find a case, it costs over 4,000 dollars a case to find tuberculosis in the age group from 0 to 14, whereas from 15 to 24 it costs only 187

dollars and grows less with each decade until after 45 years it only costs 77 dollars per case.

Thus, from the point of view of case-finding it is far more profitable to concentrate on college populations and older age groups than on school children. The educational value of such surveys among school children is also doubtful.

School surveys, however, have one value. When the number of tuberculin positives is low in a community, say up to 40 per cent, then the infection in a child may imply contact at home and it may help in tracing the source cases, in many instances. In the United States the infection rate is usually much higher than 40 per cent.

In communities where the reactor-rate among adults is relatively low the best way to carry out such surveys is to make a tuberculin test of all members of the group and to x-ray the positive reactors. Where the tuberculin reactor-rate is high there cannot be much saving in tuberculin-testing before resorting to the more expensive x-ray examination of the chest.

Great efforts are being made to lessen the cost of x-ray examination. Some of the methods that have been devised are mentioned below :—

(a) Fluoroscopy is coming into prominence day by day. Fluoroscopic examination of the lungs is not commonly believed to be as valuable as examination by x-ray films, but as an aid to further selection of the persons before x-raying them it has come to acquire a place in the routine procedures of several well-known institutions in the United States. The lesions suspected with the fluoroscope are always confirmed in roentgenographic films.

The advantages of fluoroscopy over x-ray films are that it is less expensive and more expeditious. The drawbacks are that this method requires trained medical personnel to make the examination and there is no permanent record other than the description dictated by the observer.

Experimenting on a large series of cases, the Metropolitan Life Insurance Company of New York has adjusted the relative values of the various methods of case-finding as follows :—

X-ray	..	100 per cent (arbitrary)
Fluoroscopy	..	87 per cent
Physical examination	..	36 per cent
History	..	33 per cent

(b) Paper films have been used extensively in mass surveys as a screen and suspected cases are x-rayed on celluloid films. Recently paper films in use in New York clinics have been greatly improved and in the opinion of some workers they are proving as good as celluloid films.

(c) Photographing the fluoroscopic image on 35 mm. film, sometimes called 'micro films', has been tried in several places, but on account of the tremendous magnification to which the film must be subjected for the reading of results and

consequent considerable loss of detail, this is not generally considered satisfactory.

(d) At the Herman-Keifer Hospital in Detroit, Michigan, Drs. Hollis Potter and Bruce H. Douglas, in collaboration with the General Electric X-ray Corporation, are developing a method of photographing the fluoroscopic image on a 4 × 5 x-ray film that holds promise of providing an economical and yet satisfactory film that will obviate the necessity of magnification for routine examination. I had the privilege of reading a number of these films with Dr. Douglas and after some practice found no difficulty in making out even very small lesions without magnifying the film.

### *Isolation and treatment*

Having found the cases the next logical step is to isolate and treat them.

In early days sanatoria were as a rule situated far away on mountain tops or in deserts. The functions of a sanatorium in the United States were at best those of a first-class boarding house under medical supervision, where advanced and moderately advanced cases lived for a few years of comparative comfort.

An epochal step was the inauguration in 1908 of the International Congress on Tuberculosis in Washington, D.C., which was attended by outstanding leaders from all parts of the world. The proceedings of this convention gave precision to the existing knowledge of the disease and the principal recommendation made was that 'institutional treatment of tuberculous be given as a preventive measure'. This fact, together with the development of the idea to 'cure the patient in the climate in which he expects to live', brought the sanatorium close to the door of the people. More recently, with better knowledge of the epidemiology of the disease and improved methods of treatment, a modern sanatorium (the term hospital is preferred) is the virtual headquarters for all anti-tuberculosis work in the area it serves. Besides treatment of the patients such an institution runs a diagnostic out-patient service, guides and assists local authorities in conducting case-finding clinics, provides medical and technical experts for examination and portable x-ray machines where needed, helps private practitioners in the diagnosis and treatment of tuberculosis, supervises public health nursing services, initiates and helps surveys of students and other special groups, trains public health nurses and social workers for tuberculosis work, provides instruction to medical students and pupil nurses and post-graduate instruction to physicians and, finally, serves as a centre for tuberculosis research.

It is a hospital of this type that Plunkett (1938) has in mind when he says that 'The modern tuberculosis hospital and the well-equipped, well-conducted case-finding and follow-up clinic are society's most valuable administrative weapons against this disease.'

They are more formidable still when combined into one service'.

Years ago, a careful socio-medical study of tuberculosis in a representative community was conducted in Framingham, Massachusetts. On the basis of this study a minimum standard of one bed for each annual tuberculosis death was arrived at. More recently, Chadwick (1933) has recommended a goal of two beds per death and this is now generally recognized as representing the minimum requirements of a community for adequate hospitalization of the tuberculous.

The annual average number of tuberculosis deaths in the United States is 70,000. There are about 1,300 institutions containing 100,000 beds, or a ratio of 1.4 beds per annual death. The aim is to have at least 50,000 more beds so that the standard of two beds per death is achieved.

For large cities the goal of two beds per death is within the range of possibility of attainment and in the long run they save money by providing the required facilities, thus eliminating a terrific economic drain in loss of life and man power. For the rural areas and small towns, however, it seems difficult, if not impossible, to achieve even the minimum standard, particularly because a vast majority of these patients can pay little or nothing towards the cost of their treatment. In this connection a quotation from the Report of the Committee on 'Tuberculosis Among Negroes (1937)' published by the National Tuberculosis Association is illuminating:—

'The important rôle which sanatorium treatment plays in any programme for the control of tuberculosis is almost universally recognized. We wish to emphasize, however, one fact which is sometimes overlooked, namely, that adequate facilities for hospitalization are doubly important in dealing with the Negro tuberculosis problem. The Negro race as a whole, being in the lower economic stratum, lives in greatly over-crowded quarters the presence in which of an open case of tuberculosis often exposes relatively large numbers of individuals to massive and repeated doses of virulent tubercle bacilli. There are rarely facilities for caring for the patient at home, the diet is usually inadequate, and there is in most instances a dearth of knowledge as to what should be done. In the vast majority of Negro homes it is utterly impossible to provide for the patient those things which we know are essential for his recovery and equally impossible to give any adequate protection from infection to other members of the family.'

When it is difficult to provide adequate facilities for the hospitalization of the tuberculous there are certain measures which while less effective are also less costly and it is quite justifiable to promote the use of such temporary measures.

#### *Burr cottages*

In the Southern States poor families in rural areas live in one or two-room shacks. Their families are usually large. An open case in such a family has no chance whatever to rest and it is impossible to protect other members of the family from infection. In such circumstances Burr cottages are being used extensively

in the absence of proper hospital accommodation.

Fig. 1.—A Burr cottage.

The Burr cottage is a wooden structure usually 8 feet  $\times$  10 feet. It is screened and ventilated and can be easily carted about in a truck by unscrewing the six parts—four for the sides and two for the roof and floor. The cottage is fixed at a short distance from the residence of the family and, where climate permits, a patient can remain in the cottage throughout the year. With the help of an adequate public-health nursing service and a capable physician a great amount of benefit can be derived both by the patient and his associates.

#### *Screened porches*

Many homes in rural areas have porches which if screened can serve as fairly satisfactory quarters for a tuberculosis patient.

#### *Homes for custodial care*

These are 'homes for incurables' which furnish custodial care rather than sanatorium

Fig. 2.—A Negro home in the south being screened.

treatment for far-advanced cases and are found chiefly in Southern States for the benefit of the negro community for whom facilities for hospitalization are far short of requirements. These provide the patients with essential medical and nursing care, adequate food and a place to rest at a comparatively low cost and at the same time take out of circulation open cases of tuberculosis.

#### *Ambulatory pneumothorax clinics*

In Philadelphia and Chicago, ambulatory pneumothorax clinics have been developed with considerable success. Selected cases, such as arrested cases, cases with negative sputum, or those who are waiting for accommodation in a sanatorium, are given ambulatory treatment. This plan, although no substitute for hospital care, provides some treatment for a number of patients who would otherwise go without it and also has value in training physicians. An outstanding example is the large chest clinic of the Henry Phipps Institute, Philadelphia.

#### *Beds for the tuberculous in general hospitals*

During recent years there is a definite trend towards the use of beds in general hospitals for tuberculosis patients. By 1938, one hundred and seventy-seven general hospitals in the United States had made arrangements for the care of tuberculosis patients. An outstanding example is the University Hospital, Ann Arbor, Michigan. Two whole floors of this hospital are reserved for tuberculosis cases. Some Canadian provinces are so convinced of the utility of this plan that all general hospitals receiving governmental aid are required by law to reserve 10 per cent of their beds for this purpose. To be fully effective this arrangement calls for careful supervision by the staff of a close-by sanatorium.

Fig. 3.—University Hospital, Ann Arbor, Mich., where two whole floors are reserved for tuberculosis cases.

#### *Collapse therapy as a public health procedure*

Unfortunately there is no specific for this disease. There is no drug similar to quinine in malaria, no antitoxin as in diphtheria. Indirect methods of treatment must be relied upon.

In the past, reliance was placed on rest in bed, and with less justification, on climate and altitude. On analysis of the reports from institutions in various parts of the United States, some noted for their climate, others not, the results are found to be essentially the same and most disappointing except for minimal cases. For this reason many institutions, until recently, admitted only 'early' cases. Obviously such institutions were not contributing much toward the control of the disease, for the patients with advanced disease who were refused admission were the very cases that were keeping tuberculosis a serious problem in the country. If they could be got out of the way, 'early' cases would not be developing.

Collapse therapy has changed the picture. A large percentage of cases who show no signs of progress on rest in bed alone show rapid improvement on collapse of the tuberculous lung and, what is most important from the public health view-point, the output of tubercle bacilli is cut short. The present view is to employ collapse therapy as an epidemiological procedure rather than as a therapeutic individual measure. Another great advantage gained is that by this means it has become possible for a sanatorium to convert ten or more open cases to closed cases per bed as against 'curing' one or two cases only per bed every year. This is of particular significance in areas where bed accommodation is limited. It is understood that the programme includes an efficient follow-up service and that necessary facilities for refills at proper intervals exist in the locality where the patients reside.

#### *Follow-up and rehabilitation*

A very important part of a tuberculosis programme is the provision of effective medical 'follow-up' to see that improved cases are properly advised and the least signs of reactivation of the disease detected before any harm is done to them or before they become open cases and a menace to others again. Such supervision is exercised either by the local public health department or by the sanatorium service. In

Fig. 4.—Free mobile x-ray facilities for diagnosis and follow-up are available in most States.

the case of the former, on account of their multifarious and apparently more urgent duties, often a very secondary place is relegated to this activity.

Rehabilitation of ex-patients is perhaps the most difficult problem to tackle in the tuberculosis campaign. There are several reasons for it. In the United States, compensation laws make it very difficult for a person with this handicap to be employed in industry. There is a general prejudice in the public mind against the employment of such persons. Then again, of the 100,000 patients who are discharged annually from the 600 odd sanatoria in the United States it has been estimated that about half of them need vocational training to fit them for a productive life.

Rehabilitation is the least developed phase of the anti-tuberculosis programme. The National Tuberculosis Association are making an intensive study of the problem and have launched an experimental programme in various sanatoria throughout the country. Provision of sheltered occupations is finding favour and is being pushed.

#### *Reporting and registration of cases*

Any attempt to control tuberculosis, in the absence of good reporting, will be futile. It is only when we know accurately the incidence of the disease that we can judge how and where to direct our activities to the best advantage. Moreover, in the absence of reliable and complete vital statistics we cannot evaluate the success of our programme. The paramount importance of the practitioner, who is consulted by a large majority of patients in search of diagnosis, is therefore obvious. Much depends on his ability to diagnose early cases and the amount of co-operation he extends in the way of notifying and advising the patients and their associates.

There are several reasons why a physician may fail to report. Among them are indifference or under-developed sense of responsibility towards the public, a desire not to displease the patient who wishes to conceal his disease and unwillingness to permit health department agents to visit the patients. All these objections have to be met and can be met by mutual understanding.

For the physician to be able to diagnose early cases and to administer the most modern forms of treatment special training is necessary. Several means are employed to achieve this and to fit him for anti-tuberculosis work.

(a) *Internships and residencies* in hospitals and sanatoria are the best means of imparting special training to physicians in the diagnosis and treatment of tuberculosis.

(b) *Special courses*.—An outstanding example is the comprehensive course held at Saranac Lake regularly every year. Eminent authorities on various phases of tuberculosis from several institutions participate in this course.

(c) *Teaching clinics*.—These have proved useful in training negro physicians. The first one was organized at Memphis, Tennessee, on a co-operative basis, the clinician in charge being provided by the National Tuberculosis Association, nursing service by the city health department, and clinic space by one of the negro hospitals. Negro physicians are invited to bring their patients personally to the clinic for expert consultation. The clinic is held once a week. The clinician in charge makes a careful examination of the patients, explaining and demonstrating his findings to the attendant physicians. It is, however, made clear to the family physician that the patient is to be under his care whatever the findings. Many other cities have adopted this plan.

(d) *Institutes for physicians*.—A short but very intensive programme of lectures and demonstrations by outside physicians of repute is arranged periodically, the object being to arouse and maintain the interest of physicians in tuberculosis and also to bring to their attention from time to time new developments in the diagnosis and treatment of tuberculosis. These are becoming very popular.

#### ANTI-TUBERCULOSIS LEGISLATION

In New York City, a generation ago, an ordinance was passed making it possible for the authorities to arrest and imprison an incorrigible consumptive, i.e., an open case of tuberculosis who after repeated warnings refused to obey the regulations concerning the destruction of sputum and other measures to prevent his spreading infection among his family and associates. The enforcement of this law was impossible for ethical and social reasons as well as because of the great numbers involved, but there is no doubt that it had a good warning effect on the negligent patient and also helped in drawing the attention of the public pointedly to the danger of an open case. Since then most communities in the United States have framed more practical laws for the control of the disease in the light of its communicable nature.

Anti-tuberculosis legislation falls into two categories, coercive and enabling. Coercive laws are directed towards the prevention of spread of infection by making the reporting of cases by physicians mandatory and by enjoining all such precautions as are necessary to prevent the transmission of the disease from the sick to the well. Enabling laws permit the governmental bodies such as State Boards, Municipalities and County Councils to raise funds to meet the cost of the various procedures of the control programme and to put them into execution.

#### *Conclusion*

The control of tuberculosis in the United States is by no means an accomplished fact, but the tremendous and far-reaching advances in the knowledge of the disease that have taken place during the past decade have brought the

ultimate victory over this age-old foe of mankind within the realm of possibility. There has already been a definite reduction in the death rate from tuberculosis, the rate now being less than one-third that which obtained at the turn of the century. Dr. H. R. Edwards, Director of Tuberculosis, New York City Department of Health, sums up the position in these words: 'If we had no further knowledge than that now available there is no reason why with the proper application of methods the disease cannot be eradicated'.

Finally, I may quote the words of Dr. Esmond R. Long, Director of the Henry Phipps Institute, Philadelphia, from his lecture to the Medical Association of Puerto Rico: 'The way seems perfectly clear. The mechanism for the control of tuberculosis is understood. In the same general form as in the United States, with modifications to suit each local situation, it is proving effective throughout much of the world to-day. Admittedly the cost is great. But the chief requirement is an aroused public interest and it is highly gratifying to see this public interest rising throughout the Americas'. Thanks to the initiative of Her Excellency the Marchioness of Linlithgow the same is coming true of India too.

#### Summary

Before the bacterial origin of the disease was known the public health campaign against tuberculosis lacked specific direction. Emphasis was laid on the unfavourable conditions of life that helped in producing this disease. With the discovery of the tubercle bacillus the communicable nature of the disease was established, but it took almost two decades before this fact was fully appreciated.

More recently extensive studies on the exogenous mode of infection in human beings and the virtual eradication of bovine tuberculosis in the United States have brought the contagious nature of the disease to the fore, and have led to the attention being focussed on the elimination of the opportunity for infection in the mass control of tuberculosis.

The key-note in the modern anti-tuberculosis campaign is to find the open cases of tuberculosis and, having found them, to isolate and treat them. A constant and proper correlation between case-finding and case-supervision is essential for the successful conduct of the programme. This is best achieved by having a unified control over the two activities. A close co-operation between the medical practitioner, philanthropic organizations and the governmental public health department is further necessary for the success of the programme.

In the finding of cases, when the means at our disposal are limited, it is best to concentrate on groups likely to yield the greatest results. Examples of such groups are contacts of open cases, inhabitants of congested areas, workers exposed to silica dust, and adults.

School surveys are not a fruitful means of case-finding, but can help in locating source cases in communities where infection rate is not very high.

Tuberculin-testing all members of a community and x-raying the positive reactors is perhaps the best method to detect cases. X-raying is still a very costly procedure. Alternative methods are being devised to cut down the costs without affecting the efficiency in diagnosis.

The isolation of open cases in a sanatorium is of the utmost importance in the mass control of the disease. A standard of two sanatorium beds per annual death is considered the bare minimum requirement. Where this standard cannot be achieved certain compromise measures are adopted. Treating tuberculosis cases in general hospitals is becoming increasingly popular.

Collapse therapy is now looked upon not only as an individual therapeutic measure, but as a public health procedure of great significance. With its aid, cavities get closed and sputum is rendered negative much sooner than is otherwise possible. This cuts down the spread of infection and also enables the hospital beds to register a quick turn-over of cases.

The after-care of the discharged patient and his rehabilitation into the community are as important as the treatment, but, while the treatment is the best developed and the most successful part of control programme, the follow-up and rehabilitation are the most difficult and least developed phases of the campaign. Vocational training and sheltered occupations seem to hold the best promise for a solution of the perplexing problem of rehabilitation.

Private practitioners constitute the first line of attack. To be able to diagnose early cases and to administer the latest forms of treatment call for their special training. It is still more necessary in the case of physicians who are to run clinics, hospitals and sanatoria which form the most vital part of anti-tuberculosis programme.

Legislation of 'enabling' and 'coercive' types is considered necessary in the United States to empower the governmental bodies to provide necessary facilities and to enforce such measures as aim at preventing the spread of infection.

# From ENGLISH MEADOWS

A WEST OF ENGLAND PASTURE

Former Stockbreeder

Cow & Gate Milk Food is made by special processes from the milk of the world-famed pasture lands of the West of England. The most modern and scientific methods are applied to every stage of its preparation, so that the valuable and exceptional nourishment of the purest and richest milk is available in *easily digestible and absolutely safe* form.

This English Food from English meadows with its wholesome nutrition has brought a great deal of happiness to mothers in India.

Firm flesh without flabbiness, sound well-defined bones, and the smile of Health and Happiness—these are some of its attributes.

Richest of all in Vitamin D (250/300 International Units per pint of milk). *It is not repacked in India.*

## COW & GATE MILK FOOD

**"THE BEST MILK FOR BABIES WHEN NATURAL FEEDING FAILS"**

Distributing Agents: Carr & Co., Ltd., Wittet Road, Ballard Estate, Bombay,  
also at Calcutta, Karachi and Madras.

## B.D.H. PRODUCTS

of outstanding clinical value

### ANACARDONE

Respiratory and cardiac stimulant (diethylnicotinamide) of high activity and negligible toxicity.

### CARBACHOL

Cholinergic substance with an action more prolonged than that of acetylcholine and active when administered orally.

### LEPTAZOL

Cardiac and respiratory stimulant and convulsant for use in schizophrenia. Administered orally, intravenously or subcutaneously.

### BROMETHOL

Basal anæsthetic for rectal injection (tribromoethyl alcohol in amylene hydrate) of proved clinical efficacy.

### DEHYDROCHOLIN

Cholagogue and diuretic for oral or intravenous administration in conditions of biliary and hepatic insufficiency and of malabsorption of fats.

### MERSALYL

Highly efficient mercurial diuretic issued in forms suitable for parenteral, oral or rectal administration alone or collaterally with cardiac glycosides.

## PHYTOFEROL CAPSULES

(Vitamin E Capsules B.D.H.)

### In Neurological and Myological Derangements

There is considerable evidence rapidly accumulating which demonstrates the remarkable value of vitamin E therapy in the treatment of neurological and myological derangements.

Following the animal experiments demonstrating that nervous degeneration followed by muscular dystrophy is a primary lesion in hypovitaminosis-E, the administration of vitamin E to human patients suffering from muscular dystrophy also to those manifesting such conditions as amyotrophic lateral sclerosis has produced considerable improvement. Indeed it has been stated that (Med. Press and Circ., February 28th, 1940, p. 174) 'the value of vitamin E in muscular and nervous disease, and in sterility, means that it is probably the most valuable vitamin, from the therapeutic point of view, yet discovered'.

Vitamin E is available as a standardised product in Phytoferol Capsules each containing the equivalent of 3 mg. of  $\delta$ -tocopherol.

OCTOBER

## A TUBERCULOSIS POLICY FOR INDIA

An important part of almost any public health scheme is the education of the public—or propaganda. Propaganda is a wide term; it doesn't simply mean warning the people of the existence of an evil—tuberculosis in this instance—and working them up into a state of panic, nor, on the other hand, telling them that they simply have to do is this or that, and all will be well—with them and their families at least. It is much more comprehensive than this. Unfortunately, during the last few years the word has acquired an unpleasant sound and has almost come to mean the repetition of an untruth so frequently that even those who originated it believe it. Propaganda may take many forms and its objects are manifold, but above all public health propaganda should aim at presenting to the people the truth and the whole truth, in as concise and comprehensible a form as possible.

A story was once told, of an Irishman who had got himself and his companions into so much trouble by his elaborate prevarications that they all agreed that the only way out of their difficulties was to make a clean breast of the whole affair and tell the truth. 'But', said the Irishman, 'we must first decide what the truth is to be!' So it must be with propaganda. We must decide what the truth is to be before we attempt to tell it to the people. That is to say, it is essential that we should first have a clear conception of our policy. We must not start off vigorously in one direction and advocate one particular measure as the only possible one to adopt, then, finding it impracticable, decry it and say 'perhaps after all that wasn't the best measure to adopt' and turn our propaganda machinery in another direction: any such suggestion of vacillation will be fatal. Though it is true that we do not know the whole truth about any medical subject and that research is always bringing to light new facts, we do know a very great deal about tuberculosis, its cause and the way it is spread, the methods by which it can be prevented and its treatment; we also know the extent of its ravages in this country, and the limitation of the public purse for putting into practice these methods of prevention and treatment. We should therefore be in a position to adopt a definite policy, one that is capable of unlimited extension and, without alteration of the main structure, modification, as new facts come to light and new discoveries are made.

It has been emphasized repeatedly by tuberculosis workers in this country that we must not adopt a tuberculosis policy directly from some more advanced country and graft it on to Indian conditions. We must shape our own policy; this policy must be based (a) on the scientific knowledge that has been gathered from the study of tuberculosis throughout the world, (b) on the special knowledge that workers in this country have gathered regarding the deviation of the disease from the universal picture, to which should be added, with caution, observations made in other countries with climates similar to those of India, (c) on our knowledge of the habits and state of education of the peoples of India and of the administrative framework on which the policy will have to be grafted, and finally (d) on a proper estimate of the funds that are available, are likely to be available, or could possibly be made available, *vis-à-vis* the economic state of the country.

In Great Britain the sanatorium is the central point of the tuberculosis policy, but in India it would be absurd to advocate a policy of sanatoria for all, because we know that such a policy could not be financed now, nor in the near future, nor even in the more distant future as far as this concerns us, our children, or even our grandchildren. On the other hand, as sanatorium treatment is the treatment of choice, in this as in any other country, we must not take the reactionary attitude that sanatoria are luxuries India cannot afford, for even if, through necessity, the centre of gravity of the tuberculosis campaign is in the dispensary, or tuberculosis clinic, the sanatorium should be the ideal at which we aim, and any comprehensive scheme must include a large number of sanatoria in different parts of the country, to stand so to speak behind the tuberculosis clinic.

We open this number with a paper by the medical commissioner to the Tuberculosis Association of India on 'organized home treatment'. Realizing that the vast majority of patients cannot hope to receive institutional treatment, and that in the ordinary way 'home treatment' means no treatment at all, Dr. Frimodt-Møller has outlined a scheme for 'organized home treatment'; this is more comprehensive than the title suggests and is in fact a scheme for the control of tuberculosis in India. He has laid down certain measures as being essential if 'home treatment' is to have any real meaning; these are:—

- (a) The tuberculosis clinic, which is to be not only the centre of diagnosis, active treatment, and dispensing, but the spiritual centre of the movement from which should come inspiration and advice to the local practitioners and the lay workers.
- (b) Hospital wards and sanatoria where selected cases are treated, and where accepted forms of treatment are used and their efficacy demonstrated, and

any new and promising forms of treatment are tested. These should be the most important centres for training tuberculosis experts.

- (c) Close co-operation between the local practitioners and the tuberculosis clinic.
- (d) Welfare committees who will co-operate with the clinic and other tuberculosis institutions.
- (e) 'Colonies or settlements for tuberculous ex-patients'.

It is only within such a framework that 'home treatment' can possibly be successful. The necessity for provision of hospital wards specially reserved for tuberculosis and/or sanatoria we have already emphasized, and, in these days of more active and surgical treatment, it is becoming increasingly important that there should be a tuberculosis ward in every large general and teaching hospital, as it is not only the specialist that should receive instructions on this disease, but every medical man and woman in the country.

The clinic, as we have suggested, will have to be the pivotal point of any tuberculosis scheme in this country for many years to come, and the necessity for close co-operation on the part of the local medical practitioner on one side and the welfare workers on the other is obvious. It is only when we come to the place of 'colonies or settlements for ex-patients' that a little doubt arises in our minds and we begin to wonder whether this is perhaps not an attempt to copy too closely western methods.

It is of course possible that this writer has in his mind a kind of convalescent section of a sanatorium, where patients who do not require any active treatment and are fit to do light work should be placed for a number of months or even years. Such a scheme is in all probability practicable but beyond this we doubt if it would be advisable to go in following methods suited to western countries. There, conditions are very different; the majority of the people are urban dwellers, and their work is of such a nature that the individual crippled by tuberculosis is unfit to return to his previous employment; there is seldom any place for a 75-per-cent man in modern industry and if he attempts to hold his own he will inevitably break down, so the colony or settlement had to come into being. But is it the same in India? Undoubtedly, parallel cases could be found, probably hundreds of them, but they are the exception as 90 per cent of India's population live in rural areas and a very large proportion of the urban dwellers keep in close touch with the villages from which they originated and will insist on returning there when their health breaks down or they require a rest. Such people will willingly stay in hospital or in a sanatorium, but it seems doubtful if they could be persuaded either to uproot their families from their traditional surroundings or to cut themselves off from them, even if it

would be economically sound to recommend such a procedure on a large scale. The life of the cultivator in India may not be a very easy one, but the strain that is put on him is not comparable to that to which the average worker in the west has to submit, and some light task by which he can help to earn his daily rice can usually be found for him.

With this possible exception we are in entire agreement with the medical commissioner's minimum requirements and his scheme for organized home treatment. He has outlined a scheme that can be adopted now and is capable of infinite expansion, as funds become available and the education of the public progresses.

L. E. NAPIER.

## THE SPECIAL TUBERCULOSIS NUMBER

For the fifth successive year we are issuing a special tuberculosis number. As in previous years, we have had the assistance and advice of some of the leading tuberculosis workers in India, and this year a special editorial committee of the Tuberculosis Association of India has collected and selected papers and other matter for inclusion in this special number.

The editorial committee consisted of Dr. C. Frimodt-Møller, the medical commissioner of the Tuberculosis Association of India, Dr. A. C. Ukil, one of the pioneer research workers in tuberculosis in India, and Dr. Sikand, until recently secretary of the Tuberculosis Association of India. The editorial committee wish the number to be representative of expert opinion generally in India and not only of their own views, or of those of the officials of the Tuberculosis Association of India; in recommending the papers for publication, the committee do not necessarily identify themselves with the views expressed. The final selection of the papers for inclusion in the number rests, of course, with the editor.

## Medical News

### TUBERCULOSIS ASSOCIATION OF INDIA

#### TUBERCULOSIS NEWS

*Broadcast talks.*—The Tuberculosis Association of India has inaugurated a series of broadcast talks on 'Tuberculosis—A Menace to India' from the Simla Radio Station.

The subject of the first talk delivered by Her Excellency Lady Linlithgow, the President of the Association, on the 5th July was 'Meeting the Menace'. Her Excellency referred to the spread of the disease in India, the steps so far taken to meet the menace and laid stress on the necessity for the training of doctors who could take charge of clinics and other tuberculosis institutions. She closed by stating that with the will to understand the problem, and with the co-operation of the individual in every walk of life, from the big industrialist and employer of labour to the poorest inhabitant of his village, success will be obtained in the campaign against tuberculosis.

Major-General G. G. Jolly, Chairman of the Association, delivered the second talk of the series on the 17th July on 'Organized Fight against the Menace'. He explained the policy advocated by the Association—not as the only policy to be adopted, but as a useful step that could be taken at the present stage of development—respecting the control of tuberculosis by organized home treatment. He emphasized that if the scheme of organized home treatment was to succeed, there were five main activities which must be carried out in association with it. Firstly, establishment of modern tuberculosis clinics; secondly, creation of facilities for institutional treatment of selected patients; thirdly, closest possible co-operation between clinics and private practitioners; fourthly, formation of cure and after-care committees; and, fifthly, establishment of colonies or settlements for tuberculosis ex-patients.

**Research.**—(a) According to a decision of the central committee until such time as the Tuberculosis Association of India is in a position to undertake independent research work in tuberculosis, it should co-operate with the Indian Research Fund Association. With this end in view a sum of Rs. 4,000 has been paid to the Indian Research Fund Association for an epidemiological enquiry on tuberculosis under Dr. R. G. Cochrane, Chief Medical Officer, Lady Willingdon Lepet Settlement, Chingleput, Madras.

(b) A tuberculosis survey is being carried out in Vayalpad by the authorities of the Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle (Madras). Up to the end of May 1940, they had examined 2,000 persons out of whom more than 45 per cent were found infected with tuberculosis. From these positive cases, strongly reacting cases were taken to the sanatorium for x-ray examination and 48 were detected to be suffering from the disease.

**Provincial Tuberculosis Associations.**—(a) The Bengal Tuberculosis Association publishes a monthly journal in which, apart from news of general interest, articles by distinguished tuberculosis workers are reproduced. The annual subscription is Rs. 3, inclusive of postage.

The Bengal Association has raised so far during the current year a sum of Rs. 14,000 by a charity performance and an appeal for the 'Kalyani X-Ray Fund', the income from the latter being used entirely for x-ray examinations of poor patients.

(b) The Punjab Tuberculosis Association have made the following grants-in-aid during the present year:—Rs. 1,000 to Anti-Tuberculosis Dispensary, Jullundur, and Rs. 9,060 for equipment for the Rai Bahadur Gujar Mal Sanatorium, Amritsar.

(c) A care committee has been formed in Secunderabad under the Provincial Tuberculosis Association for facilitating treatment of tuberculous patients by giving monetary aid to them and to their families, if left unsupported.

The Union Mission Tuberculosis Sanatorium, Arogyavaram, Madanapalle, celebrated the twenty-fifth anniversary of its opening on 19th July, 1940.

Part of the Silver Jubilee celebrations was the opening of a fine Recreation Hall and Patients' Library costing about Rs. 20,000 without equipment. The hall which seats about 500 was built with donations given by patients, former patients and their friends and associated with the hall were the names of Dr. Dr. C. Frimodt-Möller whose connection with the sanatorium from its beginning is well known. Associated with the library was the name of Miss Gertrude Dodd, another of the tuberculosis pioneers of India whose donation was used for building the first sanatorium in South India out of which the Madanapalle sanatorium grew. The opening of the hall and library was performed by G. T. Boag, Esq., Chief Adviser to the Government of Madras, and at the public meeting in the hall Major-General N. M. Wilson, Surgeon-General to the Government of Madras, Dr. C. Frimodt-Möller, Medical Commissioner to the Tuberculosis Association of India, Rev. B. Rottschäfer, President of the Sanatorium, and Dr. P. Benjamin, Medical Superintendent, spoke. Grants were also given from the missions co-operating in the work of the sanatorium and from a great number of friends.

The third of the series of broadcast talks on 'Tuberculosis—A Menace to India' was delivered by Dr. C. Frimodt-Möller, C.B.E. (Hon.), Medical Commissioner to the Tuberculosis Association of India, from the Simla Radio Station on the 15th August, the subject being the 'Individual Defence against the Menace'. He said that the individual defence against the menace of tuberculosis in these days can be carried out far more effectively than before, not only in protecting the person against infection with tuberculosis, but even in securing restoration of health in many in whom the infection has developed to real and serious disease. The modern treatment has very much improved and many cases which 20 years ago would have ended fatally are now restored to live normal and healthy lives.

As defence measures against the disease, he laid stress on eating a well-balanced diet, on taking special care of health during certain periods of life (up to the sixth year and between the ages of 15 and 24), and after certain diseases.

**Central Advisory Board of Health.**—An important subject considered at the meetings of the Board at Poona in July last was the effect of housing and overcrowding on tuberculosis. It was agreed that while the rectification of defects in an existing slum area may be difficult, there can be no excuse when, after costly slum clearance by improvement trusts and other bodies, the cleared areas are permitted to be built over without due regard to the requirements of light, ventilation and sound hygienic construction. A strict enforcement of building by-laws in these circumstances is, therefore, an urgent necessity.

**Provincial and State Tuberculosis Associations.**—H. E. H. the Nizam of Hyderabad-Deccan has been pleased to sanction the construction of a tuberculosis sanatorium at Ananthagiri at an estimated cost of Rs. 12,50,000.

The Delhi Municipal Committee has decided to charge half fees for the vacant beds in the private cottages of the Silver Jubilee Tuberculosis Hospital during summer months.

**Tours.**—Major-General Jolly visited Calcutta and Indore at the end of August and discussed with the local workers anti-tuberculosis schemes and measures being taken for expanding their work.

#### CENTRAL ADVISORY BOARD OF HEALTH

At the meeting of the Central Advisory Board of Health, which took place in Poona in July, a number of subjects were discussed and decisions taken which, if acted upon, are likely to have a far-reaching effect on the health of the people of India. The Board, consisting as it does of the representatives of the Central and Provincial Governments and of the Governments of certain Indian States, is in a position to formulate health policy on lines which should secure wide acceptance in the country. Without co-ordination of effort between the numerous health authorities in India many of the country's problems, such as, for instance, control of infectious disease, cannot be solved successfully and the Central Advisory Board of Health, during the three years of its existence, has already proved its value as an integrating force in the campaign for raising the level of health of the people.

At this year's meeting the reports of two special committees appointed by the Board at its previous meetings to investigate the possibility of introducing compulsory inoculation of pilgrims against cholera and to study the complex questions associated with the prevention of food adulteration in India occupied a large part of the proceedings of the Board.

#### Inoculation of pilgrims

The Board, in adopting the report of the special committee appointed to examine the possibility of introducing a system of compulsory inoculation of pilgrims against cholera, considered that public opinion in favour of anti-cholera inoculation had grown in recent years and that the question of introducing compulsory inoculation could now be considered by

provincial and state governments without apprehension of any disturbing effects on the minds of the people. The Board recommended that provincial governments should select suitable centres in their areas and try out a scheme of indirect compulsory inoculation on lines successfully pursued by the Government of Bombay for the past four years in connection with the Pandharpur festival.

#### *Central Committee for Food Standards*

The committee on food adulteration had examined the problem from three aspects, viz (1) the technical, including food standards and technique of food analysis, (2) the legislative and (3) the administrative aspect. The committee has so far considered only the technical aspect of the problem and it is expected that its reports on the legislative and administrative aspects will be made available for the Board at its next meeting. The committee emphasized the fact that the improvement of methods of food analysis and the prevention of food adulteration in India will have to be a continuous process and that the establishment of co-ordination between the provinces is a matter second to none in urgency. With this object in view the Board recommended the appointment of a standing committee to be called 'The Central Committee for Food Standards' which would be in a position to advise the central, provincial and state governments on all aspects of food adulteration. Pending the establishment of the Central Committee the Food Adulteration Committee itself recommended all-India standards for 17 articles of food, while in respect of a number of other articles, the standards for which are a matter of controversy, the committee recommended that these should be investigated by the proposed Central Committee for Food Standards.

The existence of different food standards in neighbouring provinces and states at present interferes with the free flow of trade. The Central Committee should be in a position to suggest standards acceptable to all the governments concerned, thereby facilitating inter-provincial trade and a uniform enforcement of food adulteration laws.

Another important function of the Central Committee would be the issue from time to time to public analysts of 'instructions' incorporating the latest available information regarding methods of analysis. The standardization of methods is as important as the unification of standards of food purity.

Among other important decisions taken at this year's meeting of the Board, the following are of general interest:—

#### *Free laboratory service*

The importance of laboratory examination for the diagnosis of many infectious diseases cannot be over-emphasized. For instance, in regard to typhoid fever, the recorded statistics of mortality represent only a small fraction of the actual events. The diagnosis of typhoid fever cannot be done, in many cases, without laboratory aid. The provision of a free laboratory service to medical practitioners is essential for a successful campaign against this and many other infectious diseases. The value of such provision was demonstrated in Bombay during an epidemic of typhoid fever in 1938 when the Government of Bombay placed the services of the Haffkine Institute at the disposal of the medical practitioners of the city. In consequence many more cases were reported than had been experienced in previous years and the health authorities were able to locate with certainty the areas most affected and take effective measures against the spread of the disease.

The Board had before it a scheme for starting a provincial laboratory service which outlined a system of small district laboratories supported by regional laboratories for groups of districts and by a central laboratory for the province, which would co-ordinate the activities of the regional and district laboratories. The Board recommended this scheme for adoption by

provincial and state governments, with such modifications as local conditions may require.

#### *The health of school children*

There are numerous problems associated with the health of school children, for instance, the inculcation of healthy habits, provision for periodical medical examination and correction of the defects discovered during such examination, and the supply of adequate nutrition. It is generally accepted nowadays that systematic attention to the health of the children is an essential preliminary to any really remunerative system of instructions, whether it be in hygiene or other subjects in the curriculum. Further, teaching is not likely to be a success if the general school environment does not conform to reasonable hygienic standards. Before a considered policy can be drawn up and commended to the authorities concerned, much information has still to be collected as to the requirements of, and the progress already achieved in, different parts of India and the possibility of remedying the defects disclosed at the least possible cost. The Board therefore recommended that a special committee including educational experts should be appointed to report on the teaching of hygiene in schools, primary as well as secondary, rural as well as urban, the medical inspection of school children and their treatment and, in the primary educational stage, also on their nutrition.

#### *The effect of bad housing and overcrowding on tuberculosis*

There is abundant evidence available from countries where tuberculosis is prevalent, that unsatisfactory housing conditions and overcrowding tend to produce an increased incidence of the disease, while the transference of tuberculous patients from unhealthy to healthy dwellings produces an improvement in their symptoms and the physical signs of the disease. The failure on the part of the local bodies in many parts of India, to enforce the by-laws relating to health matters, has been a subject of constant reference in public health reports for a number of years.

### INDIAN CHEMICAL MANUFACTURERS' ASSOCIATION

#### *Press communique*

MEMBERS of the Indian Chemical Manufacturers' Association met Major-General G. G. Jolly, Director-General, Indian Medical Service, at the premises of the Association on 25th August.

The president welcomed General Jolly and others to the meeting. He referred to the activities of the Indian Chemical Manufacturers' Association as an all-India body since its inception two years before. He stated that the manufacturers of chemical and pharmaceutical products were in a position to supply most of the drug requirements of the country, but in starting new lines of manufacture they apprehended competition and dumping from abroad after the war. General Jolly then discussed with the members the requirements of the government in respect of medicines and drugs, and the possibilities of getting supplies.

Questions of the manufacturing and importing activities of the Indian Medical Stores Depôts and facilities for the manufacturers for making clinical trial of their products in government hospitals, were also discussed. General Jolly assured the members that there would be no unfair competition from the medical stores department. Mr. Lahiri, the president, thanked General Jolly and others for their kindness in attending the meeting of the Association. Among others present at the meeting were: Bt.-Colonel R. N. Chopra, Colonel J. R. Marriot (Controller of Supplies), Major S. P. Bhatia, Major-General P. S. Mills (Surgeon-General to the Government of Bengal) and Mr. A. F. MacCulloch (Chief Advisory Chemist, Medical Stores Department).

### THIRD ALL-INDIA OBSTETRIC AND GYNÆCOLOGICAL CONGRESS

The Third All-India Obstetric and Gynecological Congress will be held this year in Calcutta from the 27th to the 30th December, 1940—both days inclusive.

The subjects for discussion are:—

- (1) Anæmia of pregnancy;
- (2) Functional uterine hemorrhage; and
- (3) Maternity and child welfare.

For particulars please apply to the Joint Honorary Secretaries, the Bengal Obstetric and Gynecological Society, 91B, Chittaranjan Avenue, Calcutta.

#### PRIZE ESSAY

1. A gold medal called the 'Rai Shambhu Dayal Sahib Gold Medal' will be presented for the best prize essay on a public health subject to be announced each year.

2. The subject of the next essay is 'How can the public co-operate best with the Public Health Department in the prevention of diseases and the promotion of the health of the people'.

3. The competition will be open to the general public, including the medical and the public health workers in the United Provinces.

4. The essay is to be written in simple Hindi and should not exceed 3,000 words in length.

5. Essays should reach the medical officer in-charge, Provincial Hygiene Institute, United Provinces, Lucknow, by 15th November, 1940.

6. The name and address of the competitor must be distinctly written on each essay submitted and the envelope should have the words 'Prize Essay' in the top left-hand corner.

7. The director of public health, United Provinces, shall judge the merit of the essay and his decision with regard to the award of the medal shall be final.

8. No correspondence will be entered into on the subject of the competition.

9. No essay will be returned.

[The above notice was received on 25th September and was included in our October number at great inconvenience to ourselves; even this is ridiculously short notice, and very unfair on would-be competitors.—  
EDITOR, I. M. G.]

### THE PHARMACEUTICAL AND ALLIED MANUFACTURERS' AND DISTRIBUTORS' ASSOCIATION, LIMITED

In our note on p. 492 of the August number we mentioned seven 'members' of the association; this was due to a clerical error; the word should have been 'signatories' and it referred to the memorandum issued by the association.

There are in fact thirty-one founder members of the association and these include a number of Calcutta firms.

## Current Topics

### The Problem of the Virulence of the Bacillus of Koch

By ALFRED BOQUET  
and

### Le Probleme de la Virulence du Bacille de Koch

By A. SAENZ

(Abstracted from the *Bulletin de la Union Internationale Contre la Tuberculose*, January 1940, Vol. XVII, pp. 4-87.

THESE two papers on the virulence of tubercle bacilli were to be read at the XIth Conference of the International Union Against Tuberculosis which should have been held at Berlin in September 1939 but was cancelled because of the outbreak of war.

The two distinguished authors are well known from their investigations on the bacteriology of tuberculosis carried out at the Pasteur Institute, Paris, in the laboratories which until a few years ago were directed by the late Prof. Calmette, whose name is associated with the B.C.G. vaccine.

As the two papers deal with the same subject and their points of view largely coincide, it may suffice to treat them together. Whereas Boquet's paper reviews the field of recent work regarding the virulence of tubercle bacilli, A. Saenz presents his latest investigations. As the conclusions of the authors for a great deal are based upon these findings, a brief account may be given.

In order to elucidate whether different forms of clinical tuberculosis can be related to certain types of virulence, thirty-two strains from human tuberculous lesions were examined, some were derived from internal foci (sputum, spinal-fluid, pleural effusions, stomach-wash, pus, urine), others from superficial lesions such as tuberculoids of the skin (apart from lupus vulgaris), the patients representing active as well as inactive forms of tuberculosis. The virulence was determined

by subcutaneous inoculation into guinea-pigs of glycerine-potato cultures in doses from  $10^{-6}$  to  $10^{-8}$  milligrammes, the animals being sacrificed after 90 days. Twenty-nine cultures were of the human, three of the bovine type. All cultures were virulent, eighteen of the human strains having a 'normal' virulence, five being 'hypervirulent' and six slightly attenuated, while two of the bovine strains were 'hypervirulent', the third being normal. When the virulences were correlated with the different forms of clinical tuberculosis, no connection between highly virulent strains and severe forms of tuberculosis or between more attenuated forms and cases of inactive tuberculosis could be demonstrated; some of the most virulent strains were for instance derived from benign cases. e.g., from a tuberculous finger-joint, whereas attenuated strains could be isolated from severe cases of pulmonary tuberculosis. It may, however, be said that the difference in virulence do not seem to exceed the limit of variations as set by the technique employed. The term 'hypervirulent' also seems rather ambiguous as none of these cultures appear to have killed the guinea-pigs within three months, not even with doses of  $10^{-6}$  milligrammes. As all the strains described were able to produce generalized tuberculosis in guinea-pigs with doses containing from one to ten tubercle bacilli, they must all be said to have a standard virulence, thus confirming the common observation of earlier workers that strains from human tuberculosis generally show a remarkably high virulence without regard to the form of lesions, apart from cases of lupus vulgaris or other exceptional cases.

The fact that the majority of lupus strains are attenuated is also corroborated by Saenz who examined nineteen lupus strains and found that of seventeen strains of human type five were slightly, nine markedly attenuated and only three of normal virulence. Of two bovine strains one was normal, the other attenuated. These results are quite in conformity with the previous investigations in England, Denmark and Germany, the only discrepancy being, as Saenz himself points out,

that the French material contains an unusually low percentage of bovine types. This observation is in line with other investigations by Saenz.

Material comprising 903 strains submitted to type determination is presented here by Saenz who found the presence of bovine types in 22 instances, i.e., 2.43 per cent. This figure although not very informative in itself is remarkably low when the various sub-groups of the material are considered. Of 176 cases of tuberculous meningitis in children only nine were bovine; of 218 cases of stomach-wash in children one strain only was dysgonic although of human type, whereas among eight cases of cervical adenitis one strain was of bovine type. These groups are just those which in other countries present a remarkably high incidence of bovine infection, even as much as 80 per cent or more, as shown by A. S. Griffith in England and Scotland and by K. A. Jensen in Denmark. Saenz concludes therefore that the bovine infection in France is of considerably less importance compared with other countries. It should, however, be noted that the Saenz' material is not entirely unselected and, as the opposite is not stated, it must be presumed to cover an urban area. From Griffith's and K. A. Jensen's investigations we know that it is essential to search for the bovine infection in areas where cattle tuberculosis is common and where milk is not exposed to pasteurization or other heating devices. Saenz mentions an investigation from Northern France by Gernez who found three bovine cases out of 471 examined but he does not state whether these were rural or urban. Further investigations must be awaited with interest.

After these investigations which follow common lines, Saenz reports some experiments of a new character, from which the two French authors draw important conclusions as to the intrinsic nature of the pathogenicity of tubercle bacilli. Ten milligrammes of heat-killed bovine cultures were suspended in 1 c.c. of liquid paraffin and injected into the testicles of rabbits. The rabbits then developed within two months extensive pneumonic processes in the lungs, a large number of the animals even died spontaneously within 25 to 60 days. On autopsy the inoculated testicles were found to be transformed into large abscesses, some rupturing into the peritoneum and giving rise to lesions in the liver, spleen and diaphragm. The most striking observation was, however, the enormous changes in the lungs; these were enlarged, consolidated and contained large areas of caseous or necrotic pneumonia, many of the foci surrounded by marked hyperæmia. The changes were very similar to those seen in rabbits after intravenous inoculation of live, virulent bovine strains, even so much so that it would not be possible to distinguish between rabbits inoculated one way or the other. Rabbits inoculated either with liquid paraffin alone or with simple heat-killed bovine cultures show no pneumonic changes whatsoever. Heat-killed cultures of the human type inoculated into rabbits in a similar way, i.e., embedded in liquid paraffin and given intratesticularly, had also no effect, the only changes in the lungs being small scattered foci of no more importance than may be seen after intravenous injection of live human cultures. The fact is stressed by the author that the two conditions, the embodiment of the dead culture in liquid paraffin and the intratesticular mode of inoculation, are indispensable for obtaining successful experiments.

Even bovine cultures of extremely attenuated virulence, as the totally avirulent B.C.G. strain would do, when inoculated in the manner described cause similar vast changes in the lungs as would the heat-killed cultures of highly virulent, bovine strains. Saenz also states that avian cultures inoculated into rabbits in the same way cause the death of the animals within one or two months, no details, however, being given.

These experiments which Saenz himself very correctly, it must be granted, characterize as *les plus surprenant*, lead the authors to the conclusions that the pathogenic power of tubercle bacilli do not depend so much upon their viability, their ability to multiply rapidly in the host organism but rather upon some special chemical or 'physico-chemical' properties of the bacillary bodies.

These peculiar properties also determine the specific type of the bacilli, which might be dormant even if the virulence of the bacilli for some reason should have been depressed, as for instance with the B.C.G. strain which although entirely avirulent, according to the author, could produce major changes in the rabbits when inoculated in the way described.

It is of course not possible to pass any sort of judgment on these quite remarkable experiments at the present stage. It is much to be regretted that the outbreak of war prevented the conference taking place, thus depriving many eminent workers in tuberculosis from discussing this and other matters relating to the problem of virulence, one of the most fascinating and important problems in tuberculosis. It is, however, evident that more detailed and fuller reports besides confirmation from other laboratories of these thought-evoking experiments should be awaited before their real significance can be assessed.

J. F.-M.

## The Rehabilitation of the Tuberculous

By PENDRILL VARRIER-JONES

In a paper which was to be read before the XIth Conference of the International Union Against Tuberculosis Sir Pendrill Varrier-Jones very clearly discusses the problem of the rehabilitation of the tuberculous. He brings out into relief several facts about this important question. He believes that the fall in deaths and notification rates is deluding the world into the belief that tuberculosis is conquered, whereas in truth there is an increasing reservoir of infection. The cost of tuberculosis is increasing with prolongation of treatment. The tuberculous people are living longer, most of them in idleness and misery at the expense of the State. The faculties which the unfortunate victims of the disease possess are being completely wasted and no serious effort is being made to rehabilitate the tuberculous. In fact 'the whole anti-tuberculosis scheme fails if it fails to rehabilitate the tuberculous'.

In the absence of rehabilitation it is no wonder that sanatoria are largely occupied by patients who have returned in worse condition than before. Persistent failure to rehabilitate the patients also reacts upon the discovery of early cases. In the face of a complete dark economic future the patient and his friends avoid discovery till some terrifying symptom like hæmoptysis occurs—by which time the case is no longer early. It surely follows therefore that failure to adopt proper rehabilitation schemes is crippling the whole anti-tuberculosis effort in the world and that the principal beneficiaries of the present schemes are neither the patients nor the State.

The problem before the tuberculosis service is not only to restore the working capacity of the patients but to provide the tuberculous opportunities to earn;—'without opportunities to earn there is no rehabilitation'.

The author then discusses the question whether it is possible to rehabilitate the tuberculous and if so whom will it benefit. He quotes the example of Papworth where ex-patients and their families instead of receiving public assistance of £17,500 a year (which could only sustain them in disagreeable and depressing circumstances) earn under a system (in which work acts as a tonic for their health) £40,000 a year. These people pay £2,000 a year towards Unemployment and Health Insurance. The State therefore benefits by this scheme to the extent of £19,500 a year while the national economy has the purchasing power of £40,000 a year instead of £17,500. Such a scheme therefore 'benefits both the patients and the State'.

Sir Pendrill then traces the reasons for the delay in the development of rehabilitation schemes. In his view it is the apathy of the patients and of the tuberculosis service itself, besides the fact that the fit fear the competition of the unfit. The latter is to a great extent due to the nature of the world trade system which has linked world production to gold.

The solution suggested is to plan on a large scale 'both the care of the community and the patient has to be taken into account', and suggests that 'each Government should establish a National Rehabilitation Board: guarantee principal and interest on the capital sums required; regard the Board as potential contractor-general for all Government and municipal supplies, and as a matter of policy adopt rehabilitation as a preferable alternative to cash compensation. 'State Funds would be involved to the extent of the guarantee, and judging from the result at Papworth, the savings in other directions would more than cover any possible loss under this head. The Board could not at once undertake the execution of all Government orders but if in principle the Government would give preference to the Board it would not be long before a large number of unfit are rehabilitated.'

### The Value of Systematic Examination for the Detection of Tuberculosis in Subjects over 15 Years of Age

By H. BRAEUNING

(Abstracted from the *Bulletin of the International Union Against Tuberculosis*, Vol. XVII, April 1940)

PREVENTIVE examination in series of those living in close proximity to tuberculous patients is a well recognized method of detecting early cases of tuberculosis. In some countries this has been extended to the examination of homogeneous social groups like regiments, police, schools, colleges, factory workers, railway and tram employees. Finally the conclusion is reached that the whole population should be systematically surveyed. Is it possible?

In a paper which was to be read before the XIth Conference of International Union Against Tuberculosis Dr. Braeuning discusses the value of systematic examination in series of subjects over 15 years for the early diagnosis of tuberculosis. This special age group has been selected because in the area covered by the author's investigation, among several thousand cases of tuberculosis, less than 1 per cent were under 16, while 21 per cent of the dispensary population was under 16. The question has been discussed under three headings: (1) why does one undertake systematic examination for the detection of pulmonary tuberculosis, (2) will the progress of a tuberculosis campaign through early diagnosis of pulmonary tuberculosis be an adequate compensation for the trouble taken, (3) what systematic examinations are essential for the detection of pulmonary tuberculosis.

The author reports that x-ray examination of healthy persons showed that pulmonary tuberculosis starts almost always as a closed lesion and during the first year 15 per cent of cases develop open lesions. In his experience 70 per cent of all cases of open tuberculosis are detected at the stage of open lesions, i.e., normally too late. If the healthy population were x-rayed at least once a year this would enable almost all cases to be diagnosed before the stage of open lesions.

Figures are quoted to show that early detection of tuberculosis has a definite influence on the progress of the disease. According to the author 5 per cent of cases of pulmonary tuberculosis diagnosed within the first 12 months die from tuberculosis 1 to 2 years later in spite of treatment. The early diagnosis of these has no prophylactic significance. Approximately 15 per cent of all these cases of pulmonary tuberculosis heal without having become open even in the absence of any treatment. The early diagnosis of these has therefore no practical value. Between the two extremes in 80 per cent of these patients progress of the disease may be modified through our therapeutic efforts. Two groups of patients, one among the members of the hospital staff who, with two exceptions, conformed to medical orders and another from the general population in whom one-third did not comply with medical orders, have been compared. The hospital staff had 4 per cent severe lesions and no deaths; among the other patients 39 per cent had severe lesions and 32 per cent died. The author concludes 'that thanks to the systematic

examination of healthy subjects in view of early diagnosis of pulmonary tuberculosis, important results may be obtained'.

However, as approximately 5 per cent of cases of pulmonary tuberculosis die 1 to 2 years later in spite of treatment, the only absolutely safe protection against fatal tuberculosis is prevention of infection. Systematic examination in series are necessary as a safety measure against primary infection—in order to discover on the one hand cases who have not yet been infected, and on the other those who involve a risk of infection to their healthy neighbours. Systematic tuberculin testing can reveal what subjects had not yet been infected. Such an age group should be kept as far as possible away from the open cases. It would be useful to carry out x-ray examinations among associates of children under such an age, as this could give a clue to the sources of infection. As in infants, small children and during growth the primary infection often coincides with morbid symptoms, a systematic tuberculin testing would enable one to find out new patients when a conversion of a reaction which was negative until then is observed.

According to the author all subjects over 15 years of age as well as younger subjects who are exposed to infection should be x-rayed at least once a year. If it is impossible to examine such large numbers one should at least x-ray, (1) all cases exposed to tuberculous infection, (2) all groups who have special risks from their associates, (3) all groups who can be easily x-rayed, e.g., soldiers, students, (4) all suspect cases.

The comparative value of radiology, radiography and radiophotography in the examination of such large numbers is discussed. The best method of carrying out x-ray examination is to screen every case and then take a photograph in the position which reveals shadows ordinarily hidden by the cardiac and diaphragmatic shadows. In order to save time and money radiography is given up in systematic examinations, and less expensive methods like radiology or radiophotography are adopted. In the author's experience both these methods give an error of 2 per cent to 10 per cent as against radiography. Radiophotography has certain advantages over radiology in that it is less time consuming, the result is noted on a permanent record and is less expensive (as the work can be left to a less experienced assistant). If on the other hand one wishes to detect the smallest lesions, paper films are recommended. With a special condenser equipment some of the latest makes of these films are reported to give results equal to plates.

The author concludes that by such a systematic campaign one part of the problem can be solved. The treatment of all cases discovered in time, even before the appearance of any symptoms so as radically to reduce the rate of those who develop open lesions, and moreover the control of open cases is a much more arduous task. He expresses the opinion that only by legal measures will it be possible to secure systematic examination of all those who need it and the early and prolonged treatment of those who require institutional care, and he believes that timely diagnosis, early and intensive treatment and prophylaxis will bring about marked decline of the tuberculosis death rate within a few decades. However, as the measures are extremely radical and costly he advises their trial as an experimental measure in one or two centres of approximately 50,000 inhabitants, to ascertain if they can be carried out at the rate of 100 per cent and what results may be expected of them.

### Recognizable Tuberculosis in General Hospitals

By ROBERT E. PLUNKETT

and

EDWARD X. MICKOL

(Abstracted from the *American Review of Tuberculosis*, Vol. XLI, March 1940, p. 381)

DURING the last several years there have been many investigations in different countries which show that the

incidence of tuberculosis among nurses is several times higher than that among the females of the same age group in other occupations and that the incidence of tuberculosis infection as determined by tuberculin test increases with each year of service. This has been most marked when student nurses are in contact with known cases of tuberculosis as a part of their training and to a lesser degree it is found in hospitals where tuberculosis cases are not knowingly admitted.

Several studies in America showed that in some States 10 to 15 per cent of deaths from tuberculosis occurred in general hospitals who had no provision for the care of the tuberculous patients. Many of the terminal cases were admitted for non-tuberculous conditions and the correct diagnosis was only made some time after admission. In order to estimate the magnitude of unrecognized tuberculosis in general hospitals x-ray study was made by the authors of 4,853 adult admissions to fourteen general hospitals in ten cities of Upstate New York in 1937 and 1938.

Previous studies by x-ray examination of all consecutive cases admitted to certain hospitals and their out-patients over certain periods showed that 1.3 to 3 per cent of patients admitted to the hospitals and out-patients had significant chest disease not detected clinically, and that 0.3 per cent to 0.5 per cent had clinically significant pulmonary tuberculosis which would have been undiscovered. As the previous studies included children in whom significant re-infection type of infection is relatively uncommon, only patients 15 years of age and over have been included in the present studies.

In order to obtain a representative cross-section of the general population, the hospitals were selected from areas varying from 50,000 to 100,000 population and the actual selection of hospitals was done at random from the point of view of bed capacity and economic status of patients admitted. Each hospital was allowed 250 to 500 x-ray films (at the expense of the State Department of Health) depending on the total yearly admissions; and the patients examined formed 9.4 per cent of the total admissions in the participating hospitals in 1937.

Single flat films of the chest were taken of all patients of 15 years of age or over admitted (including private patients) but excluding those admitted to the tuberculosis section, known cases of tuberculosis, out-patient cases and those who were too ill to be disturbed for x-ray examination. These were excluded on account of administrative difficulties. Detailed study of all x-ray films was made with the help of the Tuberculosis Division.

One hundred and twenty-eight, i.e., 2.6 per cent of the 4,853 films studied, showed evidence of a re-infection type of tuberculosis. Fifty-one or 1.1 per cent showed characteristics of clinically significant lesions. The hospital records showed that in 24 tuberculosis was suspected by the attending staff and in the remaining 27 or 0.6 per cent of the total group, x-ray films revealed the first evidence of the disease, and those cases were fairly evenly distributed in the medical, surgical and obstetrical sections of the hospitals. The authors conclude that if similar conditions prevailed in other hospitals of the country, over 40,000 cases of unrecognized pulmonary tuberculosis were hospitalized during the year. When it is realized that in the general hospitals the usual nursing and prophylactic technique falls far short of the standard requirements for a tuberculosis institution, the state of affairs would mean an increased danger of transmission of infection to nurses and others by the hidden cases.

Moreover the studies reveal the possibility of utilizing the general hospital as an effective medium for case finding in tuberculosis. Finally the routine x-ray study of the adult population has also revealed unsuspected non-tuberculous thoracic conditions. The authors conclude that, diagnostically, x-ray is often essential. To be sure it is costly 'but human economy should be considered as important, if not more important than administrative economy'.

## The Chemotherapy of Tuberculosis

By G. M. FINDLAY, C.B.E., M.D., D.Sc.

(Abstracted from the *Medical Press and Circular*, Vol. CCIII, 24th April, 1940, p. 348)

IN the chemotherapy of tuberculosis, efforts have been made to destroy the specific bacilli by stimulating the tissue resistance and by finding remedies that are directly bactericidal.

### CALCIUM SALTS

Numerous attempts have been made for more than a century, especially in France, to bring about recalcification of tuberculous tissues by the administration of calcium salts either alone or in association with vitamin D and parathyroid extract. Many cases of phthisis, however, show normal amounts of calcium in the blood and their treatment with calcium lactate causes no increase in the blood calcium. A different method of producing calcification has been suggested by Hunter and Hunter and Peill who inject into the lung gelatin impregnated with calcium chloride: 300 gm. of gelatin is dissolved in 900 c.c. of physiological saline and 100 c.c. of distilled water containing 50 gm. of calcium chloride is then added together with 0.5 gm. of acriflavine. After filtration and sterilization, injections of about 16 c.c. are given into the lung, the temperature of the mixture being about 80°C. Further evidence, however, is required of the value of calcium salts in stopping the spread of active tuberculosis.

The supposed value of cod-liver oil in tuberculosis also rests on a somewhat uncertain scientific basis. It was shown at an early stage that sodium morrhuate has no action in healing tuberculous processes in any way comparable to that of the chaulmoogric and hydnocarpic acids in leprosy. With the discovery that cod-liver oil has a high content of vitamins A and D, it was at first believed that in these vitamins lay the secret of the action of cod-liver oil. Unfortunately, the amount of vitamin D in the diet has no particular effect on tuberculosis. Vitamin A also appears not to have any direct action on the tuberculous process. A deficiency of vitamin A in the diet, however, causes keratinization of surface epithelium with a consequent decrease in the secretion of the epithelial glands. This secretion has both a mechanical action in removing, and perhaps a direct bactericidal action in killing organisms which may act as secondary invaders in open pulmonary tuberculosis. It is of interest to note that cod-liver oil has recently been successfully applied as a dressing for chronic infected conditions such as osteomyelitis. Cod-liver oil inhibits the growth of invading organisms and accelerates the regeneration of normal tissue. Although the active component is still unknown, crude is more satisfactory than purified cod-liver oil. Similar findings have been noted in the action of cod-liver oil in tuberculosis, so that possibly the same component that is active in osteomyelitis also plays a part in counteracting the secondary bacterial invaders in tuberculosis.

In view of the action of chaulmoogric and hydnocarpic acids in leprosy, their action has been tested in tuberculosis. Some improvement has been noted in lupus following intradermal inoculation of the ethyl esters of hydnocarpus oil to which has been added 4 per cent of creosote. Unfortunately the injections are attended by considerable pain and some local reaction. Intradermal injections of phenyl ethyl hydnocarpate, however, cause fewer reactions, and by this means Burgess has succeeded in healing localized patches in seven out of eleven patients. Similar results have been obtained by Wallace.

### SALTS OF THE HEAVY METALS

The action of a number of heavy metals has been tested on experimental tuberculosis in rodents. Arsenic, silicon and mercury have little or no curative action in animals, but a distinct retarding action has been reported by Walbum following injections of aluminium, barium, cerium, lanthanum, molybdenum, ruthenium, and selenium. Ferric chloride and didymium have also, it is claimed, a beneficial effect, while a bismuth-dye

preparation has some action in acute tuberculosis in rabbits; the only metals which have been used extensively, however, are cadmium, copper and gold. Cadmium in the form of an iodine-cadmium sulphide or glycine appears to stimulate the growth of fibrous tissue in animals. In man intramuscular injections of 3 c.c. of a 1 per cent colloidal cadmium suspension were found by Heaf to produce results in 27 cases quite equal to those of gold, with an almost complete absence of toxic reaction. Cornwall using either a 1 per cent cadmium sulphite in sterile olive oil or a 1 per cent colloidal cadmium sulphide, obtained alleviation of symptoms in only 13 out of 42 cases. Cadmium is, however, of such low toxicity that it can be used in patients with high temperatures and toxic symptoms.

When treatment by copper was first instituted, favourable reports were by no means infrequent but more recently doubt has been cast on its efficiency. Mercader, however, used a colloidal copper morphuate with good results in preference to copper benzoate and the various double compounds of cuprous cyanide of which cyanocuprol is the best known. Most interest has been aroused by the use of gold in tuberculosis. In the East gold has been recommended for many centuries in the treatment of disease, and its use in tuberculosis is mentioned in the Vedas as well as in the writings of Sushruta. In Western medicine its introduction is due to the alchemists who in their turn received it from the Arabs. In the sixteenth and seventeenth centuries it became so popular a remedy that Moliere in 'Le Medecin malgré lui' held it up to ridicule as capable of reviving the dead. The modern use of gold in tuberculosis dates from the observation by Koch in 1890 that simple gold salts such as the double cyanide of gold and potassium (KAuCy<sub>2</sub>) and gold chloride inhibit the growth of tubercle bacilli *in vitro*; gold chloride, however, failed to affect experimental tuberculosis in animals. Later, organic gold compounds were introduced. Krysolgan, the sodium salt of p-amino-o-auriomercaptobenzenecarboxylic acid, was found by Feldt to cause improvement in human tuberculosis, although it had little inhibitory action in animal tuberculosis. In 1924, Moellgaard, of Copenhagen, introduced the double thiosulphate of gold and sodium (AuS<sub>2</sub>O<sub>2</sub>Na), Na<sub>2</sub>S<sub>2</sub>O<sub>4</sub> under the name of crysalbine or sanocrysin. At first somewhat large doses were injected, but these frequently caused reactions not unlike those following the injection of tuberculin. It was thought that the reaction might be caused by endotoxins liberated by the disintegration of tubercle bacilli, and an antitoxic serum was therefore prepared for injection before the administration of sanocrysin; since the serum proved of little value its use has now been abandoned. To-day it is the custom to employ smaller doses of sanocrysin, particularly at first, though the amount may be gradually increased, for both animal experiments and clinical observations show that tolerance is slowly acquired.

After the introduction of sanocrysin other organic gold preparations were prepared for use (*cf.* table) in tuberculosis and also in rheumatoid arthritis. The gold compounds now on the market can be divided broadly speaking into three groups: (a) those soluble in water, (b) those soluble in oil, (c) those insoluble in oil. At first water-soluble compounds were largely employed, but at present oil-soluble preparations are preferred. Shrikande believes that oil-soluble preparations are less rapidly absorbed and less rapidly eliminated: their action is therefore more prolonged; the reactions following their use are rarer and the ease with which they can be injected is greater.

The most commonly used compounds are sanocrysin in oil and solganol B in oil (solganol B oleosum) given in weekly doses of from 0.05 to 0.1 gm., the total dosage not exceeding 1 gm.: when this amount has been injected an interval of at least twelve weeks should elapse before another course is given. A different dosage has been recommended in India by Banerjee. In febrile cases the first injection is 0.002 gm. of solganol B oleosum or sanocrysin in oil: this is increased by 0.002 gm., injections being given every four to

## ORGANIC GOLD COMPOUNDS

Chemical constitution	Proprietary name	Gold content (per cent)
Sodium and gold thiosulphate	Sanocrysin	37
	Crysalbine	
Sodium aurothiomalate	Myocrysin	50
Sodium aurothiopropionol sulphate and sodium thio-propionol thiosulphate.	Allochrysin	55
Sodium aurothiogluco-	Solganal B	50
Disodium p-sulphomethyl-amino-o-aurothiobenzenesulphate.	Solganal	36
Sodium aurothiosinamine benzoate.	Lopion	43
Sodium 2-aurothiobenzimidazole-4-carboxylate.	Triphal	47
Sodium p-N-dimethylamino-o-tolylphosphinate.	Aurophos	25
Sodium aurothiosulphate		
Sodium p-amino-o-auriomeraptobenzene carboxylate.	Krysolgan	50
Undisclosed (said to be a gold Keratinate).	Neosolganal	14

six days. In afebrile cases the initial dose is 0.01 gm. and this is doubled till 0.4 gm. is reached. A total of 5 to 6 gm. is administered.

When first introduced gold was somewhat indiscriminately given in every form of tuberculosis. Further experience has shown that the most suitable patients for chrysotherapy are those with recent exudative lesions. With discretion gold therapy may also be applied in cases of a chronic fibrotic type with acute exacerbations, and in those where it is desirable to collapse one lung by artificial pneumothorax and to check the progress of recent lesions in the other lung. When an affected lung has been collapsed gold salts have very little further curative action for, owing to its anæmic condition, the collapsed lung takes up little or no gold from the blood stream.

The value of gold salts can be judged by the disappearance of tubercle bacilli from the sputum, by the return to normal of both the red blood corpuscle sedimentation rate, and the Schilling differential leucocyte count, and by reduction of temperature and improvement in the body weight.

Although gold has now been in use for nearly sixteen years, opinions are still divided as to its true value in tuberculosis. In England, for instance, Peters and Short, as a result of controlled statistical investigations over a period of five years, concluded that among patients from sixteen to twenty-six years of age, chrysotherapy was of little value. On the other hand, in France, Bernard claimed improvement in approximately 50 per cent of cases, while in India, Banerjee obtained similar results in just over half of sixty selected cases. Against these good results must be placed the liability to toxic reactions. Although fever and erythema are not uncommon, severe reactions such as agranulocytosis, thrombopenia with purpura hæmorrhagica, aplastic anæmia, toxic jaundice, hæmorrhagic nephritis, and exfoliative dermatitis are comparatively rare. More especially in France nervous reactions have been reported of which the most serious is the possibility of a meningitis resulting from the activation and extension of a tuberculous focus. Gold salts should not therefore be administered to persons with tuberculous foci that might extend to the meninges or to those with renal or gastro-intestinal lesions. Recurrent attacks of hæmoptysis, great emaciation or fever with obvious toxæmia are also contra-indications. Large doses of vitamins A, B and C given before, during and after treatment are capable, it is claimed, of preventing a considerable number of the reactions due to chrysotherapy. The cause of the toxic reactions

seen in tuberculous patients treated with gold is still unsettled. Secher believes that many of the reactions are due to the liberation of toxins from the tuberculous lesions. The reasons for this view are that the frequency of the reactions depends not so much on the amount of gold administered as on the site of the lesions. In closed cases (pleurisy, fibrous tuberculosis, joint affections) where there is a likelihood of the absorption of liberated toxins, rise of temperature and erythema appear only in the first stage of treatment. On the other hand reactions in patients with open lesions are less common. Gold salts may give rise to conjunctivitis and phlyctenae, but phlyctenae can only be evoked experimentally by injecting gold salts into tuberculous animals. In tuberculous patients also the injection of gold salts may produce a hyperglycaemia similar to that following injections of tuberculin. Nevertheless, many of the reactions, such as agranulocytosis and exfoliative dermatitis, are not those associated with tuberculosis, but with poisoning by metals or metalloids such as bismuth, mercury or arsenic. Tuberculin injections in tuberculous patients

usually cause a rise in the red cell sedimentation rate, while gold salts produce no such change. The tuberculin-like action of gold cannot, therefore, be regarded as proven.

The action of gold in tuberculosis would seem to be due not to any specific bactericidal action on *Mycobacterium tuberculosis*, but rather to a stimulation of the reticulo-endothelial system, since gold is readily taken up by endothelial cells. Japanese workers have suggested that gold preparations are of value, not so much because of the gold they contain but because of the presence in the molecule of a sulphhydryl group in the form of an aurothio, thiosulphate or sulphite group.

The sulphonamide group of drugs in the hands of certain workers and in large doses has been found to have a retarding action on the development of tuberculosis in rodents, provided that the drugs are given at the same time as the infecting organisms. In tuberculosis in man, however, neither sulphanilamide nor sulphapyridine has proved to have any ameliorative action.

## Reviews

**MANSON'S TROPICAL DISEASES: A MANUAL OF THE DISEASES OF WARM CLIMATES.**—Edited by Philip H. Manson-Bahr, C.M.G., D.S.O., M.A., M.D., D.T.M. & H. (Cantab.), F.R.C.P. (Lond.). Eleventh Edition. 1940. Cassell and Company, Limited, London. Pp. xvi plus 1083, with 18 colour plates, 15 half-tone plates, 364 figures in the text, 6 maps and 28 charts. Price, 35s.

WAR is a great disturber of populations and no more appropriate moment could have been chosen for the publication of a new edition of what is undoubtedly the best textbook of tropical disease in the world.

It is most remarkably complete for a single-volume work on such a vast subject; none of the important diseases are skimped and few, if any, of the rare ones are left unnoticed. Further, the appendix on medical zoology will provide the average tropical worker with an efficient guide to laboratory work, which is such an essential part of practice in hot climates.

No radical changes have been made in this new edition, though additions and corrections have been made throughout, and despite careful pruning nearly a hundred pages have been added. This is in a way a tragedy, for, as we remarked in our last review, the thousand pages of the last edition was about the limit of reasonable size for a book of this kind; the present edition has 1083 pages, excluding thirty odd plates and half a dozen maps, and, though the binding is excellent, it seems doubtful if the book in its present form will stand up to four years' hard use as did the reviewer's copy of the tenth edition.

In the first chapter on life in the tropics there are some very wise observations. The author starts from the beginning, from Leadenhall Street or Mincing Lane, from the India or Colonial Office, and gives useful hints to selection boards sitting in the imperial capital. On the difficult subject of the suitability of an individual to life in the tropics, it is impossible to lay down hard-and-fast rules and any opinion expressed is sure to meet with a contrary one, for life in the tropics is far more varied than life in Great Britain; the candidate may find himself in the social whirl, if he has a fancy for whirling, of Singapore or Calcutta where he will make a greater number of friends of both sexes than he would at his local suburban tennis club, or he may find himself in the backwoods of Burma or in the West African bush where he will not meet another white man for weeks on end, or a white woman until he goes on his next leave. On the subject of alcohol the author is very cautious—and he need be. It would be interesting to collect data from those who have failed in the tropics through alcoholic excess; the

reviewer believes that a large number would be found to have been teetotallers before they came to the tropics, for it is the boy that has been brought up to take alcohol in moderation that is best armed against any temptation to take too much. It is not clear what the author means when he says 'On the whole, it may be said that the attainment of a certain degree of toughness, with a capacity for roughing it, together with that innate instinct of fending for oneself, which is so often exhibited in the hardy northern races, is a much more suitable preparation than the sheltered life enjoyed by many of the educated young people of the present day.'

Does he suggest that the 'hardy northern races' are not educated? Brave man, but would he repent this statement at the football club in Calcutta, for example? Anyway, whatever the author's meaning, the reviewer believes that 'breeding', admittedly a vague term, counts more than apparent 'toughness' in the tropics, and that the British prestige in the East would be maintained better were more attention be paid to 'social standing' in the selection of candidates for appointments in these countries. This last sentence is not as irrelevant as it might appear to be.

The new sections on diet and nutrition in the tropics is a welcome addition, as also is the emphasis the author has given to recent amenities which have changed the outlook of the European to life in the tropics, namely, the refrigerator and air conditioning; the former can be installed wherever a white man lives and will be found in many places where he doesn't, and the latter wherever there is electric current which means wherever there is a factory. Another new section is on tropical anemias; one might question the justification of including Cooley's anaemia in this category.

An excellent account of all the main diseases is given, malaria, trypanosomiasis, leishmaniasis, relapsing fever, filariasis, the dysenteries, plague, cholera, yellow fever, undulant fever, leprosy, schistosomiasis, etc., but the section on typhus seems a little confused—at least it had the effect of confusing the reviewer who thought that he had a fairly clear conception of this rather complicated subject. For example, the sporadic Brill's disease, which was only found amongst recent arrivals from European countries where epidemic typhus had occurred, is identified with endemic flea-borne typhus, and Maxcy's, Mooser's and other American investigators' work on this subject is not given its full implication. Further, Indian endemic typhus is uncompromisingly classed as tick-borne, whereas much of it is certainly not and conclusive evidence that any

# Constipation . . .

In spite of dietetic measures and exercise many patients still suffer from the devitalising effects consequent upon intestinal stasis. In such cases the attainment of perfect health is debarred. Whether in illness or convalescence intestinal stasis retards recovery.

In health and in the vast majority of pathological conditions, an efficient and safe aperient will be found in Andrews Liver Salt. It is an effervescent Saline with a pleasant taste.

Antacid in action, it stimulates the secretion of bile and of the intestinal mucosa, and presents a soft stool and a painless, easy evacuation.

Especially indicated in the constipation of childhood and old age; of inestimable value to everyone who must lead a normal life during treatment; and a valuable adjunct in the treatment of those conditions incident to hepatic congestion and torpidity.

A large size tin will be sent free, on request, to any member of the Medical Profession.

In this country, bulk producing laxatives are generally contra-indicated, because sufficient bulk is already supplied by normal diet. Constipation, in these circumstances, is best avoided and relieved by maintaining the bowel contents in a fluid condition. For this purpose, Andrews Liver Salt will be found to give excellent results.

## Confidence in Antisepsis

THE high germicidal efficiency of 'Dettol' with its safety and convenience, have won for it a leading position in hospitals and private practice, and make it a most useful disinfectant for first aid at home, for personal hygiene, and for gargling and bathing.

'Dettol' maintains its efficiency in the presence of blood and other organic matter, and can be used in high concentration, thus giving a wider margin of safety.

It is absolutely non-poisonous and non-staining, and possesses a distinctly pleasant smell.

species of this insect was the vector in any single instance of this disease is lacking.

In his descriptions of the minor diseases the author seems a little less certain, though the majority of these are also very fair accounts in the space that he could afford for them. For the treatment of infantile biliary cirrhosis the reader is told that 'According to Green-Armstrong, when cases are seen early and parents are given the necessary instructions, recovery takes place in six to ten weeks', but he is given no clue as to what these instructions are, beyond taking the child from the mother and artificially nursing it. The section on bill diarrhoea wants a little fresh blood in it, as references to epidemics in Simla in the pre-bacteriological era can scarcely serve any useful purpose. This brings one to a real complaint, that is, the absences not only of references but of any indication of the historical period in which the authority quoted worked; for example, in this particular instance the author quotes Crombie as his main authority. The reviewer, having trailed through 26 volumes of *Cumulative Index*, eventually by pure chance discovered Crombie's paper in the *Indian Medical Gazette* of 1880.

Once more Dr. Manson-Bahr has defeated the gloomy prophets who have insisted that the time is past when one man can give a comprehensive account of tropical medicine as a whole. He has done it so often that he will probably be able to do it again, but what will he do about the next edition? In its present format the book will not take another hundred pages. Will he change the format? We hope not. The book at present is a 'handbook' and should remain one. Will he divide it into two volumes? We don't believe that this would be a wise move. So he will just have to use the blue pencil freely. We believe that this could be done without seriously impairing the utility of the book, but it will be delicate work for there is nothing obviously superfluous in this edition.

**THE INTER-RELATIONSHIP OF MIND AND BODY.**—The Proceedings of the Association for Research in Nervous and Mental Disease. (Volume XIX of a series of Research Publications.) Edited by F. Kennedy, Angus M. Frantz, and C. G. Hare. 1939. Volume XIX. The Williams and Wilkins Company, Baltimore. Pp. xx plus 381, with 28 illustrations and 10 tables. Obtainable from Messrs. Baillière, Tindall and Cox, London. Price, 36s.

THE present volume is the nineteenth contribution of its kind in the last twenty years. It contains contributions from twenty-four leading American psychiatrists who, each in his own way, deals with the problem of the mutual relationship of mind and body. In their contribution, entitled 'Hypnosis in Hysterical Hyperventilation', Drs. Mandel E. Cohen and Stanley Cobb inveigh against the employment any longer of such terms as 'physical and mental', 'organic and functional', 'somatic and psychic'. They admit that the terms 'neurological', 'psychiatric', 'psychological', 'anatomical', etc., have useful meanings to most people, since they indicate to what department or to what professor a problem should be taken. On the other hand, Drs. Cohen and Cobb emphasize rightly that these terms have no biological significance. They beg of us to put aside superstition, mythology, parallelism and other outworn creeds and to accept simply the fact that all stimuli which play upon one individual are physical, that all phenomena which take place in an organism are organic and that the psychological processes, although the most complex, are not exceptions to this postulate. There is no doubt that, thanks largely to American psychiatric research, this viewpoint will in time become basic to all medical science. Adolf Meyer's concept of psychobiology was largely responsible for the turn it gave to the concepts of psychological medicine. According to Drs. Cohen and Cobb we owe it to the pathological tradition of Virchow that medical students are still taught to believe that symptoms are caused by 'lesions' and

that if no 'lesion' is detectable, the symptoms presented must arise from some mythical process known as a 'functional' state, in spite of the fact that a function must be a function of some structure, unless, of course, we are prepared to invoke structureless supernatural agencies. The twenty-four essays cover a wide area of psychology and psychopathology including the Production of Somatic Disease by Emotional Disturbance, Emotional Behaviour Patterns in Animals, Electrical Activity of the Brain, Fetal Behaviour, etc. There is also an admirable collection of graphs and diagrams.

O. B.-H.

**NEW FACTS ON MENTAL DISORDERS: STUDY OF 89,190 CASES.**—By N. A. Dayton, M.D., M.C. 1940. Charles C. Thomas (Publisher), Springfield, Illinois. Pp. xxxiv plus 486. Profusely illustrated with graphs and tables. Price, \$4.50. Obtainable from Messrs. Baillière, Tindall and Cox, London. Price, 25s.

Of its kind this book is probably unique. It is not a study of separate individuals suffering from mental disorders but a statistical study of 89,190 cases viewed as a whole. The author states in his introduction that the book is not the product of the work of one person but of many. There were at one time twenty-four field investigators working in twenty mental hospitals and state schools. Office workers brought the total employed to thirty-five persons. The scheme was financed by generous grants in 1928, 1931 and 1938 from the Laura Spellman Rockefeller Foundation and the Rockefeller Foundation. The survey is grouped under ten principal headings:—Age in Mental Disorders; Nativity and Mental Disorders; Alcohol and Mental Disorders; Alcohol and Other Factors; Marriage and Mental Disorders; Marital Status and Other Factors; Clinical Diagnosis in Mental Disorders—Age; Clinical Diagnosis and Changing Incidence—Time Changes; Clinical Diagnosis and Other Factors. Are Mental Disorders on the Increase? This last section is perhaps the most interesting of all, because it tends to show that for a long time past a great deal of nonsense has been spoken and written on the 'increase of insanity'. As a matter of fact, the figures examined show that, as far as the State of Massachusetts is concerned, the number of first admissions into the state's mental hospitals is slowly increasing, but slower than the admissions for physical disorders, such as cancer, heart disease, arthritis, etc. On the other hand the constant demand for additional beds in mental hospitals can be attributed to (1) the long hospital residence of mental patients, and (2) a definite increase in the length of hospital stay. This latter cause the author considers is brought about by society being less able than formerly to absorb recovered patients, and changes are taking place in the recoverability of existing mental disorders in spite of advances in therapy. One learns that to escape a psychosis it is better to be a Catholic than a Protestant, but best of all to be a Jew. Likewise it is better to be married than single and worst of all to be divorced. The book is profusely illustrated with admirable graphs and tables.

O. B.-H.

**FORENSIC MEDICINE: A TEXTBOOK FOR STUDENTS AND PRACTITIONERS.**—By Sydney Smith, M.D. (Edin.), F.R.C.P. (Edin.), D.P.H. Seventh Edition. 1940. J. and A. Churchill, Limited, London. Pp. xvi plus 680, with 179 illustrations. Price, 25s.

ANOTHER edition of this excellent book which aims at separating the essential from the non-essential in the matter of details has appeared after two years. Most of the points to which attention was drawn in our last review have been revised. The following deserve attention in the next edition: (i) Subgroups of A in blood groups and their inheritance; (ii) spelling of Hirschfeld (now spelt *Hirschfeld*) and Bagchi (now spelt *Bacchi*); (iii) completion of the series of slimming

## PANDEX

100 or 200 mg. at 85 kv

The Unit that made  
X-Ray History.

## LATEST DEVELOPMENTS IN X-RAY APPARATUS

WORLD-WIDE REPUTATION EARNED BY **WESTINGHOUSE**

Designed and produced by experts of the Westinghouse X-Ray Co., Pandex made X-Ray history in 1939. Nearly 900 of these units were sold in America alone and their demand grows in England and India.

Pandex has set a new high standard among X-Ray units both for Diagnostic and Fluoroscopic work. Self-contained, completely shockproof and ray-proof, it impresses by its extraordinary flexibility. No high tension switches, no cables to suspend from ceiling or drag on the floor and no costly building changes for installing.

Pandex easily surpasses other X-Ray units in performance, efficiency and appearance—yet the price is moderate. It is extremely suitable for hospitals, doctors and tuberculosis centres.

differs in many respects from the usual textbooks on this subject.

As is explained in the preface, the book is intended for the post-graduate who is familiar with the standard textbooks but desires at first-hand more practical help with the diagnosis and management of abdominal cases.

The main theme of the book, occupying two-thirds of the text, is the diagnosis and treatment of surgical dyspepsia. Surgical dyspepsia, it should be explained, signifies painful dyspepsia as distinct from medical, or painless, dyspepsia. The diagnosis of surgical dyspepsia is discussed at great length, and under such general headings as symptoms, mechanism of causation, ætiology, reflex dyspepsia, and so on. Later chapters in this section seek to define dyspepsia syndromes for certain particular diseases. Inevitably, in such a long discussion, chapters have been introduced here and there to enlarge upon certain points secondary, but necessary, to the main subject. In one such chapter the theories of the causation of peptic ulcer have been summarized, and it winds up with the suggestion that the practising surgeon should follow the theories of Virchow when engaged upon the preliminary treatment of his case, but should go over to the Aschoff camp when it comes to deciding on the type of operation to be performed.

A good description of gastroscopy is contributed by Dr. John Horan, and then comes the section on operative surgery, in which the *pièce de résistance* is the part dealing with the surgery of the stomach. Technique, especially suture work, receives great attention, and there must be few who will not find something useful among the many original ideas disclosed. The surgery of the other abdominal viscera is dealt with fully, but special mention should be made of the sections on appendicitis and carcinoma of the rectum.

The book deserves the attention of all practising surgeons, especially those who feel the need of something to help them refresh their clinical work and brush up their operative technique in times which make visits to the great surgical centres impossible.

W. McN. N.

**THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE ŒSOPHAGUS.**—By P. P. Vinson, B.S., M.A., M.D., D.Sc., F.A.C.P. 1940. Charles C. Thomas—Publisher, Springfield, Illinois. Pp. 224, with 98 illustrations. Price, \$4.00. Obtainable from Messrs. Ballière, Tindall and Cox, London. Price, 22s.

Every student of medicine is well acquainted with the names of Plummer and Vinson who provided much of the impetus for the present satisfactory management of lesions of the œsophagus. Many excellent articles have since been published on the subject by surgeons, physicians and endoscopists but they are not readily accessible to us, while the average textbooks deal with it rather inadequately from the practical point of view. It is, therefore, with some feeling that we welcome this unique monograph written by Vinson and justly dedicated to *late* Henry S. Plummer.

The book begins with general management of patients with dysphagia followed by a chapter on endoscopy. The author insists that endoscopic examination should be deferred as the last method of investigation. The various functional and organic disorders have next been dealt with. The descriptions are clear, concise and profusely illustrated.

Auscultation over the œsophagus while swallowing, formerly stressed as disclosing valuable evidence of obstruction, is now rarely employed in diagnosis. In about 40 per cent of the number of patients having dysphagia, obstruction in the œsophagus has been found to be due to carcinoma. Difficulty in swallowing solid food is usually the first symptom of œsophageal carcinoma. Dilated veins in the lower œsophagus may produce radiological evidence suggestive of a neoplastic change, but the former rarely, if ever, produce dysphagia. Plummer-Vinson syndrome has apparently been attributed to hysterical dysphagia. Nutritional disorders

including anæmia, glossitis, splenomegaly and/or achlorhydria, develop secondarily from an unbalanced diet because of the inability to swallow solid food from fear of choking. In this connection, we may say that there is a difference of opinion. For instance, Hurst attributed it to achalasia of the pharyngeal sphincter giving rise to mal-nutrition. Suzman, however, believed that dysphagia was merely a complication or concomitant manifestation of idiopathic hypochromic anæmia. Notwithstanding the fact that the œsophagus is relatively immune to formation of tubercle, a few interesting instances have been cited. In conclusion, a brief reference has been made to gastroscopy. There is a bibliography at the end of each section.

The book will prove useful to all those who are interested in œsophageal diseases.

R. C.

**THE ANATOMY OF THE FEMALE PELVIS.**—By F. A. Maguire, C.M.G., D.S.O., V.D., M.D., Ch.M., F.R.C.S. (Eng.), F.R.A.C.S., F.R.C.O.G. Third Edition. 1940. Angus and Robertson, Limited, Sydney. Pp. x plus 162. Illustrated. Price, 10s. 6d.

The majority of medical students—when their time comes for midwifery and gynaecological ward work—remember that most cynical of all mnemonics which begins:—‘Some inherit money.’

They remember that it stands for the branches of the internal iliac artery. They remember that urine flows under the uterine artery like water under a bridge. But that is about all they remember of the anatomy of the pelvis until it has been revised. *The Anatomy of the Female Pelvis* by F. A. Maguire is an excellent little book for this revision. It completely covers the female pelvis in 116 pages, it is easy reading and is well supplied with very good illustrations.

The bones, ligaments, muscles and fascia are first described and this is done well without too much detail. The supporting function of the levatores ani muscles is stressed by emphasizing their divisions, origins, and insertions. The obstetrician would like to see their function of directing the fetal occiput to the front indicated.

The urogenital diaphragm and vulva receive a conventional chapter each and the author goes on to take the pelvic viscera in general. In this chapter the three systems of viscera in the pelvis are described as having similar functions. Each has ducts of entrance—the pelvic colon, the ureters, and the fallopian tubes—each has a muscular elastic reservoir—the rectum, the bladder, and the uterus—and each has a canal of exit—the anal canal, the cervical canal and vagina, and the urethra. Their function is to receive, hold for a time and expel the fæces, fœtus, and urine, respectively.

The pelvic connective tissue is described and then the largest chapter in the book, 11 pages of text and 9 full-page diagrams, is devoted to the blood vessels and lymphatics.

The supports of the uterus are explained in fair detail. The author divides them into an upper set, the broad ligaments, the round ligaments, the uterosacral ligaments and the connective tissue sheaths of the neuro-vascular bundles, a middle set the levatores ani muscles, and a lower set the perineal body and the urogenital diaphragm. He lays great stress on the connective tissue sheaths of the vessels and nerves passing to the uterus, vagina and bladder. He describes these sheaths as passing from the lateral pelvic walls in the region of the ischial spines to the lateral walls of the cervix and vaginal vault. He compares them with the sheaths of the carotid, axillary and femoral vessels which certainly have little supporting function. Mackenrodt's ligaments, on which the undeniably successful Fothergill's operation depends, are not considered important by the author. He implies that they are a product of dissection. He states referring

to Mackenrodt's or the lateral cervico-pelvic ligaments. 'There is no doubt that dissection in a mass of connective tissue may display sheets of fibres running in various directions.' This is a view not generally accepted.

The various pelvic organs are next described separately and there is a good chapter on the applied anatomy of the female pelvis. The book is finished with an explanation of the pelvic examination of the female patient which should be helpful to the student. Inspection of the vulva, per vaginam and bimanual examinations, is described, and the reader told what to look for and how to recognize the abnormal.

A chapter on the nerves of the pelvis including the sympathetic would be a valuable addition especially in view of the work recently done on dysmenorrhœa, and a word here and there on development would add interest and help understanding and remembrance.

The illustrations, of which there are 35, are really good. It is a pity that it has been found necessary to use numbers in their description from another work. It makes it difficult and exasperating to find what each number stands for, especially as there is no order in the placing of the numbers below each diagram. All the numbers used are to be found in sequence in an appendix, but no one will wish to refer to this for the interpretation of each and every diagram.

G. B. W. F.

**SURGICAL ANATOMY.**—By Grant Massie, M.B., M.S. (Lond.). F.R.C.S. (Eng.). Fourth Edition. 1940. J. and A. Churchill, Limited, London. Pp. viii plus 472, with 158 illustrations. Many in colours. Price, 21s.

THE fourth edition of this well-known book is assured of a ready welcome. The text has been thoroughly revised with sundry additions, without however disturbing the balance between the anatomical and surgical subject-matter. The inclusion of numerous new illustrations and the replacement of nearly all the older x-ray plates have enhanced the value of the book. We have no doubt that the present volume will be found as useful as its predecessors. We strongly commend this book to the notice of medical students and their teachers. The printing, get-up and illustrations are all excellent.

P. N. R.

**STATISTICAL METHODS FOR MEDICAL AND BIOLOGICAL STUDENTS.**—By Gunner Dahlberg. 1940. George Allen and Unwin, Limited, London. Pp. 232. Price, 10s. 6d.

THIS is a book designed to serve as an elementary introduction to the methods used to ascertain the significance of biological data. It is suggested that with little mathematical equipment this book enables the research worker to dispense with the services of a statistician unfamiliar with the actual material to help him to interpret his results. The medical student and research worker will however find that considerably more than a little mathematical equipment is required to understand the book, and before they can hope to dispense with the services of a statistician the majority of research workers would have to employ such an expert to understand the mathematical formulæ given in this book. The text is in many parts too highly technical and this often defeats the end in view. Those who have the necessary mathematical equipment and are to some extent already familiar with the subject will find much of interest and value in this book.

C. L. P.

**AIDS TO INORGANIC CHEMISTRY.**—By R. G. Austin, B.Sc. (Lond.), A.I.C., F.R.M.S. 1940. Baillière, Tindall and Cox, London. Pp. x plus 348. Price, 5s.

THIS handy little volume belongs to the well-known Students' Aids Series and is designed to meet the needs of students of medicine, dental and veterinary surgery and pharmacy and also those of students of science. It does not pretend to be a complete textbook of the

subject, but is intended for use by students who have already attended lectures on inorganic chemistry. The various chemical reactions have been explained by equations and, where possible, simple interpretations of the mechanism of the reactions have been given prominence in order that students may gain some insight into the principles of chemical change and so minimize the memorizing of long equations. The most interesting feature of the book, very useful to students of medical and allied sciences, is the paragraph on the physiological action under each of the common inorganic compounds described. The book has been written in a clear style by a teacher of wide experience and should prove very valuable for those who have no time to go through the larger textbooks on the subject.

S. G.

**PREVENTION OF VENEREAL DISEASE.**—By Marie C. Stopes. Third Edition. 1939. Putnam and Company, Limited, London (42, Great Russell Street, W.C.1). Pp. xi plus 62. Price, 2s. 6d.

THIS is a useful little book written in Dr. Stopes' direct and lucid style. The author's aim is, as always, to tell the facts to those who most need to know them. The book will serve a very useful purpose and should be widely read.

**BIRTH CONTROL: WHY, WHEN AND HOW?**—By B. L. Raina, M.B., B.S. Second Edition. New Book Company, Bombay (Hornby Road, Fort). Pp. 63. Illustrated

A BEGINNING has been made. The scheme has yet to be extended and adapted to Indian conditions, climatic, economic and social.

## Abstracts from Reports

### ANNUAL REPORT OF THE KING EDWARD VII SANATORIUM, BHOWALI, U. P., FOR THE YEAR 1939

THE sanatorium remained open throughout the year and the accommodation available for the general public was occupied except during the winter months and, as usual, there was a waiting list during the season, especially for the lower classes.

Seventy-one patients remained in the sanatorium on 1st January, 1939, from the previous year and 227 patients were admitted and 228 discharged during the year under report. The daily average number of patients treated was 113.44, the largest number being 145 during the month of June and the lowest 69 in the month of January 1939.

Eighteen beds out of 150 are endowment beds reserved for the nominees of the donors and 132 beds only are therefore available for the general public. The sanatorium is, however, grateful to the donors for their standing permission to utilize their beds, when available, for use of the general public.

'B' class cottages are convertible into 'A' class accommodation. For these reasons the actual strength of patients may sometimes be less than the accommodation available.

#### *Building work and improvements:—*

The construction of the following buildings was taken in hand during the year.

*A block of six kitchens for patients of the 'C' class.*—The existing kitchens were at some distance from 'C' class block no. 2, and caused inconvenience to the patients who consequently showed unwillingness to occupy the block. New kitchens were therefore constructed close to the patients' block, out of the material obtained from dismantling the servants' quarters which were in front of and close to the administrative building and looked very unsuitable on their present site. The old kitchens were converted

'Elastoplast' applied to Impetigo.

2

An 'Elastoplast' Boil Dressing.

Fig. 1 (Bed Sore). Cleansing surrounding area before treatment.

Fig. 2 (Bed Sore). 'Elastoplast' applied.

Fig. 3 (Bed Sore). After eight weeks.

# 'Elastoplast' in the treatment of common skin lesions

## IMPETIGO (See First Illustration).

Crusts and pustules are not removed but are covered with a strip of 'Elastoplast' Bandage or Plaster without any intervening dressing.

## BOILS (See Second Illustration).

'Elastoplast' Boil Dressings (Medication: Mercury and Carbolic) may be applied, or alternatively, two or three layers of ordinary 'Elastoplast' form a very effective treatment. 'Elastoplast' splints the inflamed area, and protects the boil from counter-irritation.

## BED SORES (See Figs. 1, 2 and 3).

The lesion is cleansed and dried and covered with a single or, preferably, double layer of 'Elastoplast,' without any intervening dressing and *without stretching the plaster*. It is left undisturbed as long as comfortable.

## BURNS

The immediate and direct application of 'Elastoplast' (unstretched) to burns and scalds of the first or second degree provides an artificial scab, allays pain, forms a convenient and comfortable dressing; and, if left undisturbed for 7 to 10 days (provided neither unusual pain nor rise in temperature be experienced), healing results without any other or further application.

## BLISTERS

'Elastoplast' is applied over the threatening blister, or after piercing if the blister has formed. Immediate relief from pain is obtained and infection of the blister is prevented.

ILFORD-SELO (INDIA), LTD., Bombay, Calcutta, Lahore and Madras.

into servants' quarters. All these changes were brought about at a cost of about Rs. 1,800.

*Dining room and kitchen for female nurses.*—There was no common dining room for the nurses, who consequently had to take their meals in their own rooms. A dining room attached to the nurses' quarters and a kitchen close by were constructed at a cost of about Rs. 1,200.

*Incinerator and fuel shed.*—Owing to the larger number of patients admitted during recent years, the necessity of an additional incinerator was keenly felt, and this was constructed at a cost of about Rs. 500.

Besides the above construction, certain additions and alterations of minor importance to some of the existing buildings were done, with the idea of improving the general appearance of the institution and at the same time giving greater comfort to the patients. For instance, the open ward of the Red-Cross block was closed in by partially glazed and partially gauzed doors to enable the patients to live with comfort during the winter months. Such improvements are, however, too numerous to mention and are difficult to describe in detail.

*Police ward.*—The outstanding construction during the year under report was a ward of 12 beds for patients of the police department. The ward has been constructed from donations received from members of the U. P. Police Service as a memorial to Mr. G. W. Cole, I.P., Superintendent of Police, and Sub-Inspector Jainti Prasad, who lost their lives in an encounter with an armed murderer in the Farrukhabad District on 3rd April, 1936. The whole building consists of a hall with open verandahs in front and behind, and a ward-boys' room attached to it. The ward was opened by R. A. Horton, Esqr., C.I.E., Inspector-General of Police, U. P., on 8th October, 1939.

*Post-graduate training:*—

Six medical men came to the sanatorium for post-graduate training during the year under report.

*Social functions:*—

The 'Sanatorium Day' was celebrated on 13th and 14th May when a number of sports and competitions in indoor games were held.

A number of small tea-parties were also arranged by certain patients and they helped to brighten up the sanatorium life, giving those who participated in them a chance to forget their ills and infirmities for the time being.

The medical staff were 'at-home' to all other members of the staff and to the patients and their attendants on 20th June.

*Library:*—

The Editors of the *Hindustan Times* and *National Herald* stopped sending free copies of their papers owing to war conditions for which we are sorry. We are very grateful to the Editors of the *Statesman*, *Pioneer* and *Illustrated Weekly of India* for continuing to supply free copies of their papers in spite of the difficulties created by the war. Horlicks Limited continued supplying free copies of the *Sphere*, *Strand* and *Tit Bits* and their generous gift is gratefully appreciated. It has to be mentioned with the greatest regret that Horlicks find themselves unable to continue the gift of the three newspapers during 1940 owing to war conditions.

*My Magazine of India* published from Madras was added to the list of free copies during the year under report, and the Editor deserves thanks for the gift. One of our ex-patients presented a free copy of the *Orient*, an illustrated weekly from Calcutta, in appreciation of his recovery in the sanatorium.

The sanatorium subscribed to the following newspapers and periodicals, in addition:—

Hindi—*Arjun*, *Madhuri*, *Chand* and *Kalyan*.

Urdu—*Tej*, *Humaun* and *Nigar*.

English—*The Pioneer*, *The Leader* and *Modern Review*.

*Our most urgent need:*—

The most pressing need at the present moment is electrification of the sanatorium, the urgency of which

has been shown in the reports for the last two years. It was suggested in last year's report that 'the Government can either persuade the Naini Tal Municipal Board to supply the electric current or sanction a non-recurring grant to the sanatorium for having its own high tension line'.

The Hon'ble Mrs. Vijaya Lakshmi Pandit, Minister of Local Self-Government and Health, paid her first official visit to the sanatorium in the month of May 1939, and observed that 'the sanatorium urgently requires electricity for light without which the x-ray plant is not able to function in a satisfactory manner' and she expressed the hope that the difficulty will soon be remedied.

It must be acknowledged with gratification that since the visit of the Hon'ble Minister to the sanatorium, the Government have taken interest in the matter of electrification of the institution and is favourably considering the question of making a non-recurring grant to meet the cost of laying the high tension line from the Municipal Power House at Naini Tal to the sanatorium. The Government has even gone to the length of ascertaining through the Deputy Commissioner in-charge of Kumaon Division the views of the Municipal Board and pointing out to them that the Eastern Command having shifted from Naini Tal, they ought to welcome the new outlet for their electrical energy.

It is earnestly hoped that the Municipal Board will not try to bargain with the Government in a commercial spirit as they have done with the sanatorium, but will show a spirit of co-operation and compromise by agreeing to supply the current at reasonable rates if the high tension line is laid from the non-recurring grant which the sanatorium expects to receive from the Government for the purpose.

## TUBERCULOSIS AMONG INDUSTRIAL WORKERS

In the course of investigations into the relation of tuberculosis to industry, an examination of over 3,000 workers showed that over 80 per cent of the workers are drawn from distant rural areas and that there is a high incidence of infection and disease among them states the annual report of the All-India Institute of Hygiene and Public Health for the year 1939. Investigation of over 900 children belonging to the same group showed an incidence of infection in about 68 per cent and disease of lungs in about 12 per cent.

Active research has been pursued into various conditions of nutritional deficiency. Methods have been developed for detecting such conditions in their initial stages. One of these methods is the development of an apparatus, the visual photometer, which has been successfully used in sectional surveys of the population.

In view of the widespread vitamin-A deficiency among the population as shown by surveys, the extensive studies of the vitamin-A content of the liver oils of locally available fish were undertaken. It was found that many of these oils were even richer than imported cod-liver oils in their vitamin content. As the difficulties in the import of foreign fish liver oils are increasing every day, a strong plea is made for the encouragement of the local fish-liver oil industry.

## ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ORISSA FOR THE YEAR 1938

*Provincial birth and death rates.*—The provincial birth rate for the year 1938 was 33.8 per mille as against 34.8 in 1937 and death rate was 29.5 in 1938 as against 28.6 in 1937. Thus the birth rate in 1938 showed a decrease of 1.0 and the death rate an increase of 0.9. This lower birth rate is probably due to some amount of agricultural distress brought about by the heavy recurring floods and the increase in the incidence of malaria in 1938.

*Cholera.*—Although the province is notorious for cholera, it remained almost free from the disease during the year, compared with the previous years. The total

number of deaths recorded from cholera during 1938 was 1,309 as against 7,977 in 1936 and 5,076 in 1937.

**Smallpox.**—The total number of deaths recorded from smallpox during the year 1938 was 3,321 as against 2,269 in 1937 and 3,780 in 1936 giving a mortality rate of 0.5 as against 0.3 in the previous year.

**Plague.**—No case of plague was reported during the year. The port of Rangoon which maintains direct and constant shipping communications with Orissa through its port of Gopalpur remained infected with plague almost throughout the year, and consequently steps had to be taken at the port of Gopalpur for carrying out all necessary measures.

**Dysentery and diarrhoea.**—There were 19,816 deaths from this group of diseases during the year 1938 as against 17,194 in 1937 and 16,283 in 1936 and the mortality rate was 2.8 as against 2.5 in 1937 and 2.3 in 1936.

The epidemiology and the high incidence of these diseases have probably some relationship with high humidity in the low-lying coastal districts where they are most marked, and like some other diseases they seem to follow a curve of periodicity. To a large extent they are, like cholera, directly associated with inadequate and bad drinking water-supply and defective sanitation in the rural, and to a less extent in the urban areas. The recurring floods no doubt also play an important part in bringing about such a bad state of sanitation.

A careful study of the facts relating to bowel diseases indicates that the chief measure for their mitigation and prevention is the provision of adequate and wholesome water-supplies for drinking in the rural areas. Where protected water-supplies have been given, as in the Puri municipality, the incidence of these diseases has become remarkably low when compared with the condition before it was introduced.

**Respiratory diseases.**—Four thousand nine hundred and sixty-seven deaths were recorded from respiratory diseases during the year giving a mortality rate of 0.7 which is higher than the mortality rate from smallpox. Deaths from pneumonia and pulmonary tuberculosis, which are included, probably claim quite a big percentage of the total deaths recorded under this cause. In this connection it may be said that provincial and district tuberculosis associations have been formed and attempts are being made to organize a campaign against tuberculosis to start with in the provincial headquarters town of Cuttack, by establishing a model clinic.

**Fevers.**—The death rate under the general head 'fever' was 16.0 during the year 1938 as compared with 15.2 in 1937.

Malaria was prevalent throughout the province in more or less epidemic form during the year.

Colonel G. Covell, I.M.S., Director, Malaria Institute of India, visited the province in September 1938. He visited three localities in which the malaria problems of the province were considered to be particularly urgent, viz:—

1. Chatrapur and the portion of Ganjam district which lies between Gopalpur on the sea coast and Rambha on the shore of Chilka lake.

2. Kendrapara, a municipality in the deltaic region.

3. Chandipur in Balasore district, the headquarters of the Proof and Experimental Station of the Military Department.

After the short investigation which he made he was of opinion that the malaria problems of the province are both extensive and varied and that practically nothing is known as to the anopheline vector responsible for the transmission of malaria in different parts of the province or of the factors determining the occurrence of epidemics of the disease. He was further of opinion that in order to tackle the malaria problems with any hope of success preliminary observations by a unit composed of trained personnel is necessary. To this end he recommended the deputation of a research unit belonging to the Malaria Institute of India to be

located in the first instance in one of the villages on the shore of the Chilka lake.

Quinine worth Rs. 2,772 was sold through post offices and other vendors during the year under report. Thirty-six pounds of quinine sulphate costing Rs. 648 out of the Government of India stock was distributed free in the malaria-affected areas of the province.

**Fairs and festivals.**—The most important and famous among these are the *Snan* and *Rath Jatra* festivals which are held at Puri. They attract a large number of pilgrims from all over India. In 1938, the *Snan Jatra* was held on the 12th June, the *Rath Jatra* on 29th June, and the Return Car festival on the 7th of July. The festivals were attended by about 52,000, 83,000, and 79,000 pilgrims respectively. As usual a large number of pilgrims halted in the various dharmasalas and lodging houses. Some stayed with friends and many camped on roadsides, while a large number assembled only for a day. Special sanitary arrangements were made from the 10th June to 9th July.

All the public wells were cleaned of silt. Preliminary disinfection of private and public wells including those in the lodging houses and dharmasalas 10 days before the festivals was carried out. Subsequently, during the festivals all the public wells and those in the large lodging houses and dharmasalas were heavily disinfected from time to time so as to make the water distasteful and thus prevent people from using them for drinking. Discarding the overchlorinated wells in the lodging houses where piped water-supply had already been installed, all the wells in the other lodging houses and private houses were 'phaged' every alternate day and whenever thought necessary.

For 30 days, from the 10th June to the 9th July, arrangements were made for a continuous piped water-supply for 24 hours in the town as another measure of special facilities and precautions.

The important tanks regarded as sacred were disinfected as often as necessary and people were prohibited from collecting and carrying water from these tanks for drinking purposes. Arrangements were made through the respective health authorities of the railway and the Puri district board to treat the sources of water-supply with bacteriophage at the nearest railway stations and along the Jagannath trunk road including the pilgrim centres at Sakshigopal and Bhubaneswar. Special mention may be made of the compulsory provision that now exists that all lodging houses should have protected pipe water connection before licences to these places are granted.

As regards control over food supplies during this festival careful inspection of all the shops that dealt in articles of food was made regularly not only by health inspectors, but also by the medical officers in charge of respective wards. A vigilant watch was exercised to see that the foodstuffs were fresh and wholesome and protected from dust and flies. Such articles as were found unwholesome or adulterated were destroyed. It is satisfactory to note that most of the shop-keepers and vendors of foodstuffs fully co-operated with the health staff in the efforts made to prevent infection occurring and spreading through articles of food and drink.

Puri is a place of pilgrimage and the temple *Mahaprasad* is the main source of food supply for more than 90 per cent of the pilgrims. The temple authorities are solely responsible for the control of sale of such foodstuff.

Although there were stray cases of cholera in the town earlier in the year, since March, and the interior of the district reported a large number of cases prior to the commencement of the festival, it fortunately did not assume epidemic form during the actual festival period, thanks to the measures taken by the district board. A few cases of purging and vomiting occurred but the situation was never alarming and was checked at once. There were 44 attacks with 3 deaths. None of these cases that died was inoculated.

# The Influence of Virol on the Growth of Children

*A Summary of Investigations\* published in the  
"Medical Officer," March 30 and April 6, 1935*

A NUMBER of children, all receiving their customary home diet, were given either No Supplement, Cod Liver Oil, Halibut Liver Oil (with milk to provide equal calories) or Virol. The experimental scheme provided that each child should have a period on each treatment in turn, in such a way that every possible sequence was included. Rigid statistical control was thus possible.

## Gain or Loss in Weight on Various Supplements:—

Supplement	Total gain in ozs. over all periods	Average gain per child per week in ozs. over all periods	Total loss in ozs. during summer period only	Average loss per child per week in ozs. during summer period only
No Supplement - -	88	0.3	— 103	— 1.4
Cod Liver Oil - -	287	1.0	— 77	— 1.1
Halibut Liver Oil with milk - - -	333	1.2	— 184	— 2.6
VIROL - - - -	762	2.6	— 7	— 0.1

Whereas earlier investigations had shown that the mere addition of vitamins had no effect on growth, these investigations have conclusively proved that Virol—a balanced food containing all the necessary vitamins—has a definite and remarkable effect in bringing the rate of growth up to the recommended standard. Virol was the only one of the supplements used that promoted this ideal rate of growth.

Virol was the one and only preparation that maintained the children's weight in the hot weather.

\* The full report will be sent on application to Messrs. A. H. Wheeler & Co.,  
Sudama House, Wittet Road, Ballard Estate, Bombay.

# Baby's First Food

Allenburys Malted Rusks are a valuable food from the age of ten months onwards, and may be used even earlier as a stimulus to salivary secretion and a help to teething. Their use encourages the development of a strong, wide jaw in which there is ample room for the teeth.

Vitamin D (calciferol), in the form of irradiated ergosterol, is added to the Rusks in the process of manufacture, in order to ensure normal calcification of bones and teeth.

The Rusks retain their crispness and flavour under the most varied climatic conditions.

In tins containing  $\frac{1}{2}$  lb., 1 lb., 2 $\frac{1}{4}$  lbs.

### MADRAS MEDICAL REGISTER, 1940—COMPILED AND PUBLICATION OF CHANGES OF ADDRESSES OF MEDICAL PRACTITIONERS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—It was observed in the course of the recent elections to the Madras Medical Council as well as the Medical Council of India that the addresses of a large number of registered medical practitioners were either out of date or not known, with the result that an unexpectedly large number of voting and other papers were returned to this office. In order that the addresses of medical practitioners may be correctly recorded in the annual Madras Medical Register, not only for the purpose of elections, but for the general advantage of the medical profession, I request you kindly to invite the attention of the medical practitioners through the columns of your valued journal to this fact and to suggest that not only their present addresses but also the changes in their addresses, as soon as such changes occur, should be intimated to the Registrar, Madras Medical Council, in the form shown below:—

1. Registration Certificate No.....
2. Name as in the Registration Certificate.....
3. Present (or change of) address:.....

Yours, etc.,

H. S. HENSMAN, O.B.E.,  
M.R.C.S., L.R.C.P.,  
Registrar,  
Madras Medical Council.

100, MOUNT ROAD,  
CATHEDRAL P. O.,  
MADRAS,  
29th July, 1940.

### LOWERING OF INSURANCE FEES

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—It has come to my knowledge that some of the Insurance Companies are paying only Rs. 5 for examination of cases when, as a matter of fact, the legal fee for the same, as allowed by majority of Companies is Rs. 6 or Rs. 8 per case up to Rs. 2,000. Therefore I would request my fellow practitioners to charge not less than Rs. 6 for each case. If the Companies do not pay their scheduled fees, the examination of cases of such Companies should not be made as this would lead to illegal lowering of the fee day by day. In the interest of us all I make this appeal and hope that the medical licentiates who do insurance work will kindly respond to it.

Yours, etc.,

K. C. MISSRA, L.M.F.,  
Bhabua Missra Dispensary.

BHABUA,  
19th August, 1940.

### THE RANGE OF THE MALARIA-CARRYING MOSQUITO

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Although the range of the mosquito has frequently been a subject of scientific investigation, statements made in the past have often been based on pure speculation, therefore any positive evidence on the range of malaria-infected mosquitoes is a practical point that seems worth recording.

Stephens and Christophers (1902, *Rep. Malaria Committee*, Roy. Soc., 7th Ser.) investigating *Anopheles culicifacies* failed to find mosquitoes 600 yards from

extensive breeding places. This observation has been confirmed by more recent investigators and it is generally acknowledged that the flight of this species is limited to half a mile. Afridi and Majid (1938, *Journ. Mal. Inst. India*, I, 155) investigating the *Culex fatigans* nuisance in Delhi found marked specimens of this species a maximum distance of three miles from their point of release; there was however strong evidence that the flight was carried out in stages.

*Aedes aegypti* is essentially a domestic mosquito and seldom strays more than 100 yards from its breeding place.

In most of the investigations on this subject, overland flight has been considered where the possibilities for resting en route were innumerable, but the general impression conveyed in textbooks is that about a quarter of a mile is the maximum range of direct flight and that if a ship is moored a greater distance than this from the shore the occupants will be safe from mosquito-borne diseases, e.g., malaria and yellow fever.

The following incident indicates that there may be exceptions to this rule.

I was recently a passenger on a ship bound for Colombo (and beyond). We sailed from Southampton leaving at night; we sighted no land until we arrived at 'A' on the 10th evening where we stayed until the 12th morning. We were moored over a mile from the shore (this statement was confirmed from the bridge); the harbour was crowded and we had at least two large ships between us and the shore. A large oil lighter lay alongside us for one night and the boat was visited by many country craft and small motor boats. No passengers were allowed ashore at 'A'. I was told that it was the height of the malaria season. We next called at 'B' on the 14th; the ship was again moored at least a mile from the shore, but on the 14th evening we called at an island, 'C', and took on water; here we lay within about 600 yards of the shore.

On the 29th day of the voyage, I was asked by the ship's surgeon to see a passenger in consultation. He was a young man, aged 21, who had never left England before; he had first felt ill on the 23rd, on the 25th he was admitted to the ship's hospital with a temperature of 102°; he was slightly better next day but on the 27th his temperature rose again and he vomited, it fell to 100° on the 28th but on the 29th it rose to 102° and he vomited again. He had no rigors but he sweated profusely when the temperature fell. His tongue was furred but not markedly so and his spleen was about an inch below the costal margin, but came down to about three inches on deep inspiration. His pulse was persistently below 100. A provisional diagnosis of enteric had been made, it was suggested that the course of the disease was being modified by inoculation, for he had received his first dose of TAB vaccine on the 12th and the second on the 22nd, and after each dose there was a sharp local reaction.

His temperature chart suggested malaria, but this diagnosis had been ruled out as highly improbable in the circumstances. I felt, however, that it was worth examining a blood smear and found a heavy malignant tertian infection; there were on an average of more than two rings per field and many erythrocytes had two rings or more in them. He was given quinine and made an uninterrupted recovery.

This finding led to the reconsideration of another case, a girl, aged 15, who had been in India seven years ago, but had not had malaria.

She first complained of fever on the 24th day of the voyage and the temperature rose sharply to 102° or 103° on the 26th, 27th and 28th, falling again to normal each evening. Her guardian who was a doctor gave her atabrin on the 27th after taking a blood smear; the temperature came down after two days, but from other observations a diagnosis of *B. coli* infection was made and the film was not examined. I did not see this patient, but I was asked to examine the blood film, which had been kept, and in the first field found two malignant tertian rings.

The ship's surgeon told me that two other patients, both Indians who had been in England some years and

had not had malaria during this period, had typical clinical attacks of malaria which responded to quinine, about this time.

In the first cases of these four the malaria was certainly acquired on board, the second almost certainly. All four cases were amongst 'tourist' class passengers who were accommodated in the stern of the ship and whose cabins were at a lower level than those of the first class passengers. At 'A' a certain number of country craft came alongside selling fruit and other things. Most of the trade was done with the 'tourist' passengers.

The patients were all four in different cabins and the cabins were some distance from one another so that it seems likely that (if they were all cases of malaria), more than one infected mosquito came on board.

That the infected mosquito(es) came on at 'A' seems almost certain. That they were on board before this can surely be ruled out, as they would scarcely have been lurking inactive since the ship touched at a malarious port about two months earlier, and nine days would be too short an incubation period to allow for their coming on at 'C', even if this were malarious and about this I have no information.

The malaria-carrying mosquitoes of 'A' appear to be *Anopheles gambiae* and *A. funestus*; I have not found any references to the range of these particular species.

As to how the mosquitoes came on board there are many possibilities. They may have been blown directly from the shore or they may have 'hopped' from ship to ship; they may have come in the oil lighter or the motor boats, or finally in the country boats with the fruit. Speculation on these points will not be very profitable, but it seems most likely that they were simply blown from the shore as there was a moderate wind off the land part of the time.

The incident does seem to suggest that the passengers and crews of ships lying even a mile from a malarious shore may become infected with malaria: the same remark will apply to yellow fever, and, as many ships will now be calling at 'A' and other West African ports on their way to India, the port health authorities in this country should consider whether the precautions they are taking are adequate to deal with this added danger, the addition being quantitative rather than qualitative.

I have been told that a similar incident occurred during, or shortly after, the last war and that Australian troops were infected with malaria whilst lying in the harbour at 'A'; I have been unable to find the reference to this incident.

Yours, etc.,

L. EVERARD NAPIER.

PS. 'A' is a port in West Africa.  
'B' and 'C' are islands off the west coast of Africa.

## Service Notes

### APPOINTMENTS AND TRANSFERS

#### To be D. D. M. S. of a Command

MAJOR-GENERAL A. C. MUNRO, K.H.P. Dated 6th May, 1940.

The Governor is pleased to appoint Lieutenant-Colonel K. S. Thakur, Civil Surgeon, 24-Parganas, to act as Surgeon-General with the Government of Bengal, during the absence, on leave, of Major-General P. S. Mills, C.I.E., with effect from the 10th September, 1940, or until further orders.

Lieutenant-Colonel G. Covell, C.I.E., and Major M. K. Afridi reverted from foreign service under the Indian Research Fund Association, with effect from the 1st April, 1940, and were retained in the posts of Director and Assistant Director, respectively, of the Malaria Institute of India under the control of the Central Government.

Major J. H. Boulton is transferred to the Semi-Effective List. Dated 2nd June, 1940.

Captain Shwe Zan, Civil Surgeon, Bhamo, on transfer, made over and Lieutenant-Colonel W. J. S. Ingram received charge of the duties of the Civil Surgeon, Bhamo, on the afternoon of the 5th August, 1940.

Captain C. C. Kapila, on reversion from Military, assumed charge of his duties as Officer on Special Duty at the Pathological Laboratory, Rangoon General Hospital, on the forenoon of the 20th August, 1940.

Captain F. W. Allinson, doing general duty at the Medical College Hospitals, Calcutta, is placed on general duty at the Presidency General Hospital, Calcutta, with effect from the 13th August, 1940.

The Secretary of State for India has appointed to the Civil Branch of the Indian Medical Service the following Officers of the Indian Medical Service, with effect from the dates stated against their names:—

#### Central Government

Captain I. J. Franklen-Evans. Dated 19th July, 1939.

Captain W. S. Morgan. Dated 17th August, 1939.

Captain C. L. Greening. Dated 19th December, 1939.

Captain L. S. F. Woodhead. Dated 21st December, 1939.

#### Madras

Captain P. L. O'Neill. Dated 25th August, 1939.

Captain T. E. Palmer, O.B.E. Dated 19th December, 1939.

Captain W. A. N. Marrow. Dated 24th November, 1939.

#### Bihar

Captain L. M. Kelly. Dated 26th December, 1939.

Lieutenants (on probation) L. Nendkeolyar and B. L. Kapoor are confirmed in their ranks. Dated 1st February, 1940.

#### INDIAN LAND FORCES. INDIAN MEDICAL SERVICE (Emergency Commissions)

##### To be Lieutenants (on probation)

Dated 10th June, 1940

Harcharan Lal Bhatia.

Dated 13th June, 1940

Saiyid Safdar Ali Khan.

## A Call for Help

*Veganin Tablets present acetylsalicylic acid, phenacetin and codeine in synergistic combination, whereby the individual action of each constituent is greatly enhanced.*

*Veganin Tablets are not advertised to the public.*

*Supplied in tubes of 10 and 20.*

*A trial supply to Physicians on request.*

**MARTIN & HARRIS Ltd.,**  
Mercantile Buildings, Lall Bazar,  
CALCUTTA.

Also at Bombay, Madras, Karachi  
and Rangoon.

# THE CALL OF PAIN

The call of pain is seldom stilled, and relief is of primary importance to the suffering patient. The paroxysmal pain of dysmenorrhœa, the persistent and intense throbbing of migraine, the shooting pains of neuralgia, the pain in affections of the bones and joints, the pain resulting from accidents — all these, and many other conditions, yield with impressive readiness to the sedative and analgesic efficacy of Veganin. With Veganin there is no systemic disturbance, no habituation. It may therefore be safely entrusted to the patient as a dependable means of relieving and preventing pain.

## TABLETS

Prepared by WILLIAM R. WARNER & CO. LTD., LONDON, ENGLAND.

# ST. BARTHOLOMEW'S HOSPITAL OPERATION TABLE

with the  
Latest Improvements

including

Easy to operate Release Lever for lowering the table; Trendelenburg position increased to 55° tilt; Foot operated rubber-covered Floor Brake.

The St. Bartholomew's Hospital Operation Table is now manufactured in five different models and thus supplies a range of modern operation tables embodying the latest ideas of well-known surgeons for carrying out surgical operations.

All models can be supplied with either tripod or platform base.

Model A

In Trendelenburg position, 55° tilt, showing shoulder rests and instrument tray in position.

Model AC

in lateral position, with back elevator and lateral supports.

Over 1075 of these tables are in use at home and abroad.

*A descriptive booklet, fully illustrated, will be sent on request.*

#### LEAVE

The Governor is pleased to grant leave for the period from the 10th September to the 4th October, 1940, to Major-General P. S. Mills, *c.i.e.*, Surgeon-General with the Government of Bengal.

Major A. N. Chopra, Additional Assistant Director-General, Indian Medical Service, is granted leave for 1½ months, with effect from the 22nd August, 1940.

#### PROMOTIONS

*Lieutenant-Colonel to be Colonel*

H. Horan-Brown. Dated 30th July, 1940, with seniority from 31st July, 1936.

*Major to be Lieutenant-Colonel*

B. R. Tandon. Dated 25th August, 1940.

*Captains to be Majors*

E. H. Lossing. Dated 4th August, 1940.  
R. I. Reid. Dated 8th August, 1940.

#### RETIREMENT

Colonel F. F. S. Smith, *v.h.s.* Dated 30th July, 1940.

## Notes

### PYELECTAN

PYELECTAN is a preparation of the sodium salt of 3:5-di-iodo-4-pyridoxyl-N-methyl-2:6-dicarboxylic acid. This is the iodine compound which has achieved international reputation as a contrast medium for intravenous pyelography. The iodine content is firmly bound in organic combination, and is rapidly and completely excreted, unchanged, by the kidneys. Pyelectan is available in 20 c.c. ampoules, each containing in aqueous solution 15 grammes of the compound referred to. Literature and further details can be obtained from any branch of H. J. Foster and Company, Limited, India.

### 'TABLOID' 'THEOBA'

A USEFUL combined diuretic and sedative for use in conditions associated with high blood pressure is available in 'Tabloid' 'Theoba', a Burroughs Wellcome and Co. product containing theobromine, gr. 5 and phenobarbitone, gr.  $\frac{1}{2}$ . Its action is to dilate the coronary arteries with the relaxation of diseased arteries and this commends it for use in hypersensitive heart disease, angina pectoris and other conditions arising from high blood pressure. It may also be used to relieve intermittent claudication. 'Tabloid' 'Theoba' is issued in bottles of 25 and 100 products.

### AMINOPHYLLINE

AMINOPHYLLINE, a combination of theophylline with ethylenediamine, is a recent addition to the range of products issued by Burroughs Wellcome and Co., Snow Hill Buildings, E.C.1. This preparation possesses the valuable therapeutic properties of theophylline (considered to be the most effective of the xanthine diuretics) with a considerably reduced tendency to produce gastric and renal irritation. The greater solubility conferred by the ethylenediamine component increases its rapidity of action and also renders it suitable for parenteral administration. Aminophylline may be used as a general diuretic or a mild myocardial stimulant. Its effect in improving the blood supply of the kidney renders it valuable in relieving oedema in diseases of the kidney and heart. Further, owing to its direct stimulation of the medullary respiratory centres, it is of particular value in combating Cheyne-Stokes respiration. The product is available for oral administration as 'Tabloid' Aminophylline, 0.1 gm., in bottles of 25 and 100 products. For parenteral administration it is issued as 'Hypoloid' Aminophylline, a sterile solution supplied in strengths of 0.5 gm. in 2 c.c. (for intramuscular injection) and 0.25 gm. in 10 c.c. (for intravenous injection), each strength in boxes of 6 'Hypoloid' ampoules.

### CARBACHOL

MESSRS. BURROUGHS WELLCOME AND CO. announce the issue of Carbachol (carbamylcholine chloride)—the chemical originally introduced under the trade mark Doryl. It is a choline ester, having a pharmacological activity similar to that of acetylcholine, but much more resistant to hydrolysis; it is effective both by mouth and parenterally, and is exceptionally stable. Carbachol is particularly useful in the treatment of hyperpiesia when not due to organic disease, and is of considerable value in cases of intestinal atony. It is also effective in relieving post-operative gas-distension and pain, and retention of urine due to atony of the bladder wall or even to reflex spasm of the bladder sphincter. Other uses for Carbachol are the lowering of intra-ocular

pressure and contracting of pupils in glaucoma, and the aqueous solution is of considerable use in ozæna. To meet all these uses, Carbachol is issued as a 'Tabloid' product of 0.002 gm. for oral administration; as a 'Hypoloid' product of 0.25 gm. in 1 c.c. for subcutaneous or intramuscular injection; as 'Wellcome' (Ophthalmic) Solution of Carbachol, 0.75 per cent, with a convenient dropper; and as 'Vaporole' (Nasal) Solution, of 0.05 per cent.

### THE LOVIBOND COMPARATOR

THE Lovibond Comparator mentioned in the article 'Hæmatological Technique', Part V, by L. Everard Napier, F.R.C.P. (Lond.), and C. R. Das Gupta, M.B. (Cal.), D.T.M., on page 480 of the August number of the *Gazette* can be obtained from British Drug Houses, London, and stocks are now available at this company's depôts in India, Imperial Chemical House, Ballard Estate, Bombay, c/o H. S. Clark, Kent House, 33, Mission Row, Calcutta.

## Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

## Original Articles

### A FURTHER REPORT ON THE TREATMENT OF SOME VIRUS DISEASES OF THE SKIN BY INJECTION OF SPECIFIC TISSUE FILTRATES

By L. M. GHOSH, M.B., D.T.M.

and

P. A. MAPLESTONE, D.S.O., D.Sc., M.B., B.S., D.T.M.

(From the Department of Dermatology and Medical Mycology, School of Tropical Medicine, Calcutta. Partly financed by the Indian Research Fund Association)

THE four skin diseases known, respectively, as molluscum contagiosum, infective warts, pityriasis rosea, and herpes zoster are now accepted by all dermatologists as being caused by filtrable viruses. The infectious nature of all of them has been proved by successful transmission of the diseases (in the case of herpes by production of varicella-like lesions in children) to healthy persons by injection of filtrates of tissue taken from the lesions.

Further evidence of the presence of a virus in herpes zoster has been advanced by Goodpasture and Teague (1923) who produced herpes-like lesions on the skin of guinea-pigs by inoculation with herpes blister fluid, and other workers claim to have caused an eruption on the pads of dog's feet by the same means. de Castro Teixeira (1936) produced typical pocks on developing eggs.

Maplestone and Panja (1939) described a regular train of symptoms leading to death, following the intracerebral inoculation of rabbits with both filtered and unfiltered molluscum material, and the brains of animals dying from this cause showed pyramidal cell degeneration. They were also successful in transmitting the infection through two series of healthy rabbits by inoculation with brain emulsion of animals dying from this artificial infection, but subsequent to this the virus apparently became attenuated because it only caused slight and transient symptoms on the third passage, and none of the rabbits died. Later they showed that the majority of persons who had recovered from an attack of this disease had specific antibodies in their blood, which could be demonstrated by means of an antigen prepared by a special technique from the preserved brains of the infected rabbits.

The same workers also obtained partial success by inoculating the chorio-allantois of developing eggs, according to the technique of Burnet (1936), but as in the case of the rabbit experiments, the virus seemed soon to lose its activity, as it always died out after three or four passages.

Preliminary reports on the results of treatment of these four diseases by means of injection

with filtrates made from material removed from active lesions and killed with 0.5 per cent carbolic acid, and later on with 0.1 per cent formalin, have already appeared.

Ghosh (1934) recorded the apparently successful treatment of six cases of molluscum contagiosum. Ghosh and Maplestone (1935) had similar favourable results in 12 cases of infective warts of the plane type, but failed in five cases of papillomatous warts. Maplestone and Dey (1937) reported 28 cases of pityriasis rosea treated on similar lines, in which the average duration of the disease was reduced by about half, and finally Maplestone and Ghosh (1938) reported 40 cases of herpes zoster in which the results were particularly striking because the severe and often persistent pain of this condition always disappeared, at the latest, after the second injection.

On account of these uniformly favourable results, we have made repeated attempts to cultivate all these viruses on the chorio-allantois of developing eggs in the hope that we would thus be able to establish the strains and have a reliable source of vaccine for treatment. But with the exception of the partial success with molluscum contagiosum, mentioned above, we have always failed. We have therefore had to rely on filtrates prepared directly from material taken from persons suffering with these various diseases. In this connection we have found that filtrates prepared from a number of cases and pooled are quite as good as a filtrate made from a particular case and used on that case only, following the principle of using an auto-vaccine.

Our investigation as to how long these filtrates maintain their activity as therapeutic agents is not yet complete, but we have kept them in an ice-chest for over a year and so far there seems to be no loss of potency. The method of preparation and the dosage of the various filtrates are essentially the same as that described in the preliminary reports. This method has now been standardized, and to enable those who have not access to our former papers, and who may be desirous of trying this form of treatment, we are giving a recapitulation of these particulars in an appendix to this paper.

#### *Molluscum contagiosum*

TOTAL	64	53	..	11	..

\* These patients ceased attending before a full course was completed and returned after an interval and treatment was resumed.

*Note.*—Only two of the uncured cases showed no response, so the failure of the others to be completely cured may be ascribed to their irregular attendance and the incompleteness of the courses of treatment. It is a coincidence that in the warts and pityriasis rosea series two cases were also not improved. In herpes all cases showed improvement.

*Infective warts (plane type)*

TOTAL	102	84	..	18	..

\* See footnote to molluscum contagiosum table.

In addition to the 102 cases recorded in the above table 20 cases with papillomatous warts, with histories of duration from 2 months to 9 years, were treated in the same way. Only two responded to treatment satisfactorily, one required nine and the other ten injections to effect a cure. Four others showed slight improvement and two of the remainder had courses of bismuth injections as well as the filtrate without any apparent effect.

As a control, 20 cases of plane warts and 31 of papillomatous warts were treated with bismuth injections and only one of each type was cured. These cases were not selected in any way.

The bismuth preparation used was 'Bismo-chin' which is made by a firm of Calcutta drug manufacturers and is much cheaper than imported preparations of bismuth suitable for injection. It has been used by us in a large number of cases of lupus erythematosus with satisfactory results so it is clearly an active preparation.

*Pityriasis rosea*

TABLE A

Duration of disease prior to treatment, days	Number of cases	CASES CURED		CASES NOT CURED	
		Number	Number of injections per case	Number	Number of injections per case
0 to 7 (A)	10	6 2 1 1	4 5 6 7		
8 to 14 (B)	17	1 3 6 6 1	2 3 4 5 6		
15 to 21 (C)	23	6 6 3 2 1	4 5 6 7 7	1 1 2 1	3 4 5 7

5 × 30	1	1	8		
TOTAL	97	81	..	16	..

\*See footnote to molluscum contagiosum table.

TABLE B

The average time in weeks taken to cure cases in each group from the beginning of treatment and from time of onset of the generalized rash

Group (see table A)	Average duration of treatment (in weeks)	Average time taken to effect a cure from onset of rash (in weeks)
A	2.3	3.2
B	2.3	3.8
C	2.52	4.5
D	2.27	5.3
E	2.4	6.1
F	3.0	11.5

(The cases not cured and those taking two courses of treatment have not been included in calculating the figures of this table.)

On account of the fact that pityriasis rosea is a self-limiting disease the duration of which is said to be from four to ten weeks, according to

different authorities, it is difficult to assess the value of this form of treatment. Nevertheless the figures given in table B, in our opinion, strongly suggest that this form of treatment shortens the duration of the attack in the majority of cases. It should be noted that the duration of the disease, and consequently the time taken to effect a cure after its onset, have been estimated from the time the generalized rash appeared, because evidence of the time that the herald patch is noted, if it is noted at all, is very unreliable.

*Herpes zoster*

Duration of disease prior to treatment, days	Number of cases	CASES CURED		CASES NOT CURED

*Post-herpetic neuralgia*

10	1	1	4		
12	1	1	4		
14	1			1	3
15	1			1	3
2 × 30	1			1	3
TOTAL	5	2	..	3	..

\*See footnote to molluscum contagiosum table.

In the total of 86 cases of herpes there were no complete failures. It will be noted in the 'not cured' column that only one of the nine cases took the maximum number of injections. They had evidently improved so much that they did not attend until completely cured.

## APPENDIX

## DETAILS OF HOW TO PREPARE THE FILTRATES AND THE DOSAGE EMPLOYED

*Molluscum contagiosum, infective warts, and herpes zoster*

The lesions are cleaned, as far as possible, with a mixture of equal parts of ether and alcohol. They are snipped off with sharp scissors, curved on the flat, taking care that no normal skin is removed. The tissue is weighed by difference in a previously weighed sterile test-tube and placed in a sterile agate mortar with sterile pumice stone powder. It is energetically rubbed to make as fine an emulsion as possible and during the process sterile normal saline solution is slowly added until an amount of saline in proportion of 1 c.cm. to 1 mgm. of tissue has been used. The emulsified tissue is filtered through *Whatman's* No. 1 after which it is drawn through a *Whatman's* No. 1 candle under negative pressure. A quantity of normal saline containing commercial formalin in a strength of 2 per cent and equal in volume to the filtrate is mixed with it. This gives an emulsion in 1 per cent formalin-saline. It is tested for bacteriological sterility, and if free from contamination it is placed in a rubber-capped vaccine bottle and stored in an ice-chest for future use.

**Dosage.**—The initial dose is in all cases 0.1 c.cm. of the filtrate and in the case of warts and molluscum each successive dose is increased by 0.1 c.cm. until 1 c.cm. has been reached. The number of doses usually found necessary will be found in the tables in this paper. The interval between doses is three or four days (twice weekly). Where two courses have been given it means that the patient concerned ceased attending for a considerable time after the initial series of injections had been given, on account of considerable improvement but before cure was complete.

In the case of herpes the second dose is 0.2 c.cm. as in the other diseases but no further increase is made if more injections are needed. The injections are also given every second day instead of twice a week.

No local or general reaction has been produced even when larger doses than those recommended are employed, but as they did not appear to have any better effect there is no point in using them. In the case of herpes it is important to give no more than 0.1 c.cm. for the initial dose, because we have found if a larger dose is given it is liable to cause a severe exacerbation of symptoms.

(Continued at foot of next column)

## IMPROVED SIMPLE ENDO-TRACHEAL ANÆSTHETIC TECHNIQUE

By G. R. RAWLINGS, M.B., B.Ch. (Camb.), D.A. (Eng.)  
2/2, Harington Street, Calcutta

*Elimination of 'dead space'*

MANY anæsthetists, who have no suitable 'gas and oxygen' machine, employ endo-tracheal anæsthesia very successfully by using the simplest apparatus. Some system, such as a funnel covered with gauze and connected to the intra-tracheal tube, is frequently used to vaporize the anæsthetic agent on the principle of the original Hahn's cone. In operations around the face and neck it is often necessary to use a fairly long piece of tubing to connect the vaporizer with the intra-tracheal tube. On these occasions it frequently happens that the patient begins to breathe far more deeply than in open anæsthesia or when a carbon dioxide absorption technique is being used, and he continues to do so throughout the operation. By using a connecting tube of large bore there is little obstruction to respiration, but the respiratory depth is still much increased, so it is obvious that this is caused by a raised alveolar carbon dioxide concentration due to the 'dead space' in the tubing.

When nasal intubation is indicated one is sometimes compelled to use an endo-tracheal tube of relatively small bore. The patient

(Continued from previous column)

*Pityriasis rosca*

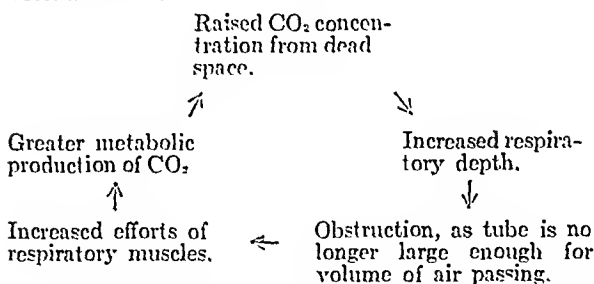

The virus of this disease gives the impression, both from its clinical manifestations and the few rather indefinite experimental records that are available, that it is of lower virulence than those which cause the other three diseases. We accordingly use a much more concentrated filtrate, and on account of the lesions being practically flush with the skin surface the method of collecting the material is of necessity slightly different.

A freshly-erupted spot 1 to 1½ cm. in diameter is selected and thoroughly cleaned with ether-alcohol. It is anæsthetized by injection beneath it of a little 2 per cent novocaine. A circular incision is made with a sharp knife. Care is taken that the depth of the incision is exactly the thickness of the skin, and it encircles the inflamed spot just inside the border so that no normal skin is included. The portion of skin outlined by the incision is dissected off carefully so that the whole skin is removed but no subcutaneous fat is taken with it. The wound is closed with one or two horse-hair sutures and dressed. The portion of skin is weighed by difference in a test-tube and shaken up with some normal saline to remove as much blood as possible. The saline is poured off and the skin transferred to an agate mortar where it is treated in the same way as already described, except that the saline is added in proportion of 1 c.cm. to 10 mgm. of tissue. After filtration an equal quantity of 2 per cent formalin in normal saline is added and if found sterile it is placed in a rubber-capped vaccine bottle and stored in the usual way.

**Dosage.**—Injections are given twice weekly beginning with 0.1 c.cm. and increasing each successive dose by 0.1 c.cm. up to 0.5 c.cm., after which no further increase is made. If by the time six injections have been given there are no distinct signs of improvement it is not worth continuing further. Many cases, however, do not need more than four or five injections to effect a cure.

breathes quite comfortably through this, but, when the apparatus has been connected for some minutes, the breathing begins to increase in depth until the respiratory efforts finally become very exaggerated and remain so throughout the anæsthesia. This is the result of a vicious circle.

To prevent this rise in the carbon dioxide concentration I have had made a simple unidirectional valve. This is inserted close to the intra-tracheal tube and thus prevents re-breathing into the connecting tube. By this means practically all the 'dead space' is eliminated, therefore making a closer approach to the normal physiological conditions of respiration.

This valve consists of two pieces of brass tubing  $1\frac{1}{4}$  inches in diameter, which fit together by a screw thread. A segment is cut from the circumference of one, and a brass plate is soldered across the resulting hole. This plate has a rectangular hole in it approximately  $1 \times \frac{1}{2}$  an inch. Another plate, in which is a hole of suitable shape, is soldered across the threaded (male) end of the other piece of tube. The shape of these holes is not important as long as they are sufficiently large to cause no obstruction to respiration. Smaller pieces of serrated brass tube, for the attachment of rubber tubing, are fixed to each end of the complete unit. Pieces of thin rubber sheet are partly stuck to the plates so as to cover the holes. These pieces of rubber act as flutter valves. I have found that 'Durofix' is a good adhesive for sticking the rubber to the brass. The metal parts can be made by any competent mechanic for a very small sum.

Figures 1 and 2 will make the construction and function clear. The rubber flap A opens on inspiration and shuts on expiration, whereas the flap B works in the opposite phase, with the

Fig. 1.—Unidirectional valve.

result that no re-breathing can take place into the connecting tube. These rubber flaps should be as thin as possible, to offer the minimum obstruction to respiration. On the other hand if too thin they will be driven through the holes.

Fig. 2.—Valve in section.

I have found that much quieter breathing results from using this valve, and thereby a smoother anæsthesia is usually obtained. When indicated, a smaller endo-tracheal tube may be used satisfactorily as the conditions causing the vicious circle, referred to above, no longer are present. It will be seen that one obvious advantage of using this valve is economy, since vaporization of the anæsthetic agent only takes place on inspiration.

A wire cage, fitted over the expiratory valve, is useful in preventing the valve from being obstructed by towels, etc.

#### *An efficient ether vaporizer*

A very efficient ether vaporizer can be made for a few annas in a short time by any one capable of using a soldering iron. The essential components are a large and a small tin, a piece of brass tube, a small tap, copper mesh, and some stout copper wire. Actually, 1-pound and 5-ounce Squibb's ether tins were used, but obviously any tins of similar shape will serve. The construction of this apparatus can be seen from figures 3 and 4. A small tap is soldered into a hole made in the bottom of the smaller tin, which is to act as the ether reservoir. A convenient and easily obtained tap is of the type used in saline infusion apparatus. It is essential that it should work smoothly and be capable of delivering a slow steady drip. A hole is made in the side of the lower part of the large tin. A piece of brass tube with a diameter not less than  $\frac{3}{4}$  inch and about  $1\frac{1}{2}$  inches long is soldered into this hole. The large tin is packed loosely with copper mesh. This is readily obtained by unravelling a copper saucepan scourer. The smaller tin is now fixed above the large one with stout copper wire, so that the tap is immediately over the centre hole in the top of the large tin.

The third tin shown at the bottom of the apparatus is not essential but, when filled with hot water, it prevents condensation owing to the rapid cooling effect of the evaporating ether. Also, the added weight makes a firm base for the apparatus.

The upper tin is filled with ether, and the side hole in the large tin is connected to the intra-tracheal tube. By adjusting the tap, a steady drip of ether falls on to the copper mesh, and is there evaporated by the passage of the patient's respirations. A hypodermic needle, pushed through the cork, maintains atmospheric pressure in the upper tin, and thereby prevents an uneven flow of ether.

Fig. 3.—Ether vaporizer.

Fig. 4.—Vaporizer in section.

I have found that, when combined with the valve described above, an extremely smooth anaesthesia can be achieved with this vaporizer. The patient is offered a steady concentration of ether, which can be rapidly and evenly increased, when necessary. Owing to this unvarying concentration of ether, a very light level of anaesthesia can be maintained for a considerable time without coughing or gagging setting in. The longest single anaesthesia, for which I have used this apparatus, was of three and a half hours'

(Continued at foot of next column)

## FURTHER CASES OF TYPHUS FEVER IN BOMBAY CITY

By T. B. PATEL, B.Sc., M.B., B.S., B.Hy., D.P.H.  
(Infectious Diseases Hospital, Arthur Road, Bombay)

PATEL (1940) reported some cases of typhus fever among the patients admitted to the above hospital from the city as suspected cases of the typhoid group; since then, we have continued our investigations and found eight more cases of a similar nature; these are detailed below.

In this series, one case is an imported one, while the rest occurred among the population of the city; each of them gave a history of residence in Bombay for the last two years or more and none of them had been out of Bombay for at least one year prior to his present illness.

From a survey of these cases, together with the cases previously reported, it is noticed that (i) all except one occurred in males, (ii) most of them occurred in different parts of the city, with the exception of two cases (no. 4271 and no. 4317) which occurred within the same mill compound, (iii) most of the cases occurred in the lower middle class and working class population, and (iv) they were distributed among all communities, Hindus, Muslims and Christians in that order of preponderance. The two cases which occurred in one mill compound were from different houses separated from each other by a distance of more than a hundred yards; one of these was a watchman and the other a clerk. The one imported case (no. 4140) was a wandering beggar who came to Bombay from Nagpur four days prior to the onset of the disease. It must be mentioned that only a very small percentage of the cases suspected of the typhoid group of infection seek admission into our hospitals in this city; and, in consequence, there is reason to believe that a number of cases of typhus fever escape detection.

Furthermore, typhus fever has all along been looked upon in this city as a disease of extremely rare occurrence and, in consequence, no special attempt has hitherto been made to look for it. From the Annual Reports of the Executive Health Officer of this city, it will be observed that one case of typhus fever has been hitherto reported in the year 1917 and also one each in

(Continued from previous column)

duration. About 10 ounces of ether were used, and the patient, who was a large man, suffered no post-anaesthetic vomiting, nor any other distress whatsoever. The apparatus is very economical, doubly so of course when combined with the valve. It may be used with a rubber face mask or with a well-fitting intra-pharyngeal airway. If ether alone is used, the apparatus is not satisfactory for the induction of anaesthesia. Used with a face mask and the valve, it is excellent for induction with chloroform owing to the steady concentration of vapour given.

1932, 1933 and 1937. With a view to discovering the ætiology of this disease, we made a searching examination for lice of each patient admitted to the hospital, and closely questioned him as to any history of insect bites; from these inquiries it would appear that both the louse and the tick could in all probability be excluded

of plague in this city, and it seems to us that there is ample justification to regard the rat flea as the vector of typhus also in this city. How far this is true needs further experimental investigation. All the cases so far investigated do not present any of the classical signs and symptoms which are regarded as characteristic

TABLE I

Reg. no.	Admitted on	Day of disease on which admitted	Sex	Age	Caste	Occupation	Locality	Clinical features	REMARKS
4271	10-12-39	8th	M.	35	H.	Watchman.	Parel	No rash; temperature up to 102°F., came to normal on 11th day of disease by lysis; drowsiness and headache on admission.	
4317	25-12-39	11th	M.	20	H.	Clerk	Parel	Toxæmia marked; temperature up to 102°F., came to normal on 16th day of disease; drowsiness; blood-shot eyes; severe headache and general body-ache which were a marked feature the first two days after admission.	
4140	9-12-39	10th	M.	60	M.	Mendicant.	Bhendy Bazar R. Side.	Toxæmia moderate; joint pains; blood-shot eyes; temperature came to normal on 12th day of disease by lysis; bronchitic signs in the chest.	Imported from Nagpur.
832	24-1-40	8th	M.	30	H.	Labourer	Delisle Road.	Complained of headache on admission; slow pulse; temperature ranged up to 101°F. and came to normal on 13th day by lysis.	
1038	4-2-40	9th	M.	42	H.	Clerk	Khetwadi	Signs of slight bronchitis; continuous fever rising to 103°F. for 11 days; emperature came to normal on 13th day of disease by lysis. Complained of headache and back-ache.	
1425	22-3-40	10th	M.	34	Ch.	Working in a bakery.	Byculla	Signs of bronchitis; continuous fever rising to 101°F., came to normal on 16th day of disease by lysis.	
1685	2-4-40	8th	M.	40	Ch.	Vendor of piece cloth.	Mazagaon	Continuous fever for 13 days; temperature rising to 103°F.; drowsiness; severe pains in all the joints and general headache; toxæmia marked; temperature came to normal on 14th day by lysis; patient complained of deafness for a fortnight after the temperature came to normal.	
1883	10-4-40	4th	F.	18	M.	Nil	Bhendy Bazar.	High temperature of 103.5°F. on admission; continued to be high with slight remissions; marked drowsiness; delirium; blood-shot eyes; severe headache, back-ache and joint pains; marked toxæmia; died on the 7th day of disease. Hyperpyrexia (106.5°F.) before death; no rash; no rigidity of neck, Kernig's sign negative; pupils reacted to light; lungs clear; spleen not palpable.	

as the causative agent. All the cases which we have so far examined have given a positive Weil-Felix reaction with X19 antigen supplied by the laboratory at Kasauli. The rat flea has been incriminated in such cases from investigations carried out in other parts of India. Rat infestation is quite a common feature in most of the houses in Bombay; they are especially abundant where the poorer classes dwell. We are all familiar with the history of the spread

of this disease, except that most of them complained of severe joint pains and general body-ache along with an elevated temperature, and that the temperature came down to normal between the 11th and the 16th days of the disease, usually by lysis, in some cases there was a marked conjunctival injection. Most of the cases were admitted to the hospital after the 7th day of the onset of fever, hence we had no opportunity of examining them at an earlier

stage. The diagnosis had to be made mainly on the positive serological tests, after excluding the typhoid group of infection. We have summarized the history and clinical features of these

3. We believe that the disease in this city is conveyed by rat fleas, an opinion based on analogy with plague, pending further experimental investigations.

cases in table I and the results of agglutination tests in table II. It must be noted that there was one death (no. 1883) in this series; this was a young girl sent in as a case of typhoid fever. On bacteriological examination, both the blood culture and the Widal test were negative; the Weil-Felix reaction gave an agglutination of 1 : 80 with the X19 antigen on the sixth day of the disease, according to the history given by the patient. Examination of blood smears for malarial parasites, a routine procedure with all cases admitted, was also negative. A differential count gave the following results: polymorphonuclears, 51 per cent; lymphocytes, 43 per cent; eosinophils, 1 per cent; and large mononuclears, 5 per cent. The temperature rose to 106.5°F. before death; and we could detect no complications in the lungs; this death was in all probability due to the intense toxæmia. There was no history of any other case of fever in the family.

#### *Summary*

1. Within the last ten months we have found 15 cases of typhus fever (based on the Weil-Felix reaction) among the cases admitted as suspected 'typhoid group' of infection.

2. In view of the prevailing attitude that typhus fever is a very rare and uncommon disease in Bombay city, a certain number of cases of typhus fever go undetected.

We take this opportunity of thanking Dr. B. P. B. Naidu who drew our attention to the possibility of typhus infection in some of our earlier cases and to his co-operation in this work and to Dr. P. T. Patel, the superintendent of the hospital, for his permission to record these notes.

cent infection. As a result of this infection a large number of the population get foot sores and anæmia which cause great disability. This entails dislocation of work, which means an economic loss to the estate. It was therefore decided in 1938 to give a mass treatment for hookworm infection by oil of chenopodium and tetrachlorethylene as recommended by Chopra (1936) and Maplestone and Mukerji (1937). Hare and Dutta (1939) have found these drugs to be of great value in this respect.

The treatment was given to practically the whole population of this estate. This estate consists of two big sections, viz (1) Baliyan and (2) Burra Bheel. In 1938 only Baliyan was given the treatment and the other side was kept as a control. Finding the results encouraging, as shown in tables I and II, both sections were treated in 1939 and 1940.

#### *Management and details of the treatment*

(1) The people were informed the previous day that they should (a) not take alcoholic drinks for twenty-four hours, (b) should come to the hospital the next morning at 7 a.m., and (c) have no food that morning.

(2) All being assembled, a thorough enquiry was made as to whether they had abstained from alcoholic drinks for the previous twenty-four hours and whether they had had food that morning. Anybody found not taking these precautions was disallowed treatment for that day.

(3) All adults and children from 6 months upwards were given the treatment.

(4) Dosage used was oil of chenopodium 1 c.cm., tetrachlorethylene 3 c.cm., and saturated solution of magnesium sulphate 2 oz. for an adult of average health. Proportionately reduced dosages were administered to younger and less robust people. These drugs were freshly mixed in a number of one-pound bottles and thoroughly shaken up before administration. The well-shaken emulsion took a milky appearance. Precaution was taken to wash the medicine glass between each patient with warm water, for fear of overdosage.

(5) The hæmoglobin index of every individual was recorded by Tallqvist's scale.

(6) They were kept under strict observation of the medical staff all the time they were at hospital. All were made to pass their stools in the hospital septic tank latrine and on no account were allowed to go into the neighbouring tea.

(7) After the bowels had moved properly a spoon diet was given to all of them consisting of boiled sago and sugar. They were all kept at hospital up to 5 p.m. when a light meal consisting of rice and dāl was given to them and then they were allowed to go to the lines with the instruction, not to take any alcoholic drinks for at least that night.

(8) An average of 236 people were treated daily with the exception of Saturday, Sunday and Monday, the days when coolies usually do most of their drinking.

(9) They were given *hazira* (wages) for the day of treatment.

#### *Complication of treatment*

There were no complications during the treatment except some cases, who in spite of warnings came to hospital with a full stomach, to which they did not admit. After taking the medicine they vomited badly, which frightened some of them. One of these cases fainted as a result of vomiting and had to be put to bed. He recovered after a while without any treatment.

#### *Cost of treatment (excluding hazira)*

Two thousand eight hundred and forty-two people were treated in 1940; medicine cost Rs. 105 and diet Rs. 175 bringing the total cost to Rs. 280; thus the average cost per head was approximately As. 0-1-7. In my opinion, this expenditure was fully justified when one considers the encouraging results and improvements as shown in tables I and II. After treatment the low-grade-anæmia cases had also to remain for a shorter period on the 'anæmic list', as shown in table III.

TABLE II

*Showing the percentages of anæmia cases before and after treatment*

BALIJAN									BURRA BHEEL								
Before treatment			After treatment						Before treatment			After treatment					
1938			1939			1940			1939			1940

13	10	3

TABLE IV

*Showing the incidence of foot sore cases before and after anthelmintic treatment*

BEFORE TREATMENT	AFTER TREATMENT	
Average of three years from 1935 to 1937	1938	1939
95	72	20

### Discussion

The result of mass hookworm treatment has proved to be a success by the decrease of low grade anæmia and appreciable rise in hæmoglobin index. By low grade anæmia is meant those whose index is 50 per cent and below. If such an improvement could be maintained in future, low grade anæmia will gradually be a thing of the past. It will be seen from tables II and III that the anæmic percentage of the whole population has been considerably reduced and the labourers on the anæmic list could be discharged three days earlier. This is not only a saving of medical expenditure but also an economy to the estate, as more labourers can be put to a full day's work, thereby reducing the cost of production. With the improvement of their blood condition, the general health and efficiency of the labour force will be much improved. It will also increase their powers of resistance, enabling them to withstand acute diseases, such as pneumonia, more effectively. This treatment has also considerably diminished the foot sore incidence of the estate as is shown in table IV. This has reduced the number of out-door patients as well as prevented the wastage of labour at a most important time. With the increase of hæmoglobin and good health it is hoped that in the near future it will have a salutary effect upon the incidence of maternal mortality, still births and infant mortality in general. The treatment was much appreciated by the labour force. Many of them hold that this treatment, 'julap' as they call it, has done them immense good.

## SHORT-TERM FEVERS IN LUCKNOW

By H. SAHAI

*Professor of Medicine, Lucknow University, and Physician, King George's Hospital, Lucknow*

and

S. C. BANERJEE

EVERY year with marked regularity, Lucknow is visited by an acute specific fever of short duration, which hitherto has been in a sporadic form, but this year has appeared in epidemic form with differences in toxicity, severity, and manifestations. The first indication of this outbreak was a sudden increase in the hospital attendance for fever. With the exception of a couple of cases of short-term fever which occurred earlier, the epidemic of short fevers began in July, thus coinciding with the breaking of the monsoon, and rapidly commenced to wane in November, no case being admitted to the hospital in December. Cases occurred among people of all classes and in both sexes, but especially in young adults. We followed a number of these cases, as many of the students of the Lucknow University, including medical college students and nurses, were admitted at the onset of the attack.

(Continued from previous column)

### Summary and conclusions

- (1) A mass hookworm treatment was carried out safely and successfully with oil of chenopodium and tetrachlorethylene.
- (2) The incidence of anæmia and foot sore has considerably diminished as a result of this treatment.
- (3) The general health and physical well-being of the labour force has much improved.
- (4) There were no serious complications arising out of the treatment.
- (5) The cost per head of medicine and feeding was approximately As. 0-1-7.

### Acknowledgments

I am greatly indebted to my chief, Dr. H. Flack, for his valuable advice while carrying out this experiment. My thanks are also due to Mr. J. Batterbury, Manager, Daimukhea T. E., for his keen interest, support and encouragement in all medical affairs. I have also to thank my compounder staff for their loyal co-operation in this undertaking.

The cases were characterized by the presence of joint pains, prostration, cough, and irritation of the throat. Some of them have been returned as cases of influenza, but the majority as 'pyrexia of unknown origin', and some as sandfly fever, dengue fever group, and febricula. These fevers are probably all alike in their ætiology and symptomatology. The ultimate diagnosis, when they are grouped in this list, depends mostly on the course the disease takes as regards time, type of fever, rash, intensity of muscular and joint pains, blood picture, and variation in pulse. All these fevers are common in the United Provinces though they are more prevalent in epidemic and pandemic forms in Bengal, Bombay, Madras and other places situated near the coast.

The main characters of the febrile attacks were as follows: The onset was usually sudden, with a feeling of chilliness not amounting to actual rigor. Pain in the eyes, deep at the back of the eyeball or a superficial burning or pricking sensation in the conjunctivæ was most characteristic, and a great diagnostic help during the first two or three days. The conjunctivæ were often swollen, reddened and injected. There were aching pains in the back and lower limbs but they were not so marked as in textbook descriptions of 'break bone' fever. The symptoms reached the height of their severity at the end of 48 to 72 hours and then diminished as the temperature fell. The temperature came down to normal on the 3rd, 5th, 7th, or 9th day with general improvement in the condition of the patient. The face lost its flushed appearance, pink eyes disappeared, the retro-ocular pain was forgotten and the patient decidedly improved. The patients now clamoured for food. In a large number of cases the convalescence was uninterrupted, but in some it was noticeable that after an apyrexia of 48 to 72 hours, the temperature rose a second time, with a recurrence of all the old symptoms, though in a milder form. On the 8th day the temperature fell again to normal and stayed there. Thus we were definitely dealing with two distinct classes of pyrexia, one with a single pyrexial period, the other with an initial pyrexia of 48 to 72 hours' duration followed by 24 to 48 hours' fall in temperature to the level of a little above normal, and then a secondary rise which lasted for 24 hours (saddle-back type). Only three cases showed rash, a generalized macular rash which lasted 3 to 4 days. The tongue was usually clean, a clinical sign of importance in differentiating from typhoid fever. Seven per cent of the cases had bowel disturbances in the form of loose and frequent motions; the rest had constipation. Five cases had nausea and vomiting during the fever. Abdominal pain was marked in several cases, and some of them started with this symptom, together with marked toxæmia simulating typhoid fever. The pulse rate was not invariably on the slow side as reported by various observers. The rise in pulse rate was

proportionate to the rise in temperature in 43 per cent of the cases. Swelling of glands was not observed. Insomnia was troublesome in a few cases. Delirium was present at the height of fever in four cases. There were no complications seen in the cases analysed. We have had no mortality in spite of alarming symptoms in some instances.

*Investigations.*—In all cases in which blood examination was carried out malarial parasites were not detected, even after repeated examination of blood smears.

The total leucocyte count was normal or raised in 68 per cent of cases, the rest had leucopenia. In some cases, as low a total count as 4,400 per c.mm. was observed. There was no definite variation in the differential leucocyte count. There was in some cases relative increase of lymphocytes and not a decrease, as reported by some observers in this disease.

Blood culture, taken in agar medium from the patient when the temperature was at its height, proved sterile after 48 hours' incubation.

The Widal reaction against *B. typhosus*, *B. paratyphosus A*, *B. paratyphosus B*, *B. paratyphosus C*, *B. faecalis alkaligenes*, and *B. suis-pestifer* was negative in twenty-five cases in which it was done.

Stool culture was negative for non-lactose fermenters and streptococci.

Throat swabs were taken from all the cases and culture proved negative for *Streptococcus hæmolyticus*.

*Animal experiment.*—Eight c.cm. of blood from the ante-cubital vein of a patient on the 2nd day of fever, mixed with 2 c.cm. of sterile 3.8 per cent sodium citrate solution, was injected into the peritoneal cavity of a guinea-pig. Also, an equal quantity of blood from a normal individual mixed with sodium citrate solution of the above strength was injected into the peritoneal cavity of another guinea-pig of approximately the same size and weight. Rectal temperature was taken morning and evening at specified hours and a careful watch was kept for any reactions that followed. Rectal temperature of another healthy guinea-pig was also recorded. This was to serve as a basis on which to judge any fluctuations in temperature following the injection. The control animal had a reactionary rise in temperature following the injection which lasted 24 hours after which the temperature came down to normal and remained there, and the animal was active again. The experimental animal had a rise in temperature to a higher level, which dropped by crisis to rise again for a second and third time. The temperature chart closely resembled that of the patient. The animal was very listless and refused food till the temperature had finally settled. This animal inoculation experiment indicates that the blood of a patient suffering from short-term fever is infective in the first few

days, but what the nature of this infection is we do not know.

### Illustrative cases

We have very carefully investigated 119 cases admitted to the King George's Hospital. They can be grouped under the following heads:—

(i) Common type ..	70 cases
(ii) Short type ..	18 "
(iii) Long type ..	14 "
(iv) Abdominal type ..	6 "
(v) Toxic type ..	9 "
(vi) Relapsing type ..	2 "

In all the cases recorded below the following investigations were done with uniformly negative results.

Blood film—Negative for malarial parasite.

Blood culture—Sterile after 48 hours' incubation.

Stool culture—Negative for non-lactose-fermenters.

Throat swab culture—Negative for *Streptococcus haemolyticus*.

Widal against salmonella group—Negative.

**Common type.**—Case 1. Female, age 18 years, was admitted on the 2nd day of fever. The onset was abrupt. The patient complained of headache (frontal), pain in limbs, and nausea. Nothing abnormal was detected on physical examination.

Rash appeared on the 4th day. It was macular and generalized. There was relative bradycardia. The temperature came down to normal by crisis on the 7th day.

CHART 1

No complications occurred. The appearance simulated enteric fever with frontal headache and slight abdominal discomfort, but proved to be one of short-term fever.

**Case 2.**—Male, age 20 years, was admitted on the 2nd day of fever. The onset was abrupt. The patient complained of headache (occipital) and pain in eyeballs. There was abdominal pain but no bowel irregularity. Nothing abnormal was detected on physical examination.

No rash appeared.

CHART 2

Rise in pulse rate was proportionate to rise in temperature. The temperature came down to normal by crisis.

Total leucocyte count—10,960 per c.mm.

Differential count—polymorphonuclears 72 per cent; lymphocytes 22 per cent; eosinophiles 2 per cent and large mononuclears 3 per cent.

No complications occurred.

Abdominal pain was a marked feature in this case.

CHART 3

**Case 3.**—Male, age 18 years, was admitted on the 3rd day of fever. The onset was abrupt. The patient complained of headache and pain in the eyes. On physical examination, throat was found congested and the spleen enlarged three fingers.

No rash appeared. There was relative bradycardia. The temperature came down to normal by lysis.

Total leucocyte count—8,400 per c.mm.

Differential count—polymorphonuclears 62 per cent; lymphocytes 34 per cent; eosinophiles 1 per cent and large mononuclears 4 per cent.

No complications occurred. The spleen was enlarged in this case probably due to previous attacks of malarial fever.

**Case 4.**—Male, age 24 years, was admitted on the 2nd day of fever. The onset was abrupt. The patient complained of headache and pain behind the eyeballs. Physical examination showed that the spleen was just palpable.

No rash appeared. Rise in pulse rate was proportionate to rise in temperature. The temperature was typically saddle-back type.

Total leucocyte count—8,400 per c.mm.

Differential count—polymorphonuclears 60 per cent; leucocytes 38 per cent and large mononuclears 2 per cent.

No complications occurred.

**Short type.**—Male, age 20 years, was admitted on the 1st day of fever. The onset was abrupt, accompanied by a chilly sensation. The patient complained of headache and pain in limbs. Nothing was found on physical examination.

No rash appeared. There was relative bradycardia. The temperature came down to normal by crisis.

Total leucocyte count—9,600 per c.mm.

Differential count—polymorphonuclears 72 per cent; lymphocytes 22 per cent; eosinophiles 2 per cent and large mononuclears 4 per cent.

No complications occurred.

**Long type.**—Male, age 18 years, was admitted on the 6th day of fever. The onset was abrupt, accompanied by a chill (not rigor), headache and vomiting. The patient complained of headache and pain in the chest. There was not much pain in his body, but he suffered from considerable restlessness. Physical examination detected congestion of throat and eyes.

No rash appeared. There was relative bradycardia. The temperature was of a saddle-back type.

Total leucocyte count—8,200 per c.mm.

Differential count—polymorphonuclears 80 per cent; lymphocytes 18 per cent and eosinophiles 2 per cent.

No complications occurred.

**Abdominal type.**—Male, age 20 years, was admitted on the 1st day of fever. The onset was abrupt. The patient complained of headache (parietal), pain in the joints and eyeballs. There was generalized abdominal pain but no bowel irregularity. On physical examination nothing abnormal was detected.

No rash appeared. Rise in pulse rate was proportionate to rise in temperature. The temperature came down to normal by crisis.

Total leucocyte count—12,240 per c.mm.

Differential count—polymorphonuclears 70 per cent; lymphocytes 27 per cent and large mononuclears 3 per cent.

No complications occurred. Abdominal pain was a marked feature in this case, and persisted throughout the course of illness.

CHART 4

CHART 5

CHART 6

CHART 7

**Toxic type.**—Male, age 20 years, was admitted on the 2nd day of fever. The onset was gradual. The patient complained of pain in abdomen (epigastrium), chest, and the whole body. On physical examination, he looked very toxic (2nd day). The tongue was coated and dry. There were sordes on teeth and lips.

No rash appeared. There was relative bradycardia.

**Differential count**—polymorphonuclears 46 per cent; lymphocytes 49 per cent; eosinophiles 2 per cent and large mononuclears 3 per cent.

No complications occurred. The patient was toxic throughout the course of illness.

**Relapsing type.**—Female, age 9 years, was admitted on the 1st October, 1939, on the 6th day of fever. The onset was gradual. The patient complained of headache in the beginning, pain in abdomen and body. No abnormal signs were detected on physical examination. The temperature came down to normal, by crisis, on the 8th day, and she left the hospital cured. She was re-admitted on the 15th of October with a relapse of fever (see charts 8 and 9).

Patient re-admitted on the 15th October, 1939. She had been afebrile for six days after the first attack.

No rash appeared.

CHART 8

CHART 9

We had only two cases of this type which were quite free from fever and other symptoms, for about six days. This may be due to the relapsing nature of this group of fevers, which is most often seen in typical dengue fever epidemics, or it may be due to the predisposition caused by early attacks of this fever during an epidemic. It seems certain that one attack does not give rise to any prolonged immunity, as it is a common experience that people may suffer from 'short fevers' repeatedly year after year.

### Conclusions

The febrile attack labelled seven-day fever, sand-fly fever, and pyrexia of unknown origin appear to be one and the same disease.

Although similarities may be detected in the course of fever, the condition is distinct from dengue, at least symptomatically, by less severe pain, less abrupt fall of temperature, and less marked relapses.

Relative bradycardia is not a constant feature of this condition.

Normal or slightly raised white blood count is more common than leucopenia.

The rash, primary or secondary (except in three cases) as commonly seen in dengue, was absent.

Lung complications and signs being absent, the condition could not be confused with influenza.

The actual cause of the disease is still unknown.

[The clinical description does not appear to exclude either dengue or sandfly fever as the diagnosis in these cases.—Eaton, I. M. (7)]

## DEMONSTRATION OF AN ALLERGEN IN FILARIASIS AND ITS UTILIZATION IN THERAPEUTICS

By R. K. GOYAL, M.B., D.Sc., Ph.D., M.R.C.P.

and

S. SUNDAR RAO

(From the Filariasis Inquiry under the I. R. F. A., School of Tropical Medicine, Calcutta)

ALTHOUGH it is now almost universally accepted that lymphangitis is in some way connected with infection with the filarial worms, *Wuchereria bancrofti* and *W. malayi*, the exact mechanism by which the exacerbations and remissions occur in these patients is by no means clear. Anderson and his colleagues (1924), as a result of careful and detailed investigation of this problem in British Guiana, came to the conclusion that 'infestation by *Filaria bancrofti*, per se, produces no symptoms; all the pathological manifestations associated with filariasis are due to secondary infection with pyogenic organisms'. This was the view held by previous workers. Wise and Minnett (1913) investigated several cases of abdominal filariasis in British Guiana in 1911 and reported the finding of streptococci in all these cases. The importance of streptococcal infections was dwelt upon by Rose (1915, 1919) and by Grace and Grace (1931). On the other hand, O'Connor and Hulse (1932) were of opinion that advanced pathological changes in filarial infection could be solely due to the parasites without the secondary bacterial infection. The work reported herein was carried out with a view to finding the rôle of bacteria in the causation of lymphangitis.

Fifty cases of filariasis in the out-patient department of the School of Tropical Medicine, mostly in the early stages of the infection, were examined for the presence of a secondary bacterial infection. The material was obtained with sterile precautions from the affected areas (glands, scrotum, leg) and cultured both aerobically and anaerobically. The results were entirely negative. Blood taken from febrile cases and cultured, similarly gave negative results. The superficial dermal lesions were not taken into consideration. In one case of a small superficial abscess in the leg, hæmolytic streptococci were isolated. The febrile attacks in these cases of filariasis thus appeared to be due, not to a bacterial factor but to the parasite alone. The periodic nature of attacks of lymphangitis suggests that these exacerbations are due to the presence of a toxin giving rise to allergic manifestations. In fact, Acton and Rao (1929, 1930) had drawn attention to the presence of a toxin in the uterine fluid of the gravid adult worm. It was therefore decided to investigate this question further. In view of the great difficulty of obtaining material from filarial cysts, the hydrocele fluid was used for investigating the presence of a toxin.

### Technique

Antisera were raised in rabbits by intraperitoneal injections at bi-weekly intervals of 10 to 30 c.cm. of hydrocele fluid containing microfilariae. Flocculation tests were put up with samples of hydrocele fluid against immune rabbit sera; the cerebro-spinal fluid was used as a control for the antigen. Serial dilutions of the immune serum were prepared in 0.25 per cent formol saline, equal amounts (0.25 c.cm. to 0.5 c.cm.) of hydrocele fluid were added and the mixtures incubated at 37°C. The reaction was visible in about 4 hours and took 48 to 72 hours to be completed. In the case of a weakly positive reaction a faint turbidity was perceptible, a granular precipitate was visible in a moderate reaction, and definite floccules were found in strongly positive cases.

In general, the low dilutions of the serum gave rise to flocculation and higher dilutions produced either a precipitate or a faint turbidity. The titre of the serum was low, i.e., 1/16 to 1/32 in cases receiving 6 to 7 injections, but the titre rose to 1/128 to 1/256 after 14 consecutive injections. Out of 152 cases examined 106 flocculated from 24 per cent to the full titre of the serum, whilst 46 cases gave positive reactions varying from 2 per cent to 12 per cent of the titre. The cerebro-spinal fluid obtained from cases of meningococcal meningitis flocculated up to 12 per cent of the titre. Flocculation up to 12 per cent of the titre was thus due to the formation of non-specific antibodies and was taken to mean absence of a specific antigen, positive results were considered to be obtained when the flocculation occurred from 24 per cent to the full titre of the serum.

The toxin content of the hydrocele fluid was determined at intervals of some weeks in a few cases, marked variations were noted in certain cases, the titre ranged from 1/32 to 1/128. The *dirofilaria* antigen failed to flocculate even with the undiluted anti-filaria sera, showing thus the antigenic dissimilarity of the two worms. The globulin fraction of the hydrocele fluid flocculated as well with the antiserum as with the whole antigen; this strongly suggested the association of the toxin with the globulin fraction of the hydrocele fluid. Fluids obtained from a case of lymph scrotum and from a blister on the leg of a case of lymphangitis gave positive flocculation reactions. Similar results were obtained with fluids aspirated from filarial cysts. The hydrocele fluid, diluted even in 1 in 4, had its activity markedly reduced, whereas the fluid from cysts, diluted even in 1 in 10, gave strongly positive reactions *in vitro*; this observation shows the maximal concentration of the toxin near the worm and one can conclude that the worm is the source of the toxin.

Heating the filaria antigen at 55°C. for one hour reduced its potency from 1/128 to 1/8. When 1/2 dilution of the antigen was exposed to 100°C. for 15 minutes, the potency was

markedly reduced. In view of the thermostability of the toxin, it should be stored at a low temperature.

The presence or absence of microfilariae did not affect the flocculation titre in any way. Quite a number of fluids free from microfilariae gave positive reactions with high dilutions of the serum. The amount of the antigen had also no close relationship with the clinical condition of the patient. Marked thickening of the scrotal skin was sometimes associated with a low toxin content of the hydrocele fluid.

The complement-fixation test also revealed the presence of the antibody in the immune rabbit serum. No antibody was demonstrable by the flocculation or complement-fixation tests in the sera of eight human beings suffering from filariasis.

The toxicity of the fluid for mice was determined; 5 c.cm. of a good flocculating antigen killed two mice in 48 hours, smaller doses had no effect. Mice which had received a smaller dose some days previously resisted the lethal dose of 5 c.cm.

An intradermal injection of 0.1 c.cm. of the hydrocele fluid into normal rabbits and guinea-pigs produced a negligible local reaction, but a well-defined papule was produced in immunized rabbits in early stages of immunization; they behaved like normal animals later on; this observation shows that the development of a state of hypersensitiveness is followed by immunity. Intradermal injections of  $L_3$ -candle filtrates of high flocculating hydrocele fluids produced a definite papule with flushing of the surrounding skin in normal persons and filarial cases. A 1/10 dilution did not produce any appreciable reaction in normal people, but a majority of early filarial cases gave a marked allergic reaction. The most marked reaction consisted of (a) marked local swelling with surrounding erythema attaining dimensions of 6 cm. by 10 cm., (b) a febrile reaction—the temperature rising to 100°F. or 101°F., and (c) definite exacerbation of the local lesion in the way of increase of swelling, pain and flushing. The reaction generally started 4 to 8 hours after the injection and lasted for 12 to 48 hours. After the subsidence of the symptoms, the patients noticed an amelioration in their condition. The observation was utilized in the treatment of cases. The early cases suffering from periodic febrile attacks and increase of swelling showed marked improvement in the majority of cases. Some of the early cases and chronic cases in general did not give any reaction but showed an improvement in their signs and symptoms.

### Treatment

Out of the 76 cases followed carefully, 20 were acute cases and 56 chronic cases. All the 20 acute cases were either cured for the time being or showed a marked improvement. Out of the 56 chronic cases, 51 decidedly improved and five were unaffected by treatment. These five were cases of either orchitis or hydrocele.

In view of the ease and frequency of reinfection, it is not possible to say if a curative agent of the early condition has been discovered, but a marked amelioration of the symptoms in early stages can be brought about in most of the patients by this treatment.

#### *Abstract of cases of special interest*

**Case 812/40.**—A Hindu girl, aged 18 years, admitted on 26th April, 1940, for elephantiasis, of both legs and left hand and forearm, of six years' duration with history of acute lymphangitis at irregular intervals of two weeks or a month or two affecting only one limb at a time, with marked general and local signs and symptoms. Patient was put on antigen treatment on 26th April, commencing with 0.2 c.cm. gradually increased to 2 c.cm. twice weekly; a total of 14.4 c.cm. was given. Patient reported after about three months that she has been free from lymphangitis since the treatment began and the swellings of the limbs considerably reduced with marked improvement in general health.

**Case 737/40.**—Hindu male, aged 59, medical practitioner, admitted on 12th April, 1940, for elephantiasis of the scrotum with history of acute lymphangitis every full moon and new moon during the first two years and at irregular intervals subsequently, temperature ranging from 104° to 105°F. each time with rigor, swelling, redness and pain in scrotum, the acute exacerbation lasting 48 to 72 hours. Filarial antigen treatment given—a total of six doses (6.7 c.cm.). Has remained free from acute symptoms for about three months and feels well.

**Case 230/40.**—Hindu male, aged 29, admitted for chyluria of five years' duration on 12th April, 1940. Chyluria has appeared and disappeared previously at intervals without treatment. Previous treatment for the condition with vaccines, soamin and antimony compounds has had no effect. Blood and chylous urine—positive for microfilariae. Filarial antigen treatment given from 12th April to 23rd July, total 44.2 c.cm. Result—Urine cleared after 1.7 c.cm. of antigen treatment and remained so for 25 days. Relapse. Result of subsequent treatment has been indifferent.

**Case 822/40.**—Hindu male, aged 24, admitted on 26th April, 1940, for epididymo-orchitis and hydrocele (R); two years' duration; hydrocele tapped on 26th April. Filarial antigen treatment given (total 14.5 c.cm.). Hydrocele has not filled up again and patient feels better generally.

**Case 261/40.**—Hindu male, aged 29, admitted on 9th February, 1940, for elephantiasis of the right leg of 14 years' duration. Acute lymphangitis off and on, the temperature often rising to 106°F. with shivering, headache, pain all over the body and extreme thirst, such attacks recurring sometimes once a week, or once in three or six months. Filarial antigen treatment given since 9th February. Total amount given up to 23rd July—41.2 c.cm. Patient has been gradually improving in health, free from fever and the leg reduced to half the original size.

**Case 655/39.**—Mohammedan male, aged 30, admitted into the Carmichael Hospital for Tropical Diseases on 20th July, 1939, for urticaria of three years' duration. He was suffering from filarial lymphangitis of the scrotum and hydrocele. The urticarial eruptions appeared at intervals to begin with, and latterly were more severe and appeared daily. Other investigation, having proved negative, the patient was referred to us for filarial investigation and treatment. Test for filarial allergy—strongly positive; flocculation test with hydrocele fluid—moderately positive. Patient was treated with filarial antigen and the urticarial attacks ceased altogether.

## OPHTHALMOPLEGIA IN PERIOSTITIS OF THE SPHENOIDAL FISSURE

By P. K. GUHA, M.B., M.R.C.S. (Eng.), D.O.M.S. (Lond.)  
Honorary Associate Ophthalmic Surgeon, Campbell  
Hospital, Calcutta

and

S. C. CHATTERJEE, M.B., M.R.C.P. (Lond.)  
Calcutta

THE involvement of nerves during their course through bony canals due to the inflammation of the periosteal lining is well exemplified by Bell's (facial) palsy. What actually happens is a pressure effect by swollen periosteum and the inflammatory exudate, and thus a temporary interference with their function. That there is no permanent damage is proved by the complete recovery of function sooner or later in all such cases. A group of symptoms that may arise as a result of almost similar periostitis of the sphenoidal fissure and the resulting pressure involvement of the nerves passing through the fissure has been lately realized and such cases have been brought to light, occasionally. But on a search into the available English literature\* on the subject we failed to find reports of any such cases within the last few years. The pathology of the condition closely simulates that of Bell's palsy, as far as the mechanism of the nerve involvement is concerned.

To understand the clinical syndrome of these cases, a short description of the anatomy of the sphenoidal fissure will be of assistance.

#### *Anatomy*

The sphenoidal (superior orbital) fissure lies between the roof and the lateral wall of the orbit. The fissure is composed of a narrow outer limb and a wider medial limb. The outer limb is closed by dura mater and nothing passes through it. All the structures pass through the wider medial limb. The structures passing through the medial part are related to the annulus of Zinn. Above the annulus pass the lacrymal, frontal and the trochlear nerves, the superior ophthalmic vein and the recurrent lacrymal

\*The condition is described in Price's *Textbook of the Practice of Medicine*.—EDITOR, I. M. G.

artery. Passing within the annulus are the superior division of the oculomotor nerve, the nasociliary and the sympathetic root of the ciliary ganglion, the inferior division of the oculomotor and the abducens, and sometimes the inferior ophthalmic vein, in this order from above downwards. The abducens nerve passes from below the inferior division of the third to lie lateral to and between the two divisions. Below the annulus, nothing passes as a rule; rarely the inferior ophthalmic vein takes this course.

(From 'The Anatomy of the Eye and the Orbit'—Eugene Wolff.)

### *Ætiology and symptomatology*

Periostitis of the sphenoidal fissure forms a part of orbital periostitis. It occurs in all ages from puberty onwards. The periostitis may result as an extension of infection from the nose and the accessory sinuses. Syphilis also may be a contributory factor. Besides these cases there occurs a group of cases, in which no definite ætiological factor can be ascertained. They are usually thought to be due to rheumatic infection. It may be pointed out that gummatus affections of the orbit are extremely rare. The incidence is from 1 per cent to 2 per cent of all cases of syphilis of the eye and 0.013 per cent of all diseases of the eye as opposed to the so-called rheumatic group of cases which is gradually being found to be comparatively more common.

The chief feature of this condition is interference with the function of the structures passing through the sphenoidal fissure. The structures mainly involved are the nerves passing through the fissure. The onset is usually sudden, with pain and slight proptosis and there is slight tenderness on pressing the globe backwards. These signs are soon followed by involvement of the ocular nerves, the sixth nerve

is usually affected first; gradually the fourth nerve, the first division of the fifth, the third and the second divisions of the fifth nerves are involved in the order mentioned. The patient may complain of diplopia to start with. In a fully developed case, there is complete ptosis, with slight proptosis. The pupil is dilated and light reflex is either absent or sluggish. The eyeball is practically immobile owing to ophthalmoplegia. In spite of ocular palsy the patient at this stage does not complain of diplopia because of ptosis. There is some degree of anæsthesia in the distribution of the ophthalmic division of the trigeminal nerve, i.e., on the forehead of the affected side. The condition usually subsides within a period of six to eight weeks. In some cases it may be prolonged for a few months. Complete recovery is usually the rule.

Before a case is diagnosed as sphenoidal periostitis one should exclude the possibility of orbital tumours and metastatic carcinoma of the orbit, and a skiagram of the orbit and the accessory sinuses should be taken as a routine procedure, for the sake of completeness of investigation.

Treatment is chiefly symptomatic. Local application of warmth, mercury and salicylates orally, and analgesics for pain may be given. In cases where spirochætal infection is the ætiological factor, antisyphilitic treatment should be advised. To start with, mercury and iodides are given orally, followed by arsenic and bismuth injections.

### *Illustrative case*

A middle-aged male complained of pain in the right eye, headache, a sensation of fullness and throbbing inside the right eye. The onset of this group of symptoms was fairly sudden. About two or three days before these complaints, he had occasionally double vision on looking to the right. When first seen, he had slight proptosis and paresis of the right external rectus, the right pupil was comparatively larger and showed a less brisk light reflex compared to that of the left side. When next seen about a week later, he showed complete ptosis, all the muscles of the eyeball were paralysed, the eyeball remaining practically immobile, the pupil was dilated and light reflex absent. The eyeball was tender. There was slight anæsthesia over the right side of the forehead. The vision in the right eye was 5/6 partial with approximate glasses and the fundus oculi was normal.

There was nothing noteworthy in the past history. The general development of the patient was fair. Blood pressure was S/D = 140/100 mm. of Hg. Urine showed no abnormality. Blood sugar was 100 mgm. per 100 c.c.m. of whole blood. Hæmoglobin was 80 per cent, red blood cells—4,160,000 per c.c.m., white blood cells—5,600 per c.c.m., polymorphonuclears—70 per cent, lymphocytes—23 per cent, large mononuclears—1 per cent, eosinophils—6 per cent. Coagulation time—three minutes.

Wassermann reaction of the blood was strongly positive. Radiology of the skull and the orbit and sinuses revealed no abnormality.

The patient was advised local application of warmth, rest to the eyes, and was given iodides and salicylates and later on iodides and mercury orally. The eye condition returned to normal within a period of eight weeks. He was given a course of arsenic and bismuth later on.

## HEALTH CONDITIONS AND HEALTH WORK IN A FAMINE AREA

By C. M. NICOL, M.A., M.D., D.P.H.

LIEUTENANT-COLONEL, I.M.S.

Director of Public Health, Punjab

IN 1939, as in the preceding year, rainfall was lower than normal in the Punjab, and in certain areas of Hissar, Rohtak, and Gurgaon districts rains failed entirely.

Hissar district has suffered from famine repeatedly during the past 50 years or more, but within living memory famine has never been so intense or so prolonged as it has been during the latest visitation.

Scarcity of food was being felt in Hissar by the middle of 1938, and famine was officially declared in December of that year; in Rohtak and Gurgaon districts, test works were established in December 1938 and February 1939, respectively.

An idea of the extent to which these districts were affected may be gathered from the number of individuals who were attending relief works

(Continued from previous page)

This case presents all the typical features of sphenoidal periostitis. The negative radiological evidence, rapid onset and complete clearing of all symptoms definitely exclude the possibility of any tumour in the orbit, either primary or metastatic. Williamson-Noble (1926) brought to notice a rare group of cases, diagnosed as 'inflammatory pseudo-tumour' of the orbital tissue causing 'proptosis, limitation of movements, increase in bulk of the orbital tissue and possibly swelling of the orbit'. Actual palsy of the oculomotor nerves has not been mentioned. The onset of this condition is very slow. The reported case does not seem to belong to this group. It is very difficult to state whether the case is one of so-called 'rheumatic' or of syphilitic infection. The condition improved completely within eight weeks with iodides and mercury orally, which may be taken as a therapeutic test for syphilitic infection. But the usual course of such periostitis in the rheumatic group of cases is about eight to ten weeks. The positive Wassermann reaction therefore may be a matter of coincidence, the case belonging to the so-called 'rheumatic' group of cases and syphilis may not be the actual ætiological factor.

### Summary

(1) A case of sphenoidal periostitis with ophthalmoplegia is reported.

(2) The case illustrates all the classical features of the condition.

(3) The ætiology and the symptomatology have been discussed.

### The earlier effects of famine

In February 1939, the diets and state of nutrition of 90 families in the famine areas, consisting of 529 individuals, were investigated by Dr. M. M. Khan, nutrition officer, Punjab public health department. The figures relating to diets and state of nutrition quoted below are taken from data collected by him.

The families were classified as follows :—

(1) Those whose members were engaged on relief works, lived in their villages, and came daily to work;

(2) Workers who had come from a distance and had arranged accommodation for themselves near the works; and

(3) Villagers not engaged on relief works.

Table I shows the average daily diet of 30 families in each of these three groups.

Table II gives the approximate nutritive values of the average diets detailed in table I.

The calorie values of the diets may be regarded as satisfactory, taking into consideration the comparatively light character of the manual labour on which the workers were engaged.

The most striking feature of the diets is their qualitative defects. Animal fat in any shape or form is either absent or present in negligible amount. Milk also is either absent or present in very small amount, and then only as skimmed milk. Green vegetables are entirely absent. The comparative absence from the diets of milk, ghee and vegetables means that the diets are very low in vitamin content: vitamin 'A' is present in quite inadequate quantity and vitamins 'C' and 'D' are absent altogether. Of the mineral salts calcium is very definitely deficient. Animal protein also is present in very small amount.

In short, the diets if adequate in quantity are extremely ill-balanced and contain a preponderance of carbohydrate material.

The state of nutrition of 279 workers and 144 non-workers, living on the diets detailed in table I, was estimated by physical examination: 82 per cent of the former were considered definitely subnormal physically and 50 per cent of the latter. The relatively better physical condition of non-workers appears significant: these individuals were not only consuming more milk and ghee than the workers, but also were exerting themselves to a much lesser extent.

Of 423 persons examined, 6 per cent complained of night-blindness, 25 per cent showed

TABLE I  
Average daily diet of families

Class of individuals	Number of families	Number of individuals	FOODSTUFFS EATEN									NUMBER OF FAMILIES HAVING				
			Cereals	Pulses	Vegetables	Fat	Skimmed milk	Sugar	Condi-ments		Milk		Green vegetables	Ghee or other animal fat		
									Salt	Chillies	Number	Average amount daily.		Number	Average amount daily.	
1. Relief workers living in their villages.	30	188	876	31	2	N	66	..	17	2	8	240	0	1	2	
2. Non-relief workers living in their villages.	30	190	782	79	18	2	256	..	19	3	18	432	0	5	13	
3. Workers from a distance living at the works.	30	151	799	12	7	..	..	..	10	5	0	..	0	0	..	

The quantities of foodstuffs are stated in grammes per adult male consumption unit.

The outstanding characteristic of these diets is the complete absence of green vegetables, the complete absence of animal fat in group 3 and the negligible (N) quantity of animal fat partaken of in the other two groups. Milk is also absent in group 3 diets and very small amounts of milk are included in the diets of the other two groups.

The 'average' daily diet was estimated as follows:—

The quantities of foodstuffs consumed by each family per day were accurately weighed and recorded before cooking, on two successive days. The total of these quantities divided by 60 gives the average diet per family per day in each group.

TABLE II  
Nutritive values of diets

Class of individuals	Number of families	Number of individuals	Total calories	PROTEIN		FAT		Carbo- hydrate	MINERAL SALTS			VITAMINS		
				Total	Of animal origin	Total	Of animal origin		Calcium	Phosphorus	Iron	(In inter- national units)		
												'A'	'B'	'C'
1. Relief workers living in their villages.	30	188	3,243	99	2	22	..	656	0.4	2.5	48	1,217	1,128	..
2. Non-relief workers ..	30	190	3,142	117	10	22	2	606	0.8	2.8	49	1,436	1,424	..
3. Labourers from a distance living at the works.	30	151	2,854	93	..	18	..	575	0.4	2.5	47	1,098	1,509	..
Minimum requirements for an adult male.	..	..	2,800 to 3,000	100	20	45 to 60	22 to 30	500	0.6	1.0	30	3,000	300	30

Quantities of protein, fat, carbohydrate and salts are stated in grammes. Iron and vitamin C are in milligrammes.

the dry roughened condition of the skin described as phrynodema, and 65 per cent smokiness of the sclera—signs of vitamin-A deficiency: 1 per cent showed signs of active rickets and 6 per cent of old-standing rickets, indicating vitamin-D deficiency.

These were the findings, notwithstanding the fact that a scale of relief pay higher than that authorized by the Punjab Famine Code had been introduced. It seemed clear that there was a danger of food deficiency conditions developing in more acute form and in increasing

numbers, and also that other diseases might be expected to prove much more serious in a community in which vitality had been lowered by qualitative and quantitative food shortage.

Arrangements were made for fresh vegetables to be made available to relief workers to as great an extent as limited supplies made possible, and individuals reporting sick at dispensaries with definite signs of A and D vitamin deficiency were treated with cod-liver oil.

Intensive general measures of hygiene were maintained including chlorination of water-supplies, the sanitation of camp areas and lines of work, the protection of 194,539 individuals against cholera by anti-cholera inoculation, and systematic vaccination throughout the district: 246,500 vaccinations were carried out.

#### *The later effects of food scarcity*

With the onset of the cold weather greater physiological demands on the famine-stricken population became inevitable, and during the closing months of the year 1939, a rather rapid deterioration in health conditions occurred. Investigations during December showed that, compared with the findings of February, the population as a whole looked more poorly fed, the minor effects of qualitative food deficiency were much more readily detectable, fully developed acute deficiency disease (scurvy) had made its appearance, and many individuals in the areas worst affected by the famine were suffering from frank starvation of varying degrees. This decline in health was much more marked among those remaining in their villages than amongst workers at relief works.

#### *Preventive and curative measures—germinated grain as a prophylactic against scurvy*

In devising means to meet the worsened health conditions it was recognized that the problem was to a large extent physiological. Other facts being constant, food requirements are proportionate to energy expended and in cold weather relatively more food is required to maintain body temperature. These fundamental principles had to be taken into consideration in the first instance. The task of workers was therefore reduced by 50 per cent from the end of January 1940, and new works were organized so that villagers did not have to walk long distances to and from their work. Weakly individuals were relieved of work altogether. In addition, the health organization, both curative and preventive, in rural areas was rearranged and expanded. The district was divided into a series of 50 health circles, each in charge of a medical officer, a circle including the villages within 5 miles of a central dispensary. Special treatment centres were established to which the acutely ill, whose condition allowed of their being moved short distances, were evacuated for care and treatment, and arrangements were

made for the regular visiting of sick in villages by the medical officers of dispensaries and treatment centres, who were required to tour regularly in their circles and make systematic search for sick people.

The most important specific preventive measures adopted to check the development of deficiency disease were the introduction of germinated grain as a prophylactic against scurvy, and of the Indian gooseberry (*amla*) for the treatment of that disease. The *amla* was advocated by Dr. W. R. Aykroyd, Nutrition Research Laboratories, Coonoor, following the work of K. V. Giri (1939) on Indian gooseberries (*Phyllanthus emblica* Linn.) as a source of vitamin C.

During the latter part of December 1939 and January 1940, specific measures were limited to the treatment of developed cases of deficiency disease. It was found that scurvy in the most acute form and advanced degree responded rapidly to treatment with *amla* juice.

It was not until the first week of February 1940 that regular issues of germinated grain to all labour on relief works were commenced. The free issue consisted of half a *chhatak* (1 ounce) of germinated wheat, millet, or gram twice a week, and in many villages the inhabitants were persuaded to prepare this prophylactic for themselves. By the middle of February more than 200,000 individuals were taking this protective food regularly.

From 27th May women and children ceased to attend relief works except once a week to receive their gratuitous relief pay, and on that occasion were given one *chhatak* of germinated grain each.

Germinated grain has much to commend it as a preventive against food deficiency conditions. Grain in some shape or form is available everywhere, and the procedure for producing germination is simple. The people are already familiar with grain in this form, as it is partaken of at certain festivals, and it does not offend religious susceptibilities. It contains vitamins A and B, and particularly C in abundance, and small quantities added to an otherwise defective diet make good what is lacking.

#### *Results of preventive measures*

The famine began in 1938 and its general effect on health may perhaps be gauged more accurately from a consideration of mortality figures than by any other means:—

Number of deaths in Hissar district			
1937	..	..	20,910
1938	..	..	28,505
1939	..	..	37,767

If mortality figures for the first six months of the years 1937 to 1940 be compared, an

approximate idea may be obtained of the results of the curative and preventive measures applied :—

	Deaths			
	1937	1938	1939	1940
January ..	1,746	2,052	3,885	2,299
February ..	1,619	1,587	3,193	1,918
March ..	1,607	1,961	3,036	2,177
April ..	1,783	2,564	3,096	2,643
May ..	2,101	4,225	4,101	3,290
June ..	2,168	3,730	4,026	2,982
TOTAL ..	11,027	16,119	21,337	15,309

That there should be a reduction, compared with the previous year, of over 6,000 in the number of deaths in the first six months of what was really the third year of continued famine is significant. Not only had the downward trend been arrested but a definite positive improvement had been effected.

A consideration of the actual number of cases of sickness admitted to hospitals, dispensaries, and treatment centres, and the number of cases attending as out-patients at dispensaries, may indicate the extent to which specific measures against deficiency disease were effective.

*Morbidity in Hissar district—December 1939 to June 1940*

	Total sick admitted to hospitals and dispensaries	Cases of scurvy admitted (new cases)	Cases of night-blindness out-patients attending (new cases)
December 1939 ..	523	67	1,412
January 1940 ..	696	80	746
February " ..	421	60	1,282
March " ..	452	9	1,167
April " ..	446	..	883
May " ..	354	..	895
June " ..	332	..	1,007

The general decline in sickness of such a severity as to warrant admission of the individual to hospital, dispensary or treatment centre is marked.

The dramatic disappearance of scurvy after the introduction of germinated grain in the first week of February is very striking. From January 1940 onwards, villages were systematically combed for cases of this disease.

A reduction in the number of cases of night-blindness attending as out-patients occurred, but the fact that so many cases were still reporting sick during the month of May and that there was an actual increase in June, indicates that germinated grain, as might be expected, was not in the same degree a preventive of this condition as of scurvy.

There were on an average 35 cases of malnutrition, other than night-blindness and scurvy, being admitted to hospitals and dispensaries every month during the first six months of 1940. A consideration of these cases, together with the persistence of night-blindness, suggests that the

almost entire absence of animal fat from diets was making itself very definitely felt. The fact that tuberculosis and other infections began to appear more frequently as causes of death during this period points in the same direction, but it cannot be definitely stated that there was an increase in these diseases owing to the fact that from January 1940 diagnoses were more accurate than they had been during the corresponding period of 1939, when the majority of sick people were not seen by a doctor and many cases of these diseases were almost certainly missed.

During the first six months of 1939, there were 481 deaths from smallpox in Hissar district. During the corresponding period of 1940, the number had fallen to 79. A total of 184,921 vaccinations were performed between November 1939 and the end of June 1940. The vaccination campaign was just as vigorously carried on during 1938-39, but the reporting of cases was very defective at that time: in 1940 the fact that villages were being regularly visited by medical officers resulted in cases coming to light immediately on their occurrence, and preventive measures could consequently be much more quickly and effectively applied.

In the spring of 1940, for the second year in succession, mass anti-cholera inoculation was carried out amongst workers: by the end of June 193,874 anti-cholera inoculations had been given. Cholera was absent from the district in 1939 and had not appeared up to the end of July 1940.

From the foregoing, I think one is justified in believing that the major epidemic and deficiency diseases were brought under control, and that the specific preventive measures introduced were not ineffective. Lesser degrees of malnutrition were, however, still prevalent at the end of June 1940, resistance to disease in general was apparently low, and health conditions extremely unstable.

Throughout 1939 the effect of the famine on the mentality of the people was very noticeable: there was an air of depression throughout the community and many seemed completely indifferent to what happened to them. The lifting of this depression was one of the most striking results of the expansion and extension of health measures.

*Famine conditions and mortality*

Innumerable statements regarding death rates in the famine areas have been published, many of them grossly exaggerated and most of them misleading. A few figures may serve to bring mortality in Hissar into proper perspective.

*Deaths in Hissar district*

Average annual number of deaths, 1934-38	Actual deaths, 1939
24,794	37,767

*Deaths in the young and old in Hissar district*

	AVERAGE NUMBER	ACTUAL NUMBER		
	1934-38	1937	1938	1939
Under 10 years	11,044	11,764	16,854	21,160
60 years and upwards.	2,372	2,779	3,973	6,836

It will be observed that the brunt of the famine fell on the young and the old. 74.1 per cent of the total deaths occurred in individuals under 10 and over 60 years of age. For every 100 males who die, 114 deaths occurred amongst females, as compared with an average of 107 during the preceding five years.

*Causes of death*

Of the 37,767 deaths, no fewer than 30,522 were registered as due simply to 'fevers'. Smallpox was given as the cause of 480 deaths, diarrhoea and dysentery of 627, enteric fever of 854, tuberculosis of 567, and pneumonia of 1,172.

Compared with the average for the years 1934-38 the number of deaths from pneumonia and other respiratory diseases was more than doubled during 1939, and dysentery accounted for nearly twice as many. As compared with the figures for 1934-38 nearly 12,000 more individuals died from 'fevers'.

Cholera and plague were absent from the district. Deaths from smallpox occurred during the early months of the year, but by the month of May the disease had been brought under control and did not appear again as a significant cause of death throughout the remainder of the year.

A contributory cause of the increased death rate was the fact that numbers of families, particularly Rajputs—both Hindu and Muslim—considered it beneath their dignity to accept Government relief which they regarded as 'charity', or to bring themselves or their women folk to associate with what they were pleased to regard as 'coolie labour' on relief works.

It is of interest to compare the 1939 mortality figures for Hissar district with those for 1900, which was a year of famine in some degree comparable in severity to that of 1930.

	Actual number of deaths	Death rate	DEATHS FROM PARTICULAR DISEASES		
			Cholera	Dysentery	'Fevers'
1900 ..	74,798	96.4	6,399	2,823	54,324
1939 ..	37,767	42.0	Nil	638	30,522

These figures may be regarded not only as evidence of the greater effectiveness of famine relief measures, but also of the greater control

over disease in general, which has been developed since the beginning of the present century.

Very few of the 37,767 individuals who died during 1939 were seen by a doctor during their final illness (there were only 201 deaths in hospitals and dispensaries), since most of them occurred in villages in which there are no doctors, and not until the end of the year were arrangements made for doctors to tour in rural areas. Careful inquiry has elicited information regarding the character of the last illness in certain areas, particularly in families in which several members died, and in which the survivors were found to be suffering from acute scurvy. The survivors were most emphatic in maintaining that their relatives who had died had the same complaints and showed the same outward signs of illness as themselves.

It is probable that many of the deaths recorded as due to 'fevers' were really caused by starvation and deficiency disease, and that many of the pneumonias and dysenteries were merely terminal illnesses in individuals primarily suffering from malnutrition.

*Morbidity*

Reliable information regarding the character of the illness from which people suffered can be obtained only from the records of hospitals and dispensaries in which diagnoses are made by qualified medical practitioners. The number treated at such institutions rose from 440,582 in 1937 to 479,182 in 1938 and 557,916 in 1939. The majority of these individuals were out-patients, only 8,328 in-patients being treated during the year 1939.

If we may regard the approximate half million of patients who attend at or are admitted to hospitals and dispensaries in a year, as a representative sample of the sick population throughout the district, then certain tentative deductions may be made regarding morbidity. Table III gives the chief causes of illness in patients of this class. The figures are from the official records of the inspector-general of civil hospitals.

The illnesses from which by far the larger proportion of patients suffered remained practically the same over the three-year period. The increase in number in the larger groups (numbering 10,000 or more) is progressive, and the rate of increase fairly uniform, the only notable exception being in the case of malaria.

In these larger groups the striking increase in diarrhoea and dysentery in 1939 is noteworthy. An interesting point is that these larger groups, which include by far the majority of sick people who sought treatment, do not include the specific food deficiency diseases, or illnesses such as tuberculosis which are known to tend to increase as a result of malnutrition. The increase in these larger groups might be regarded as indicating the occult effect of malnutrition in lowering resistance to disease in general, and to prevalent infections, such as dysentery, in particular.

TABLE III

*Chief causes of illness in patients treated at hospitals and dispensaries in Hissar district, 1937-39*

	1937	1938	1939
Eye diseases (excluding trachoma, glaucoma and cataract).	63,951	70,914	83,659
Respiratory diseases (excluding pneumonia and pulmonary tuberculosis).	25,178	32,357	41,117
Malaria .. ..	34,553	27,301	35,537
Trachoma .. ..	21,031	22,911	26,550
Diseases of the digestive system (excluding diarrhoea, dysentery and tumours).	19,398	21,136	25,996
Injuries .. ..	21,847	23,926	25,331
Diseases of teeth and gums (excluding tumours).	15,985	18,526	20,188
Diarrhoea and dysentery ..	10,268	11,936	19,907
Diseases of the intestines (excluding diarrhoea, dysentery and tumours).	13,254	15,425	19,186
Diseases of the stomach (excluding tumours).	10,491	12,322	16,309
Diseases of the nervous system.	11,048	12,963	14,358
Diseases due to deficiency or to disorders of nutrition or metabolism (excluding osteomalacia, rickets and scurvy).	568	545	9,160
Pyrexia of uncertain origin and other diseases due to infection.	2,925	3,922	5,216
Diseases of the blood and spleen.	1,692	1,588	2,117
Pneumonia .. ..	1,409	1,707	1,942
Tuberculosis of lungs .. ..	696	652	973
Tuberculosis (non-pulmonary)	762	724	912
Enteric fever .. ..	282	272	539
Rickets .. ..	160	123	208
Scurvy .. ..	52	4	116
Osteomalacia .. ..	40	77	75

When we come to consider the disease groups or individual diseases in which the numbers are relatively smaller (under 10,000) the points of interest are the increase in pyrexia of uncertain origin and other diseases due to infection, pneumonia, and diseases of the blood and spleen, and the enormous increase in 1939 in unspecified disorders of nutrition or metabolism. Compared with the latter the specific deficiency diseases are small in number.

The progressive increase in tuberculosis, both pulmonary and non-pulmonary, and the increase in enteric fever in 1939 are striking.

#### *Summary and suggestions*

Even when adequate relief in the form of relief pay is provided, the ill effects of famine are likely to be felt acutely and at an early stage, if individuals be left to themselves to procure their food from stocks available locally.

Under such conditions a progressive deterioration in health is to be expected and this may be hastened by conditions which make increased demands on energy.

Fully-developed deficiency disease such as scurvy may be a later feature of deterioration in the health of the community, but prior to its appearance death rates from other causes are likely to have increased greatly. The young and the old are likely to suffer most severely from famine, and women more than men.

The approach to famine relief work should be along physiological lines. In the past the primary and main objective has been to provide the individual with means for obtaining a certain quantity of food. This alone is likely to be to a great extent ineffective in maintaining health: arrangements should be made for the individual to procure food of the right kind; money spent will be largely wasted if a sufficiency of the protective foods—particularly fresh green vegetables and animal fat of some kind—be not made available.

Even the quantity of food required will depend on energy expenditure. An individual can get along on remarkably little if he be simply sitting about at home. His requirements are vastly increased if he has to perform manual labour all day and walk 5 to 10 miles to and from his work. The ideal would be the elimination of relief works altogether, but as this does not appear to be feasible for administrative reasons, the task prescribed should be nominal and the place of work within easy reach.

In the Punjab, the relief allowance for growing children and adolescents is a quarter and a half, respectively, of an adult allowance, yet the physiological needs of these two groups are relatively greater than those of adults, if growth and development are to be maintained at a normal rate and deficiency disease kept at bay. The same applies to child-bearing women and nursing mothers. Scales of wages and allowances should be arranged accordingly, and the allowances for a family should be calculated on the number of adult male consumption units composing the family.

In arranging for the maintenance of animals in a famine area, due regard should be paid to conserving the milk supply. Present practice in the Punjab is for the villager to retain a pair of ploughing bullocks and one milk animal, and Government supplies fodder for these. Other milk animals have to be sold or sent to a cattle concentration camp. At these camps many cows and buffaloes bear calves and become milk producing. The preservation of the existing milk supply would appear to be the only practicable method of making animal fat available to a large famine-stricken population, quite apart from its food value in other respects. It seems reasonable to suggest that the maintenance of milk animals in villages should be a first consideration in planning famine relief. The supply of fodder by Government could be made conditional on an equitable distribution of milk

# FURTHER NOTES ON THE APPLICABILITY OF THE VITAMIN-C TEST OF URINE IN ESTIMATING HORMONAL VARIATIONS IN THE SYSTEM

By A. P. PILLAY, O.B.E., M.B., B.S.

Whitcaway Building, Bombay 1

In the paper (Pillay, 1940) I answered in the affirmative the question—Does the quantitative estimation of vitamin C in the urine help to decide the day of ovulation? The following additional interesting findings based on the same test have since been observed by me:—

GRAPH 1

After 300 mgm. of Redoxon for each test.

the affirmative the question—Does the quantitative estimation of vitamin C in the urine help to decide the day of ovulation? The following additional interesting findings based on the same test have since been observed by me:—

(i) During the luteal phase of the menstrual cycle, the excretion of vitamin C in the urine is higher than during the follicular phase. Graph 1 illustrates this point.

(Continued from previous page)

throughout a village community (in accordance with the needs of individual families. Even from the limited view-point of economy, in a famine area it does not seem sound practice drastically to reduce supplies of the most important of all articles of diet and one which the community is producing within itself.

The conservation of existing food supplies in the area and arrangements for individuals obtaining a sufficient quantity of food of the right kind constitute the first line of defence against the effects of famine. Even when this has been achieved, the occult influence of minor degrees of malnutrition, both qualitative and quantitative, in lowering resistance to disease, is likely to make itself felt. Every means of guarding against infections should therefore be systematically applied—general environmental sanitation including chlorination of water-supplies, specific measures directed against individual diseases (vaccination, anti-cholera and anti-typhoid inoculation) and, should circumstances require, the issue of prophylactics calculated to ward off specific food deficiency disease.

Germinated grain is an effective preventive of scurvy when given in quantities of 1 ounce (dry grain) per head twice a week.

## REFERENCE

Giri, K. V. (1939). *Indian Journ. Med. Res.*, Vol. XXVII, p. 429.

(ii) There is vast difference in the amount of vitamin C excreted in the urine when progesterone and oestrin are administered, large quantities being excreted during progesterone administration and smaller quantities during oestrin administration. Graphs 2 and 3 illustrate this conclusion. Graph 2 is that of a case of severe secondary amenorrhoea and graph 3 that of a case of virilism.

GRAPH 2

After 200 mgm. of Redoxon for each test.

GRAPH 3

After 300 mgm. of Redoxon for each test.

These findings make it legitimate to conclude that the estimation of vitamin C in the urine forms a method of gauging the amount of progesterone and oestrin present in the system.

At this stage of the investigation it will be rash to attempt to explain how and why this is so. The following possible explanations, among others, are offered. When progesterone is present in excess in the system, as during the luteal phase of menstruation or when it is administered, the body requires or retains only small quantities of vitamin C. When progesterone is absent or deficient, as during the follicular phase of menstruation or when oestrin is administered, the system requires or retains large quantities of vitamin C. It might also be that progesterone takes the place of vitamin C or otherwise acts as a tonic on the system and dispenses with the necessity for large quantities of

this essential vitamin. That the same variation in the excretion of vitamin C is seen in the male also during the administration of progesterone and œstrin lends colour to this (graph 4).

GRAPH 4. MALE

After 200 mgm. of Redoxon for each test.

The horizontal lines in the graphs indicate the days of the menstrual cycle, unless otherwise stated. The hormones were administered in all cases by injection. O stands for ovulation, O.C. for Ovocyclin (Ciba), L.C. for Luto-cyclin (Ciba).

If progesterone acts on the system as a tonic, the interesting question arises as to whether any other hormones act likewise and have similar effects on the vitamin-C excretion. Graph 5 is that of an elderly, æsthenic male during administration of adrenal cortex hormone (Percorten, Ciba) and testicular hormone (Perandren, Ciba). The æsthenia steadily improved when the system was 'soaked' with these hormones and concurrently the vitamin-C excretion in the urine increased.

GRAPH 5. MALE

After 100 mgm. of Redoxon for each test.

What causes the decolorization of the dye solution is also difficult to dogmatize on. If it is not due to vitamin C itself, it may be that

progesterone (or its excretion product, pregnandiol) decolorizes the dye solution or it liberates some other, as yet unrecognized, substance in the urine which causes the decolorization.

Whatever may be the explanation, the tests with vitamin C have many practical applications, such as estimating the deficiency of either of the ovarian hormones, their doses for therapeutic purposes, the time required to produce the maximal effect with them and so on.

(iii) According to Wilson, Randall and Osterberg (1939) large amounts of pregnandiol in the urine of a regularly menstruating woman immediately after she misses a period is indicative of pregnancy. Based on my findings, this means that the vitamin-C excretion in the urine should be consistently high in cases of early pregnancy. Estimation of vitamin-C excretion in urine is therefore a test for diagnosis of early pregnancy. Graph 6 illustrates this conclusion.

GRAPH 6

After 300 mgm. of Redoxon for each test.

There were a few atypical cases in my series, with low excretion of vitamin C during the luteal phase, but these only indicate a deficiency of progesterone in the luteal phase and not a fallacy in my conclusions. I consider the atypical cases lend support to my contention that the vitamin-C test gives the measure of the deficiency of progesterone in the system.

The results of my experiments on the practical application of the vitamin-C test in diagnosis and treatment of conditions such as amenorrhœa and sterility due to normal defects will be published in due course.

#### The vitamin-C test

The test is done as follows: The woman is given orally 300 mg. of vitamin C (Redoxon, Roche) three to six hours before the test. One tablet of dichlorophenol-indophenol (Roche) is dissolved in 50 c.cm. of water. Five c.cm. of the solution is pipetted into a beaker. Freshly voided urine is titrated quickly into this solution from a burette and the quantity required to decolorize immediately the blue of this solution gives the quantity of vitamin C present in the sample of urine. The test should be completed within two minutes after the urine is passed.

In my earlier experiments I used to give 300 mgm. of Redoxon before every test. Now I give this dose only before the first test to estimate the actual deficiency of vitamin C in the system. The dosage for the further tests is

## GASTRIC ACIDITY IN CHOLERA

By C. L. PASRICHA

MAJOR, I.M.S.

Professor of Bacteriology and Pathology

K. S. MALIK, M.Sc.

and

S. K. GHOSH, B.Sc.

*(From the Cholera Bacteriological Inquiry, Indian Research Fund Association, School of Tropical Medicine, Calcutta)*

As vomiting is one of the prominent symptoms of cholera it was thought desirable to determine

*(Continued from previous page)*

decided for each case after noting the amount of initial deficiency. 150 to 200 mgm. are found to be sufficient for the follow-up tests in most cases, provided the initial vitamin-C deficiency is corrected. Unsurcharged urine is apt to give fallacious results as its vitamin content is liable to be affected by variations in diet and other factors. With urine highly surcharged with vitamin C, the daily variations of its excretion may often be so small as to be overlooked if very careful observations are not made.

In the graphs published with my first paper, the vertical lines indicated the quantity of urine in c.cm. required to decolorize 5 c.cm. of the dye solution, while in the graphs given here, the vertical lines indicate the vitamin-C content of the urine in mgm. per cent. This is arrived at by dividing 10 by the quantity in c.cm. of the urine required to decolorize 5 c.cm. of the dye solution, which is equivalent to 0.1 mgm. of l-ascorbic acid.

*Summary*

Estimation of vitamin C in the urine helps in deciding

- the day of ovulation,
- the type of the cycle, whether anovulatory, uniovulatory or multiovulatory,
- the deficiency of either of the ovarian hormones in the system,
- the dose of ovarian hormones required for therapeutic purposes,
- the time the ovarian hormones takes to produce maximal effects,
- the effects and progress of hormone therapy, and
- whether a woman who has missed a period is pregnant.

*Acknowledgment*

For this study, hormones were supplied by Messrs. Ciba Ltd., and Redoxon and the dye tablets by Messrs. Hoffmann-La-Roche Ltd. and I am grateful to their representatives in India for this help.

whether, on recovery from the disease, there is any evidence of impairment of digestive function (as judged by a test meal). In this paper are recorded the results of the examination of 25 cholera patients.

In order to avoid variable factors of age and sex in the subsequent analysis only males between the ages of 18 and 35 years were examined. The patients were of the labouring class and those selected for examination were moderately well built and not suffering from any apparent anaemia.

The test meal examination was made on the day of discharge from the cholera ward, when patients were able to walk about and were on ordinary diet—usually 7 to 10 days after the onset of the disease. In 17 patients the diagnosis was confirmed by the isolation of *Vibrio cholerae* from the stools during the acute stage of the disease and in the remaining eight, in whom *V. cholerae* had not been isolated from the stools, agglutinins in significant titres for *V. cholerae* were demonstrated in blood taken on about the tenth day of convalescence. In all patients the attack of cholera was clinically typical but comparatively mild. There had been vomiting during the acute stage of the disease, but this had not been as copious nor as frequent as in the more severe types of the disease.

The alcohol test meal was used. After the fasting stomach contents had been withdrawn, 50 c.cm. of 7 per cent alcohol in distilled water was injected into the stomach through a Ryle's tube. About 10 c.cm. samples of gastric juice were withdrawn every fifteen minutes up to a maximum of 10 samples. The samples were examined for free hydrochloric acid and total acid by titration with decinormal caustic soda solution, using Topfer's reagent and phenolphthalein as the indicators. Further examinations, as for example for acid deficit (or the amount of acid which must be added before a test for free hydrochloric acid is obtained) in samples which had no free hydrochloric acid, and for the presence of enzymes (pepsin and rennin), were made, according to methods described by Levinson and MacFate (1937). In this paper only the free acid is considered.

The results have been classified according to the grouping adopted by Napier *et al.* (1938) and are shown below.

Hyperchlorhydria—Over 65 c.cm. of N/10 NaOH per 100 c.cm.

Normal range High—over 45 but under 66.

Average—25 to 45.

Low—under 25 but not below 10.

Hypochlorhydria—Below 10 c.cm.

Achlorhydria.

According to this grouping the results obtained in 25 cholera patients are:—

Hyperchlorhydria— None

Normal range—

High	None
Average	3 or 12 per cent
Low	8 or 32 " "

Hypochlorhydria— 5 or 20 " "

Achlorhydria— 9 or 36 " "

As judged by the residual gastric juice after the fractional test meal the stomach empties more rapidly than normal in the majority of these patients.

It was not convenient to carry out a histamine test in patients with complete absence of free hydrochloric acid after the alcohol meal. As considerable persuasion was necessary to secure patients who had recently recovered from an attack of cholera to attend at the laboratory and submit to a fractional test meal, it was thought inadvisable to risk frightening any of them by injections and/or a possible severe reaction following histamine. It is hoped, however, to examine a further series of patients and to test a certain number of cases of achlorhydria with histamine.

The results show that there is achlorhydria in 9 (36 per cent) of the 25 patients examined. If we accept the incidence of 9 per cent achlorhydria (to the alcohol meal), which is the figure arrived at by Napier *et al.* (*loc. cit.*) for their non-anæmia cases (13 cases of achlorhydria in 151 cases), then the incidence of achlorhydria in 36 per cent of cholera convalescents is a finding which is unlikely to be due to chance or error of sampling. The observed difference is 2.7 times its standard error.

The incidence of low acid secretion is extremely high. An average normal range of acid secretion was present in only 3 (12 per cent) of the patients and in the rest (88 per cent) there was low acid or no acid secretion. There was hypochlorhydria or achlorhydria in more than half the patients (56 per cent). The absence of a single case of hyperchlorhydria in the 25 patients examined is by itself of significance.

The occurrence of low acid secretion in a large proportion of cases following an attack of cholera can be explained by one or more of the following hypotheses:—

1. It is the result of an acute gastritis, which leads to the development of achlorhydria or hypochlorhydria in a large proportion of cases. Hurst (1937), writing on diarrhoea, states: 'If the diarrhoea is accompanied by vomiting a test meal should be given a month after the termination of the attack even in the absence of all symptoms, as the accompanying acute gastritis may have led to achlorhydria which is likely to give rise to chronic diarrhoea or other trouble later unless the underlying chronic gastritis is overcome'.

## THE BACTERIOLOGY OF COLD DRINKS IN CALCUTTA

By C. L. PASRICHA

MAJOR, I.M.S.

Professor of Bacteriology and Pathology  
and

G. PANJA, M.B., D.Bact.

Assistant Professor of Bacteriology

(From the Department of Bacteriology and Pathology,  
School of Tropical Medicine, Calcutta)

AERATED and non-aerated refrigerated drinks were examined for the number of bacteria per cubic centimetre and for the presence of *Bacterium coli*. The samples were collected from certain shops situated in different parts of the city. The non-aerated cold drinks after being served out by the vendor were transferred to an eight-ounce sterile screw-capped bottle and brought to the laboratory for examination, which was made soon after receipt of the samples. The aerated drinks were bought in the original bottles and these were opened in the laboratory at the time of the examination. The examinations were made according to methods advocated by the Ministry of Health, 1939, and are summarized below:

(Continued from previous column)

2. It is one of the sequelæ of the state of anhydræmia which follows loss of water, acid, and neutral chlorides during the acute stage of the disease.

3. It is the result of a natural selection that has taken place in the sample of cholera convalescents. This presupposes that the disease occurred in individuals who at the time of infection with *V. cholerae* had deficient acid secretion in their stomachs and that those with high normal or hyperchlorhydria escaped infection. Whether such natural selection occurs is difficult to establish.

It is hoped to follow up some of the cases and to determine by repeated test meal examinations whether the gastric juice returns to normal, particularly in cases showing achlorhydria.

### Summary

In 25 individuals who had recovered from an attack of cholera, achlorhydria (after a standard alcohol test meal) was found in 9 or 36 per cent, hypochlorhydria in 5 or 20 per cent, low normal acid curve in 8 or 32 per cent and an average normal acid curve in 3 or 12 per cent.

Napier, L. E., *et al.* (1938). *Indian Med. Gaz.*, Vol. LXXIII, p. 65.

## (A) Presumptive coli test.

The sample bottles were shaken twenty-five times before removing portions for examination, which were inoculated as follows:—

Fifty c.cm. into a fermentation tube containing 50 c.cm. of double-strength MacConkey's broth (lactose bile-salt neutral-red broth).

Ten c.cm. into each of five tubes containing 10 c.cm. of double-strength MacConkey's broth.

One c.cm. into each of five tubes containing 10 c.cm. of single-strength MacConkey's broth.

The tubes were incubated for 24 hours at 37°C. and the results noted. If there was no gas formation the tubes were reincubated for another twenty-four hours. Platings were made on MacConkey's neutral-red bile-salt lactose agar from four of the tubes showing the greatest volume of gas. After incubation for twenty-four or forty-eight hours colonies suggestive of the coliform group were selected and a part of each colony transferred to peptone water, two tubes of glucose phosphate broth and citrate medium for the indole, Voges-Proskauer and methyl red, and the citrate utilization tests. The most probable number of coliform bacilli are computed according to the probability tables given in the Ministry of Health report (*v.s.*).

## (B) Total colony count.

With non-aerated drinks 1 c.cm. of a 1 in 10 and 1 c.cm. of 1 in 100 dilution (made with sterile tap water) were plated. In the case of aerated drinks 1 c.cm. of the undiluted sample and 1 c.cm. of a 1 in 10 dilution were plated. For each plate at least 12 c.cm. of nutrient agar was used and the agar after melting was maintained in the melted condition in a water-bath at 45°C. before seeding and pouring. The plates were incubated for forty-eight hours and the plates that contained between 30 and 300 colonies were counted under standard conditions. The average of the duplicate plates multiplied by the dilution factor was taken as the number of bacteria per cubic centimetre of the sample.

A total of 42 samples of cold drinks was examined, of these 22 were samples of non-aerated drinks and 20 of aerated drinks. The standard taken for comparison was that the number of bacteria per cubic centimetre should not exceed 100 and that *Bacterium coli* should be absent in 100 c.cm. or if present be not more than two coliform organisms per 100 c.cm. of the sample. This is based on the classification of non-chlorinated piped water supplies recommended by the Ministry of Health (*loc. cit.*) and reproduced below:—

	Presumptive coliform count per 100 c.cm.
Class 1. Highly satisfactory ..	less than 1
Class 2. Satisfactory ..	1-2
Class 3. Suspicious ..	3-10
Class 4. Unsatisfactory ..	greater than 10

According to the above grading not one of the 22 samples of non-aerated drinks examined would be considered satisfactory. Two samples were of class 3 and the remaining 20 samples fell in class 4. The majority of such samples gave a presumptive coliform count of 180 or over. Coliform organisms of the faecal type (*Bact. coli* type I from eight samples and type II from one sample) were isolated from 9 (41 per cent) of the 22 samples of non-aerated drinks. Members of the intermediate-aerogenes-cloacæ group were isolated from the majority of the samples with

yeasts predominating in the sweeter drinks. The colony count (plate incubated at 37°C.) was about 1,500 colonies per c.cm. in two samples and more than 3,000 colonies per c.cm. in the remaining 20 samples.

According to the results of the presumptive coli test the 20 samples of aerated drinks were of the following classes—

Class 1. Highly satisfactory ..	6 samples
Class 2. Satisfactory ..	2 "
Class 3. Suspicious ..	4 "
Class 4. Unsatisfactory ..	8 "

No faecal type of coliform organism was isolated from any of the samples. Organisms of the intermediate-aerogenes-cloacæ group were isolated from eight of the samples. The colony count was satisfactory (*i.e.*, below a 100) in eight samples, 250 in one sample, between 1,000 to 1,750 in three samples and more than 3,000 in the remaining eight samples. The latter were samples of flavoured and sweetened drinks.

The above results, although based on numbers too small to justify any definite conclusions, reveal (as judged from bacteriological standards) an unsatisfactory condition of the cold drinks, particularly the fruit juices and other non-aerated drinks, offered for sale to the public in Calcutta.

This finding is not surprising when it is realized that many of these drinks are prepared under conditions which cannot be considered as hygienically desirable. The aerated drinks are more satisfactory, and of these soda water appears to be best. It is interesting to note that similar results were obtained by Dzen and Chow (1936) in their examination of refrigerated drinks in Shanghai.

## Summary

Forty-two samples (22 non-aerated and 20 aerated) of cold drinks offered for sale in Calcutta were examined for the number of bacteria (colony count) and the presumptive coli test. Out of 22 non-aerated drinks examined not one sample conformed to the standard—all exceeded the permissible limit of bacteria and from 9 (41 per cent) of these samples faecal types of coliform organism were isolated. Of the 20 aerated drinks examined only eight conformed to the standard. Faecal types of coliform organism were not isolated from any of these samples.

These results, though based on a small number of samples, suggest the need for further work, the establishment of standards suitable for local conditions and the supervision and control of the manufacture of such drinks.

# ASCORBIC ACID IN THE URINE AND ITS RELATION TO INDIAN DIETARY

By BEHARI LAL, B.Sc., M.B., B.S., D.P.H. (Eng.).  
D.T.M. & H. (Lond.)

District Medical Officer of Health, Mirzapur

The quantitative determination of ascorbic acid is based upon the active reducing properties of the substance. The urine was titrated with the dye dichlorophenol-indophenol, each molecule of ascorbic acid reducing one molecule of the dye to its colourless leuco-base, itself being oxidized to dihydro-ascorbic acid. The method is not very accurate as there are other substances which reduce the dye, but the determination of the state of tissue saturation with respect to vitamin C is made possible by this chemical method.

The urine of 223 persons was examined. The subjects were chosen from various classes so as to give a correct idea of the nutritional condition of the people. These people were under usual dietary conditions prevalent in the district. The excretion of vitamin C in the urine of individuals on different articles of food is shown below :—

*Group 11.*—Candidates selected for a teachers' training class, well built, having good physique, doing mental work, residents of the villages of the district.

*Groups 12 and 13.*—Students of rural middle school, ages 8 to 16 years, residents of villages.

*Group 14.*—Old persons, ages 55 to 65 years. All had cataract; in a poor state of nutrition.

*Group 15.*—Residents of city. Middle class, ages 25 to 35 years. Employed in Government offices.

*Group 16.*—Students of well-to-do families. Ages 12 to 16.

*Group 17.*—A retired government gazetted officer about 62 years old.

*Discussion.*—The water-soluble vitamin C is present in urine in proportions depending on the diet and nutritional condition of the individual. The vitamin deficiency may appear either through failure of the individual to include in his diet an adequate amount of various essential foods rich in these substances or through failure properly to utilize the vitamins in diet, because of disturbances of digestion and absorption. It was observed that when the diet consisted only of rice and arhar dāl (*Cajanus indicus*) there

TABLE

Serial number	Number of persons whose urine was examined	Average weight in pounds	Diet consumed before the collection of urine	Average mg. ascorbic acid per 100 c.cm. of urine	Average daily excretion of ascorbic acid in mg.	REMARKS
1	19	119.6		1.50	15.0	The excretion was subnormal. Persons were recently drawn from villages where the diet was very poor in vitamin contents, that is, their tissues were unsaturated, and so no increase in ascorbic-acid excretion was caused.
2	15	121.6	Wheat, brinjal, potato	0.81	8.1	
3	15	116.0	Potato, gram dāl, wheat	0.61	6.1	
4	15	119.3	Wheat atta, arhar dāl (red gram), brinjal.	1.17	11.6	
5	14	112.9	Wheat, gram kulfa	1.21	12.2	increase in ascorbic-acid excretion was caused.
6	15	113.2	Rice, arhar dāl	0.68	5.9	
7	18	114.4	Arhar dāl, brinjal, wheat	1.50	14.5	
8	18	121.7	Wheat, cabbage	1.50	18.0	
9	18	..	Milk, fruits in addition to the diet of meat.	1.50	15.1	Students of urban area.
10	18	..	Wheat atta, a few had milk, dāl.	0.91	10.6	Students of middle school.
11	17	108.5	Wheat, dahi, kharbooja (melon).	3.20	31.5	Candidates for normal and training schools.
12	9	..	Wheat, dāl, curd, chana	1.91	19.1	Students of rural schools.
13	15	..	Arvi (colocasia) ghee	0.24	2.5	Old "persons" having "cataract. Well-to-do persons. Students.
14	10	..	Wheat, dāl and no vegetable	0.63	6.3	
15	4	..	Wheat, spinach, dāl	3.50	35.0	
16	2	..	Fruits	1.54	15.0	
17	1	..	Fruits with Indian daily diet	0.90	..	Low ascorbic acid. The subject was 62 years old.

*Note.*—Groups 1 to 8 were of ages ranging between 25 and 45 years. They were agriculturists of average physique and were maintained on the following diet during the period of observation—

Wheat atta—5 chatak, vegetables—2 chatak, and fat—half a tola per meal.

*Groups 7 and 8.*—Students of a Muslim high school, non-vegetarian, between 7 to 18 years of age, doing mental work.

was an excretion of ascorbic acid much below the normal (less than 15 mg. per day) (group 6). When the vegetable, brinjal, was added the excretion approached the normal (group 4). The consumption of this diet by those persons whose diet was deficient in vitamin-C content previously did not cause an increase in the excretion of ascorbic acid, showing thereby that their tissues were not saturated with vitamin C; that is, the vitamin was stored in the tissues of

such individuals (group 2). It was also observed that excretion of ascorbic acid varied in different age groups on the same diet; that is, with the increase in age there is also decrease of vitamin-C excretion (group 8 as compared with group 12). This is due to the fact that the absorption is not so efficient as in the case of young persons.

When cabbage was added to the diet urinary excretion of vitamin C rose very high (group 8). It was on an average 1.8 per cent, or roughly 18 mg. per day. Potato was found to be a good source of vitamin C in Indian dietary.

Students who were put on meat diet with no vegetable showed the output below the standard of 15 mg. per day (group 9), whereas when milk was added to the diet the excretion came up to the normal.

The age of this group was from 7 to 18 years.

In another rural school, the diet of students consisted of wheat atta, dāl (*Phaseolus mungo*), curd, gram, and arbi (colocasia). The excretion was normal (group 12). The intestines of these young persons could absorb the vitamin C of the food to the full extent, though their food was not a good source of vitamin C.

The addition of dahi (curd) to the diet helps in the absorption of ascorbic acid from the food and it is itself a good source of the vitamin. In this group (11) the average excretion was 31 mg. per day. The eating of melon also resulted in great output of ascorbic acid in the urine.

Old persons, that is, between 50 and 65 years, when put on diet containing a good quantity of vitamin C excreted ascorbic acid much below the normal (group 17).

The consumption of spinach (palak) cooked in the Indian way increased the vitamin-C content of the urine to a marked extent. The average excretion was 3.5 per cent; that is, about 35 mg. per day (group 15).

People excreting less than 1 mg. in 100 c.cm. of urine showed definite signs of vitamin-C sub-nutrition; sallow, muddy complexion, loss of energy, gingivitis, unhealthy teeth, dullness of eyes and dull, tired expression (groups 2 and 3). The tonicities of muscles was less than that of a healthy man. They were apathetic and took no interest in life. The heart sounds were feeble.

All cataract cases showed very low excretion of vitamin C in their urine. It indicates that with the diminution of metabolism on account of deficiency of vitamin C in diet, the lens is affected. The consumption of vitamin C will keep the lens in a healthy condition. The ageing processes were quick in individuals showing less excretion, that is, they looked older than their years (group 14). From the analysis of their dietary it was found that their food consisted of diet poor in vitamin C.

## SULPHATHIAZOL IN EXPERIMENTAL STREPTOCOCCAL AND PNEUMOCOCCAL INFECTIONS

By R. SANJIVA RAO, M.B., B.S. (Mad.), D.T.M. (L'pool)

and

K. GANAPATHI, M.Sc. (Mad.)

(From the Haffkine Institute, Bombay)

THE present paper deals with the therapeutic action of sulphathiazol, a compound synthesized by one of the writers (Ganapathi, 1940; Ganapathi and Nandi, 1940), in experimental streptococcal and pneumococcal infections in mice.

### Methods of testing

The strains employed in the tests reported here were a pneumococcus type I strain and

(Continued from previous column)

### Conclusions

1. The vegetables of ordinary Indian diet contain sufficient vitamin C, provided they are regularly taken. Even cooked leafy vegetables produce good results. The addition of dried mango pulp in the process of cooking prevents the destruction of vitamin C of vegetables.

2. The Indian method of cooking does not destroy the vitamin-C content of the food, as is commonly supposed.

3. With the diminution of the absorbing capacity of the intestinal tract, the daily output of vitamin C in urine is very much diminished in spite of the high content of vitamin C in food.

4. There is sub-optimal intake of vitamin C in villagers as compared to the city dwellers, so special attention should be given to vitamin-C values in the daily choice and use of food in villages. This can be obtained if plenty of amaranth (chaulai), cabbage, coriander in the form of chutni, be taken daily. There are other cheap articles of food obtainable in villages, such as leafy vegetables, etc.

*Note.*—During the course of the above experiment it was found that daily output of urine in 24 hours was 800 to 900 c.cm. and the results are based on these findings.

[Ascorbic acid passed in the urine becomes oxidized in course of time. The rate of oxidation is increased by bacterial infection and by warmth. This test for ascorbic acid was devised and has been mainly used in temperate countries. In warm countries the rate of oxidation is markedly increased for two reasons, on account of the warmth itself and because warmth encourages bacterial growth in the urine.

In order to decrease this error the test must be done immediately the urine is passed, or a preservative must be used and the urine kept in a cool place.

If this is not done the results obtained will be very irregular and of little value (*vide Annual Reports of the Calcutta School of Tropical Medicine*, 1938, p. 96 and 1939, p. 108). These limitations often present an insuperable difficulty in practice.

In this paper no mention is made of the procedure adopted to prevent oxidation of the ascorbic acid in the urine.—*Error, I. M. G.]*

drug under test was made into an emulsion with gum acacia such that 0.5 c.cm. of the emulsion contained the required dose. This quantity of the emulsion was introduced into the stomach of the mouse by means of a pipette. The mice were observed for a period of 10 days in streptococcal infection and 15 days in pneumococcal infection, and the average survival time was calculated according to Whitby (1937). For comparison, tests were also put up with sulphapyridine in the case of pneumococcal infection and sulphanilamide and sulphapyridine in the case of streptococcal infection.

The following tables summarize the results of some typical experiments :—

*The therapeutic effect of sulphanilamide, sulphapyridine and sulphathiazol in experimental hamolytic streptococcal infection in mice. The drugs were administered in 10 mg. doses soon after infection and repeated 6, 24, 48 and 72 hours later*

[illegible]

*The therapeutic effect of sulphapyridine and sulphathiazol in different dosage in experimental pneumococcal (type I) infection in mice*

[illegible]

TABLE III

The therapeutic effect of sulphathiazol in experimental pneumococcal (type I) infection when administered in single and divided doses

Dosage of sulphathiazol	Number of mice out of groups of 10 dying on each day after infection											Survivals	Average survival time (days) (max. 10)
	1	2	3	4	5	6	7	8	9	10	11-15		
45 mg. once daily for 6 days.	0	0	0	0	1	0	1	2	0	1	0	5	8.3
22.5 mg. twice daily at 12 hourly intervals for 6 days.	0	0	0	0	0	0	0	0	0	0	0	10	10.0
15 mg. three times a day at 8 hourly intervals for 6 days.	0	0	0	0	0	0	0	0	1	1	0	8	9.7
Not treated (controls)	6	2	2	..	..	..	..	..	..	..	..	0	0.6

Discussion

In hæmolytic streptococcal infection sulphathiazol gives distinctly better\* results than either sulphanilamide or sulphapyridine (table I). In pneumococcal infection sulphathiazol is at least as good as sulphapyridine when administered in large doses (table II), but the results with sulphathiazol are distinctly poor when a smaller dosage is employed, due to the fact that this drug is excreted much more rapidly than sulphapyridine.

This agrees well with the findings of McKee *et al.* (1939) who have reported that sulphathiazol† when administered in 1 per cent concentration in food is as good as sulphapyridine while in 0.5 per cent concentrations it is slightly inferior. This is easily understood when we compare the blood concentrations of the drugs following their ingestion. It has been reported by van Dyke *et al.* (1939) that after a single dose of 0.5 g. per kg. in mice the maximum blood concentrations in the case of sulphapyridine and sulphathiazol are 21 mg. and 12 mg. per cent respectively, whereas with 1.0 g. per kg. doses the concentrations are 24 mg. and 26 mg. per cent respectively. So it is to be expected that with less intensive treatment sulphathiazol should be inferior to sulphapyridine, as was found by Cooper *et al.* (1939).

The drug is much more effective when given in two or three divided doses per day than when the same amount is given as a single dose (table III).

Summary

1. The therapeutic value of sulphathiazol in experimental hæmolytic streptococcal and

\* Statistical criticism of the results reported in this table does not confirm the statement that sulphathiazol is better than sulphanilamide. To establish their claims, which may be correct, though they are not supported by other workers (*see* p. 686), the writers would have to use a much larger number of mice.  
† The compound referred to by these American writers is sulfathiazole, or 2 *p*-amino-benzene sulfonamide thiazole, prepared by Fosbinder and Walter (*J. Amer. Chem. Soc.*, 1939, 61, 2032). The compound which was prepared by one of the present writers and called sulphathiazol is presumably the same compound.

pneumococcal (type I) infection of mice has been appraised.  
2. Experimental evidence presented shows that this drug is distinctly superior to sulphanilamide and sulphapyridine in streptococcal infection and is as good as sulphapyridine in pneumococcal infection.

Acknowledgment

We are indebted to Lieut.-Colonel S. S. Sokhey, I.M.S., Director, Haffkine Institute, for his kind advice throughout the course of this work.

LECITHINOPHILE EOSINOPHILIA AND ERROR IT MAY CAUSE IN CASES OF TUBERCULOSIS AND ASTHMA\*

By S. D. S. GREVAL  
LIEUTENANT-COLONEL, I.M.S.  
Imperial Serologist's Laboratory, School of Tropical Medicine, Calcutta

THE intention is to draw attention to some cases of eosinophilia whose blood gives a positive or doubtful Wassermann reaction though they are not suffering from syphilis. The latter fact is established by following them up without giving treatment for syphilis. When the eosinophilia decreases or disappears the Wassermann reaction also becomes negative.

\* This paper was selected for the special tuberculosis number of this journal, issued last month, but was held over on account of lack of space.

It is proposed to designate the condition 'lecithinophile eosinophilia' in view of the affinity of the blood serum for the lecithin in the Wassermann antigen, in the reaction of complement fixation. The writer (Greval, Chandra and Das, 1940) has suggested for several reasons that the Wassermann reaction should be re-named lecithin-complement-fixation (LCF). One of the reasons is that it is looked upon, more or less, as diagnostic of syphilis and such is definitely not the case in the tropics. The condition under description is another reason.

'A wise precaution is to examine the sputum for tubercle bacilli in all cases of asthma' (Young and Beaumont, 1937). Some cases suspected or proved to be cases of pulmonary tuberculosis may be cases of lecithinophile eosinophilia also. The question then arises whether they are suffering from syphilis in addition. The writer has experience of such cases.

A toxic form of asthma is known which 'clears up when a positive Wassermann becomes negative or when diabetics become sugar free' (Rackemann, 1933): or does the positive Wassermann reaction become negative when asthma clears up?

The following illustrative cases are taken from a previous publication (Greval, Sen Gupta and Das, 1938):—

*Case 1.*—Eosinophilia associated with a positive Wassermann reaction (WR).

S., a Hindu female, aged 13 years, was admitted for low fever and cough and enlarged tonsils. She had 80 per cent eosinophils and the WR was positive. No other abnormality was detected. When her tonsils were removed the patient became afebrile. She was then given a course of arsenic injections. After six injections her WR was negative. Her total eosinophil count had also decreased to 12 per cent.

In this case, unfortunately, arsenic was given. With the quantity given, however, so rapid a change in the Wassermann reaction could hardly be effected in a case of syphilis.

*Case 2.*—Asthma associated with a positive Wassermann reaction.

C. S. W., an Anglo-Indian male, aged 29 years, was admitted for asthma—duration 12 years. Usual signs of asthma present. Examination of blood showed an eosinophilia of 45 per cent. His WR was positive. History and signs of syphilis were absent. Injections of peptone were given for asthma after the acute phase had subsided. There were no further attacks in hospital. The WR repeated was found to be doubtful. Eosinophils were now only 5 per cent. Before discharge the reaction was completely negative.

In this case no arsenic was given at all.

These cases were observed in the Carmichael Hospital for Tropical Diseases, Calcutta.

The Wassermann reaction was done in accordance with the technique of method no. 4 of the Medical Research Committee (British, now Council, 1918).

All cases of eosinophilia are not lecithinophile, nor is lecithinophile eosinophilia confined to pulmonary cases, although found in them often. Further, many cases of the condition give a

(Continued at foot of next column)

## A CHEAP FLUSH-OUT LATRINE

By T. R. RANGASWAMI, M.B., B.S., B.S.C.

CAPTAIN, A.I.R.O.

In a previous article (Rangaswami, 1940) the advantages of bore-hole latrines in villages were discussed. Although these are undoubtedly the best type of latrine for villages on account of their small cost permitting of them being made available for each household separately, they are not capable of universal application as they cannot be bored in unsuitable soils such as 'black cotton' soil, rocky ground, or very sandy ground in which they will cave in.

The writer has accordingly devised a cheap flush-out latrine the cost of which though much higher than that of a bore hole is not prohibitive if a larger number of people share in its use. It is capable of adoption in rural areas and bungalow types of houses. It has *pucca* walls, glazed earthenware closet and disposal chambers. This type of latrine is very much better than the bore-hole type.

When sub-soil water comes within a few feet of ground level there is the possibility of flies, mosquitoes and other insects breeding in an open bore-hole latrine. By this 'water-sealed' type of latrine, these dangers can be completely eliminated. Further, it has a much better appearance, and splashing of water on the users is avoided. The cost per seat is Rs. 122-8 and, assuming six individuals in a house, cost per individual is Rs. 20-7.

The nitrogen conserved will yield a return of 14 per cent on money spent which is no small

(Continued from previous column)

doubtful ( $\pm$ ) reaction which may be read as positive (+) at times.

This short communication, detached from the general subject of complement fixation in syphilis, is made with a view to emphasizing the existence of this important condition which is likely to add wrongly the diagnosis of syphilis to the diagnosis of tuberculosis or asthma.

### Summary

Some cases of eosinophilia give a false positive Wassermann reaction. When suspected or proved to be suffering from pulmonary tuberculosis they are wrongly suspected to be suffering from syphilis also. It is proposed to call them cases of lecithinophile eosinophilia.

# A NOTE ON WELLS AS DAY-TIME RESTING-PLACES OF *ANOPHELES TESSELLATUS*

By T. RAMACHANDRA RAO  
and

PAUL F. RUSSELL

*Anopheles tessellatus* is uncommon in Tanjore District, Madras Presidency, where we have been making malaria studies (Russell, Menon and Rao, 1938; Russell and Rao, 1940). In Pattukkottai Taluk for the period of three years from March 1937 to February 1940, we found only 158 adults of that species among over 290,000 adult anophelines collected in the course of visits to dwellings of all types. In Tanjore Delta, during twelve months commencing March 1938, we collected only 17 among nearly 10,000 adults of all species taken in dwellings. It is therefore of interest to note the discovery, in December 1939, of the remarkable habit of

(Continued from page 677)

advantage, especially as the latrine problem is completely solved. Aesthetically it is distinctly preferable.

The seat is capable of easily dealing with the nightsoil and waste water from 20 people. Then the cost per seat will only be Rs. 6-2 per individual which is cheaper than a bore-hole latrine, which has been shown to cost Rs. 6-4 per individual; both estimates provide for decent permanent structures.

Thus it is cheaper than a bore-hole latrine when used for schools, colleges, factories and such other institutions, where it is sufficient to provide seats at the rate of 1 seat per 20 persons.

In his own bungalow the writer had a single-seat flush-out latrine on the lines described above with a disposal chamber only 6 feet deep and 2½ feet diameter, and this gave him entire satisfaction for about two years. Almost every month the disposal chamber was observed by opening the man-hole cover. As the writer left the station on transfer personal observations later could not be recorded. The rate of absorption was such that there was no possibility of the disposal chamber getting full. Even during a severe rain, when the compound was full of water for two days and when only the seat and step alone were above water, this worked satisfactorily.

The writer recommends a water-sealed, flush-out type of latrine, where water is readily available. In places with deficient water-supply the dry type of slab can be used and the closet-pan flooded with two or three gallons of water from a bucket, after use.

In the drawings the closet pan shown is Twyford's best English-made, Indian pattern, 23 inches in size.

Plastering is done with cement mortar.

## REFERENCE

Rangaswami, T. R. (1940). *Indian Med. Gaz.*, Vol. LXXV, p. 222.

adults of this species of resting during day-time hours in open wells. In 25 wells which we searched and in which we found anophelines resting, we found *A. tessellatus* in 17, and were

Fig. 1.—Type of well where *A. tessellatus* was found. Exterior view.

able to collect 61 adults of this species (males 25 and females 36) out of a total of 94 adults of all anopheline species found. On one morning (13th December, 1939), 25 *tessellatus* adults were found in four wells, with only 2 adults of other species.

It should be noted that at the time the predominating species of anophelines, as judged from larva and adult collections, were *A. culicifacies*, *subpictus*, and *hyrcanus* var. *nigerrimus*, and none of these species was caught regularly in wells. If the resting of *tessellatus* in wells had been due merely to chance, *culicifacies*,

Fig. 2.—Collecting *A. tessellatus* adults in crevice in concrete-lined well. (Same well shown in fig. 1.)

*subpictus* or *hyrcanus* adults should have been found in far greater abundance than *tessellatus*. The ratio of *tessellatus* adults to the other species in wells was 2 to 1, while in collections in dwellings the ratio was 1 to 1,110.

It must also be mentioned that repeated searches of some of the wells, where *tessellatus* adults were found, failed to reveal larvæ of that species. The only larvæ regularly found in such wells were *varuna* and *culicifacies*. (Numerous culicine adults, sometimes more than

a hundred, have been found in these wells.) In over a thousand larva collections in wells in these areas, not one *A. tessellatus* was found.

Fig. 3.—Collecting *A. tessellatus* adults in crevices of brick-lined well.

This seems to indicate that the presence of the adults in wells was due to a day-time resting-place in preference.

The *tessellatus* wells were of ordinary types, having diameters of 3 to 5 feet, lined and unlined, sometimes shaded by parapet walls. In some wells where *tessellatus* was caught, there was no visible dampness at the place where they were found resting. Often they were caught in crevices in the sides, but, quite as often, on smooth vertical sides (see figures). Water levels were usually within 4 or 5 feet of the ground and there was always abundant light.

## A Mirror of Hospital Practice

### A UNI-OVULAR TWIN PREGNANCY WITH SPONTANEOUS DELIVERY OF A DOUBLE MONSTER

By A. V. RAMA RAO, L.M.P. (Madras)  
Assistant Medical Officer, Singareni Collieries  
Company, Ltd.

A PATIENT aged 26 years, 3rd para, was admitted to the Singareni Collieries Company Ltd. Main Hospital at Singareni on the morning of 5th June, 1940, with the history of being 8 months' pregnant. She had been in labour at her home for about six hours and the membranes had ruptured about three hours previously.

Fig. 1.

*On admission.*—The breech and two apparently normal lower limbs had delivered themselves; a few minutes later the rest of the foetus (still-born) was delivered spontaneously. It was then seen that in addition to the two normal lower limbs, there was a third lower limb projecting from the sacro-coccygeal junction with two big toes opposing each other—an indication of a fusion, which would otherwise have resulted in two lower limbs.

There were two heads normal in appearance imposed on a single trunk with normal upper limbs. In addition, there was a third upper limb springing from the back of the trunk between the two heads. This third upper limb had two hands attached in the normal position of the hand and opposed to each other. The gums of both mouths presented the appearance of having complete sets of upper and lower dentures, which had a cartilaginous feel. There were also two rudimentary male genitalia one below the other. There was only one placenta and one umbilical cord. The patient made an uneventful recovery. The photographs show anterior and posterior views of the foetus.

Fig. 2.

A skiagram was taken which showed clearly that there were two spinal columns and two sets of ribs and that the two normal-appearing arms had their origins from two separate shoulder girdles, the common arm having, apparently, no bony shoulder girdle.

I am indebted to Dr. P. M. Little, Chief Medical Officer to the Singareni Collieries Company Ltd., for permission to record this case.

*X-ray reveals uniform density of Agarol.*

## ... Agarol has had a physical examination

THE X-ray says: "Look for uniform density throughout as evidence of soundness". Agarol is a thoroughly uniform emulsion that acts the same way with every dose.

The microscope says: "Look for the small uniform oil globules" as a sign of thorough emulsification of Agarol. It means stability, freedom from oiliness, ready miscibility with water, milk, fruit juices or any other liquid.

*The microscope shows extremely fine division of oil in Agarol.*

The pharmacist says: "If it pours freely, it is the sign of a good emulsion." Agarol is a good mineral oil emulsion that has thoroughly proved its value in the relief of acute constipation and in the treatment of habitual constipation.

Descriptive literature and a liberal supply of Agarol supplied gratis to Members of the Medical Profession on request.

MARTIN & HARRIS LTD.,  
Mercantile Buildings, Lall Bazar, Calcutta.

*Also at Bombay, Madras, Karachi and Rangoon.*

Prepared by WILLIAM R. WARNER & CO. LTD. LONDON, ENGLAND.

## NEUTRASIL

(Hydrated Magnesium Silicate B.D.H.)

Neutrasil represents the most recent advances made in the improvement of antacids. Neutrasil exerts both an immediate and a prolonged neutralising action. Repeated doses at short intervals are unnecessary, since soluble alkali is only released from Neutrasil by excessive acid. Alkalosis, therefore, cannot be produced by the administration of Neutrasil. The release of alkali is accompanied by the formation of a gel which is adsorbent and forms a protective film on the alimentary mucosæ.

Neutrasil is ideal, therefore, for the treatment of all forms of gastric hyperacidity, especially that associated with peptic ulcer. Its efficacy will be manifested even in the most severe cases, and there are no contra-indications to its use in the lowest degrees of gastric acidity.

## MANGANESE BUTYRATE B.D.H.

### For the treatment of Recurrent Boils

The injection of Manganese Butyrate B.D.H. has produced dramatic results in cases of recurrent boils; in many such cases the infection is rapidly and completely cleared up after only two injections, further multiplicity being prevented.

Manganese Butyrate B.D.H. is injected intramuscularly; in the average case it is usual to make two injections—one injection of 10 c.c. followed by a second injection three to six days later of 1.5 c.c. If necessary a further course of two injections may be given six weeks to two months later.

*Stocks of Neutrasil and of Manganese Butyrate B.D.H. are held by the principal chemists and full particulars are obtainable from:*

NOVEMBER

## THE TREATMENT OF INFECTED WOUNDS

Up to the present in India we have been saved from the horrors of war, but it is by no means certain that we shall continue to enjoy this immunity; further, war is not the only source of infected wounds and with the ever-increasing mechanization and industrialization of the country the profession will be called upon more and more frequently to treat lacerated and infected wounds. Little good ever comes out of war, but on the credit side must be placed the intensive experience of the surgeon in the treatment of the infected wound. Great steps were made in the last war, the advances were consolidated during the years of peace, and further advances were made in the Spanish war, so that the prospects of the wounded soldier or civilian are considerably better in 1940 than they were in 1914.

We need not trace the progress of treatment of wounds from the time of primitive man, who probably licked his wounds like the dog does to-day, to the days of strong tissue-destroying antiseptics, if progress it may be considered, nor recount the various stages through which surgical practice passed during the last war, in which B. I. P. P. and other devices waxed and waned, but, to summarize the position at the end of the war, there were three main lines of practice, the Carrel-Dakin method of intermittent irrigation with hypochlorite or other bland antiseptic solutions, the application after free drainage of hypertonic sodium chloride or magnesium sulphate solution, paste, or even powder to ensure an active lymph flow, and, thirdly, again after free drainage, the method of immobilization, the application of abundant absorbent dressings, and non-interference for a long period. None of these three methods has yet been abandoned; in fact, the two latter methods, and particularly the last-named, have been developed considerably.

It is a matter for cynical observation that the commonest and most deadly of the bacterial flora of an established wound, the streptococcus, is introduced seldom at the time the wound is received but during the time it is being treated, and that the commonest source of infection is the nasopharynx of the patient himself or of his friends, the dressers, nurses, or doctors, for investigations have shown that the percentage of wounds infected with streptococci rises from 12 per cent to 20 per cent to 90 per cent as the wounded man passes from casualty clearing station through the base hospitals. A recent

development has, however, provided us with a means of dealing very successfully with this man-made complication and the chemo-therapeutic advances that were initiated with the introduction of sulphanilamide undoubtedly constitute the most important advance of the inter-war period in the treatment of infected wounds.

The two points about the usual war wound are that it is a lacerated wound in which considerable damage has been done to the tissues, so that they are in a very suitable condition to receive infection, and secondly that infection is abundantly provided by the clothes, soil, and other debris that were introduced at the time the wound occurred. Fortunately, there is a lag period of 4 to 12 hours from the time that the infecting organisms are introduced into the wound to the point at which they are able to establish themselves in the tissues. If therefore during this lag period we can contrive to remove all foreign and autogenous debris and infecting organisms, whilst at the same time avoiding introducing others, and approximate the cleaned edges of the wound, it will heal by first intention. 'All' is a big word and is an ideal that it is not actually necessary to achieve, for the healthy tissues of the body are capable of dealing with a considerable number of organisms, and therefore their destruction should never be pressed (*e.g.*, by the use of strong antiseptics) to the detriment of the healthy tissues; on the other hand, it is important that all foreign matter should be removed and damaged tissues cut away. The general rule is to consider that if *débridement*, as removal of the debris and cleaning up the wound is called, can be carried out within 6 hours there is a good chance that the wound will heal by first intention, that if this can be done from 6 to within 12 hours it is worth attempting to achieve primary healing, though the patient should be watched very carefully, and that if 12 hours have elapsed there is little chance that the wound will heal by first intention whatever is done and that the more extensive the *épluchage* (paring of the edges of the wound) the more harm is likely to be done in removing the tissue defences and spreading the infection.

If this early surgical treatment of the wound can be contrived the subsequent treatment of the patient consists in applying abundant antiseptic and absorbent dressings and resting the limb or part. How this can best be done, by a plaster-of-paris case, wire splints, or other means of immobilization, circumstances and to some extent the prejudice of the surgeon will dictate. Subsequently, the patient rather than the wound should be watched, and any signs, such as a high temperature, an increasing pulse rate, a general toxic appearance, or swelling and œdema of the limb beyond the wound, are indications for removal of the dressings and opening and draining the wound without further delay.

After the 12-hour safe period has passed the wound is accepted as probably an infected one and is freely opened and drained. The *débridement* in this case is conservative and only foreign matter, and obviously devitalized tissue, blood clot, etc., are removed; this is done by means of a swab with the occasional aid of a pair of scissors; the knife plays a very minor part and any cutting into healthy tissues, where a defense barrier is already established, is carefully avoided. The method of draining is again open to the choice of the surgeon but vaseline gauze, though it lacks certain very temporary advantages possessed by plain dry, antiseptic-impregnated, and salt-impregnated gauze, has other enduring qualities, namely, that it keeps the track open, does not get entangled in granulations, and is slowly extruded as the wound heals, which endear it to the surgeon. When free drainage has been ensured the wound is covered with a thick layer of absorbent dressings and the part immobilized.

It is in the subsequent treatment of the wound that there has been a change of ideas since the last war; the French practice of using plaster-of-paris has been developed considerably, first in the Winnett-Orr method of treatment of osteomyelitis and later its manifest advantages were demonstrated in the Spanish war. The general tendency now is wherever possible to encase the limb in plaster-of-paris and, ignoring the very unpleasant smell that arises as the discharges soak through the dressings into the plaster case, leave it for a week or more without further interference. The plaster may not be necessary where the patient has not to be moved, and in certain cases other means of immobilization, e.g., a Thomas' splint, may be necessary; whatever the method of immobilization the practice of non-interference is rigidly maintained. One other point is worth mentioning; whenever possible, the limb is elevated to obviate, or reduce, œdema and ensure a good blood supply.

The next important modification of procedure, and one whose potentialities have not yet been fully explored, has been provided by the intro-

duction of the sulphanilamide group of drugs. The systematic administration of sulphanilamide to all the wounded may not yet be the accepted procedure, but it has more advocates than opponents. The dose given is 1.5 grammes, *statim*, in 1 per cent citric acid to ensure rapid absorption, followed by 0.5 gramme two hours later, 0.5 gramme four-hourly for the next 24 hours and then 1 gramme eight-hourly to the end of the fourth day.

In a case where *débridement* is undertaken at an early stage, an alternative and possibly preferable measure is to powder the wound freely with sulphanilamide, introducing anything up to 15 grammes of the drug, for, not only has the drug a direct action on the organisms infecting the wound, with which it comes in contact, but the absorption of this amount of the drug into the general circulation makes the oral administration for the next 48 hours superfluous.

In a case of established infection in which prophylactic sulphanilamide has not been given a dose of 1 gramme hourly in citric acid solution for three doses followed by the usual therapeutic dosage by mouth will be far more effective than local application, for the drug might not be absorbed in the presence of much purulent discharge. The action of sulphapyridine on organisms other than streptococci, including the organisms of gas gangrene, is greater than that of sulphanilamide but the danger of the complication of vomiting after the former drug adjusts the balance in favour of the latter for routine use.

Recent experience with the wounded evacuated from France appears to have justified amply the prophylactic use of sulphanilamide, as wounded men who had received no surgical treatment arrived in England in far better condition than did men in 1918, and in the trying circumstances of the evacuation from Dunkirk the advantages of plaster-of-paris over other means of immobilization were well demonstrated.

(An important series of articles on this subject appeared in *The Lancet* from 30th March to 1st June this year.)

## Medical News

### TUBERCULOSIS ASSOCIATION OF INDIA. (TUBERCULOSIS NEWS)

#### TRAINING COURSES

THE Tuberculosis Association of India, with the co-operation of the Bombay Province Anti-Tuberculosis Association, will organize a medical postgraduate course for training in tuberculosis in Panchgani and Wanlesswadi, from the 13th January to 1st February, 1941, both dates inclusive. During the first two weeks lectures and practical demonstrations will be held in Bombay at the Seth G. S. and Grant Medical Colleges and other institutions and during the third week at the Tuberculosis Sanatoria in Panchgani and Wanlesswadi.

The class will be limited to 25 registered medical practitioners. Fifteen seats will be reserved for practi-

tioners in Western India, including Indian States, and the remaining for candidates from other parts of India.

Applications for the course in prescribed form should reach the Secretary, Tuberculosis Association of India, New Delhi, by the 22nd November, 1940.

The Tuberculosis Association also hope to organize a similar course in Calcutta early next year with the co-operation of the Bengal Tuberculosis Association. As soon as the preliminaries about this course are settled, a press note will be issued for general information.

#### KASAULI SANATORIUM SCHEME

1. Consequent on the transfer of the work connected with the manufacture and issue of anti-rabic treatment, the Association of the Pasteur Institute have offered

to place a major portion of their extensive estate measuring about 30 acres in area at the disposal of the Tuberculosis Association of India, free of cost, for the establishment of a Tuberculosis Sanatorium on such terms and conditions as may be mutually agreed upon.

2. The whole scheme for the establishment of the proposed sanatorium at Kasauli has been examined by an Advisory Committee appointed by Her Excellency the President of the Association and this Committee after careful examination of the proposals has approved the project and recommended that it be proceeded with subject to the receipt of certain grants which have been applied for.

3. The Sanatorium, when ready, will serve as a central institution for—

- (a) the modern treatment of pulmonary tuberculosis, especially difficult cases requiring advanced surgical treatment,
- (b) the training of doctors, nurses and health visitors in the modern methods of diagnosis and treatment of the disease, and
- (c) research work in tuberculosis including bacteriological research.

#### REVIEWS

(a) *Indian Red Cross Society, Mysore State Branch, Annual Report, 1939.*

During the year under report anti-tuberculosis work was carried on in the State under the auspices of the State Red Cross Branch. The nurses attached to the two solaria visited the houses of patients and the doctor in-charge checked their work and advised patients and their contacts. Contacts under 12 years of age who showed positive reactions to the tuberculosis test attended a solarium, where they were given graded sun-baths, cod-liver oil, fruit juice and milk. Anti-tuberculosis propaganda work was conducted by distribution of literature regarding infection and prevention.

(b) *Bengal Public Health Report for the year 1938.*

(i) The Director of Public Health, Bengal, writes that the increasing dust nuisance in the towns and even in the rural areas, on account of the increasing number of motor-cars and buses, has a direct repercussion on the incidence of respiratory diseases in general and pulmonary tuberculosis in particular. Hence arrangements should be made by the local bodies for the proper watering of the roads in towns and of putting a smoother surface on the roads, which will not produce dust.

(ii) The number of deaths in the province from pulmonary tuberculosis during the year under review was 14,668 giving a death rate of 0.29 per mille.

#### NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS, LONDON, NOTES

This Association has planned an interesting, enjoyable programme of health films, specially suitable for children. No mention is made of the word 'tuberculosis', but the children are taught the need of fresh air, the care of the teeth, cleanliness, etc. Teachers have expressed their whole-hearted approval of this programme.

#### ACTIVITIES OF INDIAN RESEARCH FUND ASSOCIATION

*Steps to improve Indian diets.*—Since it came into existence in 1911, the Indian Research Fund Association has devoted increasing attention to the study of nutritional problems and to the practical application of the fruits of such study to the improvement of the diet of the people, states the Report of Scientific Advisory Board of the Association for 1939. During the year under review, nutrition research has proceeded on the lines of surveys of the state of nutrition and the dietary habits of the people in various parts of the country, the analysis of the common foodstuffs of India for ascertaining their nutritional value, research into various nutritional problems, including that of

discovering cheap substitutes in order to meet recognized deficiencies in Indian diets, the training of health personnel in nutrition and educational work in order to encourage the application of the fruits of research for improving the diet of the people.

Rice, as the staple diet in many parts of India, received special attention during the year. A memoir entitled 'The Rice Problem in India', which deals with different aspects of the subject, has been recently published by the Indian Research Fund Association.

The results of over 50 diet surveys in different parts of the country have been embodied in a special publication by the Association and this should prove to be of value to provincial Departments of Agriculture in shaping agricultural policy in order to meet existing diet deficiencies.

#### TRAINING OF PERSONNEL

The training of health personnel in nutrition work, which was started in 1937, continued in 1939 and seventeen workers from various provinces and Indian States attended a three-months' course.

A new edition of *Health Bulletin No. 23*, entitled 'The Nutritive Value of Indian Foods and the Planning of Satisfactory Diets', was issued during the year and a nutrition museum was established at the Nutrition Research Laboratories at Coonoor, which is maintained by the Indian Research Fund Association.

Researches into different nutritional problems involved investigations in many centres, including medical colleges in Lucknow and Bombay, the Departments of Chemistry in Dacca and Calcutta Universities, the All-India Institute of Hygiene and Public Health, Calcutta, the Nutrition Research Laboratories, Coonoor, and the Imperial Agricultural Research Institute, New Delhi.

The Malaria Institute of India took a leading part in directing anti-malarial operations and research on scientific lines. The Director and other officers, through tours and by conferences with civil and railway health authorities, helped to place the expert services of the Institute at the disposal of these authorities for the solution of their malaria problems.

The annual class for training in malaria for medical officers from different parts of the country was carried out at Delhi by the Institute and 24 medical men attended this course. A considerable amount of laboratory research was carried out.

A new *Health Bulletin* entitled 'Lectures on Malaria' was prepared and a new edition of the practical entomological course for medical officers was published.

#### TRIALS OF PLAGUE SERUM

Plague research is mainly centred at the Haffkine Institute, Bombay. At the Cumbum Valley in Madras Presidency various field studies in regard to the control of epidemic outbreaks of the disease have also been in progress for the past eight or nine years.

At the Haffkine Institute research work on an anti-plague vaccine with maximum protective power was in progress. A serum for the treatment of plague patients had been prepared by this Institute and had undergone limited trials with encouraging results, during certain epidemic outbreaks of the disease.

At Cumbum Valley the research consisted mainly of work on the prevention of plague by the use of cyanogas for rat destruction in rat holes and by the reduction of rat infestation in houses through improved construction.

An investigation was carried out into the existence of varying degrees of disability among the population of certain areas in Madras Presidency as the result of high concentrations of fluorides in the drinking water supplies of these areas.

A considerable amount of research by field and laboratory studies into leprosy was in progress during the year. It has been shown that, in respect of chronic bone and nerve pain associated with leprosy, the adoption of a wheat diet by the patient affords him considerable relief. Another important finding is that the administration of skimmed milk to children with the

more severe forms of leprosy appears to help towards a cure.

The enquiries supported by grants from the Indian Research Fund Association covered a wide field including most of the major diseases affecting the health of the people of the country. A total sum of nearly Rs. 4,76,000 was distributed during 1939 in the form of grants to different enquiries conducted under the auspices of the Association.

### NUTRITIVE VALUE OF INDIAN FOODS

'APART from specific contributions to science, the Coonoor research unit has since its inception laboured to put nutrition on the map in India and to-day the importance of nutrition in relation to public health in India is generally realized' says the Note on the work of the Nutrition Research Laboratories, Coonoor.

Nutrition work in Coonoor has been financed throughout by the Indian Research Fund Association. The Raja of Parlakimedi, impressed by the importance of nutrition in India, made a donation in 1926 of one lac of rupees for nutrition research under Colonel McCarrison, the first Director of the Laboratories. This sum has been devoted to financing two research scholarships of the monthly value of Rs. 150 each.

### DIET SURVEYS

During the last five years great attention has been paid to diet surveys and up to the present time over 60 diet surveys have been carried out in various parts of India. The main object of diet surveys is to discover the defects of Indian diets and indicate the changes and improvements which are desirable from the standpoint of nutrition. A considerable number of points of importance in connection with agricultural and public health policy have emerged as the result of the surveys and these have been summarized in a note which has been circulated to agricultural departments.

### NUTRITION ADVISORY COMMITTEE

The Nutrition Advisory Committee is concerned with the development of nutrition work in India and includes as members the Public Health Commissioner, the Agricultural Commissioner and the Animal Husbandry Commissioner with the Government of India, the Director of the Nutrition Research Laboratories, some university professors of physiology and others with special interest in and knowledge of the subject.

### NUTRITION CLASSES AND PROPAGANDA

Since 1937 nutrition classes, lasting two to three months, have been held annually in Coonoor. Some 60 pupils from all over India have attended. Pupils are now employed as full-time nutrition officers in many provinces and states in India. Propaganda and educational work have been carried out by them in various parts of India and in general the scheme has resulted in the spread of knowledge of nutrition.

In addition to holding training classes and issue of popular bulletins, the Nutrition Research Laboratories deal with many requests for information which are received from all over India. Posters and other propaganda material are distributed to applicants, and from time to time popular lectures are delivered and press notes issued. There is no doubt that as a result of these efforts much progress has been made in spreading knowledge about diet in India in recent years.

### DRUG MANUFACTURE IN INDIA

'If essential raw and basic materials are available, the manufacturers in India could supply not only the whole of the normal requirements of the country in respect of medicines but would also be able to cater for export market' said Sir P. C. Ray, while presiding at the Second Annual General Meeting of the Indian Chemical Manufacturers' Association held on the 3rd

October, 1940, at Calcutta. As regards the heavy chemical industry, Sir P. C. Ray stated that many of the acids with few exceptions were being produced in this country. Some concerns had also started the production of alkalis, viz, soda ash, bleaching powder, caustic soda, etc., on a small scale and within a short period India would be producing these materials in sufficient quantity. Besides, several concerns have under project the manufacture of sodium and potassium bichromates, acetic acid, oxalic acid, tannic acid and other acids and alkalis. If, however, the stimulus provided by the war continued, the time would not be far off when, provided encouragement and support of the Government of India were available, this country would have a fully fledged chemical and pharmaceutical industry.

Sir P. C. Ray then referred to the question of co-ordination between the manufacturers and research institutions. In India, he said, several universities and other institutions were carrying on research on a number of items but there had not been much co-ordination so far between the institutions and the industry. He appealed to the research institutions as well as the manufacturers to put their heads together and suggested the establishment of a Chemical and Pharmaceutical Research Advisory Board consisting of representatives of the Indian Chemical Manufacturers' Association and of research institutions for exchanging views and advising the institutions about the subjects on which researches would be useful to the industry.

Coming to the handicaps under which the pharmaceutical industry in this country is labouring, Sir P. C. Ray stated that some of the provincial governments still hesitated and refused to implement the recommendations of the excise conference held in 1937. For instance, the Government of Bombay refused to reduce excise duty on spirituous medicinal preparations that might be used for other than medicinal purposes and toilet preparations and perfumes from Rs. 25-10 to Rs. 17-8. The Government of Sind also refused to reduce the excise duty on absolute alcohol and rectified spirit. He urged these governments to take steps to translate into action what they themselves approved at the excise conference, failing which he suggested that the Government of India, at whose initiative the conference met, should use their good offices to persuade these governments to implement the recommendations of the conference without delay.

The necessity of reducing high railway freight on raw drugs and medicines, which prevented the masses in India from getting cheaper medicines, was also emphasized. Coming to the activities of the Medical Stores Depôts, Sir P. C. Ray stated that although the requirements of the government in respect of medicines had considerably increased, the manufacturers were not benefited by the increase and the production of several items at the depôts was increased. There was no reason, according to him, why the manufacture of tinctures, spirituous preparations and extracts should be continued and extended at the depôts, when the drug industry was able to meet the normal requirements of the country both civil as well as military, the quality was reliable, and the prices were also cheaper.

While congratulating the Government of India for enacting the Drugs Act, 1940, Sir P. C. Ray regretted that the Government of India failed to appreciate the importance of having on the Drugs Technical Advisory Board representatives of the manufacturers. He also requested the Government of India to make arrangements with Indian States for enacting similar legislations or for adopting the Drugs Act, by the time the Act was enforced in British India.

### PRIZE ESSAYS

At a meeting of the subscribers of Sir Bhalchandra Krishna, Kt., memorial fund held on the 11th July, 1924, the following resolution was adopted:—

'That from the funds collected to perpetuate the memory of the late Sir Bhalchandra Krishna, Kt., a memorial prize medal be founded to be awarded every

year on the anniversary of his death to a member of the medical profession who submits a thesis or delivers a lecture on any medical subject before a meeting of the medical profession to be held under the auspices of the Bombay Medical Union, preference to be given to one who submits any original or research work especially with reference to indigenous medicine on western lines.'

In consonance with the above resolution, members of the profession are invited to submit a thesis or a paper by the 15th March, 1941, for submission to a selection committee for making the above award.

The thesis or paper will have to be read by the prizeman on the day of the award at a meeting of the profession to be held in accordance with the above resolution.

The following subject has been selected by the Bombay Medical Union for competitive thesis for the gold medal called the Dr. B. S. Shroff Memorial Gold Medal of the Bombay Medical Union for 1940:—

'The question of mortality in infants and children in India, laying special emphasis on measures to control it, and on detailed treatment of the various diseases causing it.'

The competitor must be (i) a duly qualified member of the medical profession holding a degree or degrees and diplomas from Indian and other Universities created by statute, or (ii) a duly qualified member of the medical profession holding the diploma of membership of College of Physicians and Surgeons of Bombay.

The thesis must be sent in six clear typed copies so as to reach the Honorary Secretaries, Bombay Medical Union, Blavatsky Lodge Building, French Bridge, Chowpatty, Bombay 7, on or before the 31st December, 1940.

The thesis should be designated by a motto instead of the writer's name and should be accompanied by a sealed cover containing the name of the writer and his post-office address. The name of the prize, the year of competition, the subject of the thesis, and the writer's motto should be superscribed on the cover.

No study or essay that has been published in the medical press or elsewhere will be considered eligible for the prize, and no contribution offered in one year will be accepted in any subsequent year unless it includes evidence of further work.

The accepted thesis shall be the property of the Bombay Medical Union.

All other theses shall be returned if not accepted provided the return postage expenses are paid in advance by the writer.

In the award of the prize to the successful candidate, the decision of the committee shall be final.

#### MEMBERS OF THE ACADEMIC COUNCIL OF THE DELHI UNIVERSITY

In pursuance of item (V) of sub-clause (1) of clause 5 of the First Statutes set out in the Schedule to the Delhi University Act, 1922 (VIII of 1922), His Excellency the Chancellor of the Delhi University is pleased to appoint the persons hereinafter named to be members of the Academic Council of the said University:—

Major-General G. G. Jolly, C.I.E., K.H.P., Director-General, Indian Medical Service.

#### ORDER OF ST. JOHN OF JERUSALEM

The King has been graciously pleased to sanction the following promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem:—

##### *As Knight*

Major-General Ernest William Charles Bradfield, C.I.E., O.B.E., K.H.S., I.M.S.

##### *As Officer (Brother)*

Colonel Thomas Crawford Boyd, M.R.C.P.I., F.R.C.S.I., D.P.H., I.M.S.

#### *As Serving Brother*

Lieut.-Colonel Robert Forrester Douglas MacGregor, M.C., M.B., M.R.C.P.E., I.M.S.

#### THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

THE following students are declared to have passed the L.T.M. Examination, Session 1940.

##### *Passed*

(Arranged in alphabetical order)

Musaddilal Aggarwal, L.M.F., junior honorary house surgeon, Chittaranjan Hospital, Calcutta.

Krishanlal Anand, L.S.M.F., private practitioner.

Satya Brata Bagchi, L.M.F., medical officer, Union Board Charitable Dispensary, Saidpur.

Rabindra Nath Banerjee, L.M.F., private practitioner.

Susanta Kumar Bhattacharjee, L.M.F., private practitioner.

Gobinda Chandra Bhattacharyya, L.M.F., house physician, Chittaranjan Hospital, Calcutta.

Hari Pada Chattopadhyaya, L.M.F., clinical assistant, Laboratory, S. K. Hospital, Mymensingh.

Bhupendra Kumar Chowdhury, L.M.F., private practitioner.

Ajit Kumar Das, L.M.F., private practitioner.

Sukhendra Kumar Das, L.M.F., private practitioner.

Hari Narayan Das Gupta, L.M.F., epidemic doctor, Darjeeling District Board.

Upendra Nath Das Gupta, L.M.F., private practitioner.

Gopal Chandra De, L.M.F., private practitioner.

Jyotirindra Nath Deb, L.M.F., private practitioner.

Debi Lal, L.M.P., sub-assistant surgeon, Victoria Hospital, Ajmere.

Prafulla Kumar Dora, L.M.P., honorary sub-assistant surgeon, Bargarh Dispensary.

Ganga Prasad, L.M.F., private practitioner.

Bimal Kumar Ghosh I, L.M.F., private practitioner.

Narendranath Ghosh, L.M.F., private practitioner.

Sukumar Ghosh, L.M.P., honorary physician, Purnea Hospital, Bihar.

Jodhraj Gupta, L.M.P., medical officer in-charge, Manglaur Dispensary, Saharanpur.

Sudhir Kumar Khastgir, L.M.F., private practitioner.

Baij Nath Khanna, L.M.F., private practitioner.

Dattatray Balvant Kothari, L.M.P., private practitioner.

Amitabha Maitra, L.M.F., house surgeon, Sadar Hospital, Berhampore.

Sasanka Shekhar Majumdar, L.M.F., sub-assistant surgeon, B. N. Ry.

Hari Narhar Mandke, L.M.P., private practitioner.

Sarat Chandra Misra, L.M.P., sub-assistant surgeon, Government of Orissa.

## CORRIGENDUM

## REPORT OF AN ENDOCRINE CLINIC: SPACKMAN

In the above paper which appeared in our September issue, p. 555, under the heading *Disorders of lactation*, 2nd paragraph, the last three lines read 'The effect is not impressive and begins within 24 hours, the injections occasionally are rather painful' should read 'The effect is most impressive and begins within 24 hours; the injections occasionally are rather painful'. The mistake originated through a typing error in the author's typescript.

## Current Topics

## Sulphathiazole

(From *The Lancet*, Vol. I, 11th May, 1940, p. 883)

It has been freely predicted that the successes of sulphanilamide and sulphapyridine in the treatment of bacterial infections would lead to therapeutic claims for other similar compounds which the chemists can readily prepare. Such a compound is 2-(para-amino-benzene-sulphonamido) thiazole, a preparation in which sulphanilamide is linked to thiazole, a heterocyclic compound, in the same way as it is linked with pyridine in sulphapyridine.

Sulphathiazole.

Sulphapyridine.

This preparation, provisionally called sulphathiazole, and its 4-methyl derivative (sulphamethylthiazole) have been distributed in America for experimental and clinical trial, although not yet released in the open market. Early tests suggested that sulphathiazole and

... more effective than sulphapyridine in the treatment of bacterial infections, and Helmholz has lately shown that *in vitro* the urine of patients receiving these drugs is bactericidal for both *Staphylococcus aureus* and *Streptococcus faecalis*. Another report from the Mayo Clinic on the results obtained with these two preparations in urinary infections caused by coliform bacilli (15 cases), *Streptococcus faecalis* (7 cases) and *Staphylococcus aureus* (5 cases) claims a 65 per cent cure rate. These results naturally prompt us to ask how these new drugs compare in activity and toxicity with those already in use for the treatment of bacterial infections. Perrin Long has presented a report to the American Council on Pharmacy and Chemistry which summarizes the available American data on these two points. It seems that in experimental pneumococcal infections the new drugs are rather less effective than sulphapyridine, in streptococcal infections they are about equal, and in staphylococcal infections (which are more difficult to assess) they are somewhat superior to sulphapyridine. Clinical data from America on the treatment of infections due to these bacteria are, with the possible exception of staphylococcal infections, still too scanty to allow an opinion on the usefulness of these preparations. However, a similar product, called Ciba 3714, has been clinically tested, in doses similar to those adopted for sulphapyridine, in a variety of bacterial infections by Gsell. Among 60 patients with pneumonia, of whom 23 had lobar pneumonia and the others bronchopneumonia and post-influenzal pneumonia, there was in general a rapid amelioration of symptoms and only 1 death, while 7 cases of acute cerebrospinal fever

all recovered. The concentration of the drug in the cerebrospinal fluid was 4-6 mg. per cent, some 50-60 per cent of the blood level. Cases of gonorrhoea, erysipelas, and coliform pyelitis and cystitis were also treated with success but 2 cases of generalized staphylococcal infection failed to respond. Staphylococcal infections are indeed likely to be a stumbling-block for ... : cause of their great tendency to form ... . If it is to be effective the drug must be given very early, for without surgical drainage it has little chance of success once pus has accumulated.

As regards its pharmacology and toxicity, sulphathiazole is readily absorbed from the bowel and quickly excreted, while a smaller percentage of the drug becomes acetylated and inert than is the case with sulphapyridine, although experience with the latter drug shows that ... conjugated drug varies greatly in ... . With doses of 4 to 6 g. of sulphathiazole per day the concentration in the blood seems to range between 3 and 5 mg. per cent (the Swiss workers claim higher levels), and higher concentrations are difficult to maintain despite increases in the amount of drug prescribed. This is presumably due to the rapid excretion of the drug, and may be a point of some practical importance, especially in severe infections. Experimentally in mice the chronic toxicity of sulphathiazole is greater than that of sulphapyridine, while the sodium salt of the methyl derivative is as acutely toxic as the corresponding salt of sulphapyridine. In man, nausea and vomiting are less common than with sulphapyridine, and according to both the Swiss and American investigators are never severe enough to interfere with the use of the drug, even with doses of 8-12 g. per day. If confirmed, this is a point definitely in its favour. Drug rashes and drug fever are quite common, and some patients have shown an acute congestion of conjunctiva and sclera in association with a rash resembling that of erythema nodosum. Haematuria has been noted in several cases, and is more likely to occur with sulphamethylthiazole which is poorly soluble. In other words, the toxic effects are much the same as those produced by sulphapyridine except that the latter drug is more liable to cause vomiting.

The position with regard to the new preparations is admirably summed up by Lond: 'The evaluation of these new chemotherapeutic compounds', he says, 'will necessitate extensive experimental and clinical investigations in order to determine their efficiency in the control of infections and their clinical toxic manifestations. Until the time when such data are in hand, it is to be hoped that enthusiasms do not outrun common sense'.

[In *The Lancet*, i, 18th May, 1940, p. 946, a correspondent (W. R. Throver) pointed out that sulphathiazole was prepared in the laboratories of May and Baker early in 1938. They found it less effective against pneumococcal infections than M. & B. 693, but are now re-investigating its anti-staphylococcal value.]

## Comparative Effects of Phenobarbital and Dilantin Sodium in the Treatment of Epilepsy

By L. J. ROBINSON, M.D.

and

R. OSGOOD, M.D.

(From the *Journal of the American Medical Association*, Vol. CXIV, 6th April, 1940, p. 1334)

MATERIAL for this study comprised a group of 100 patients at the Monson State Hospital, who were selected on the basis of frequency and regularity of convulsive attacks regardless of diagnosis, age, sex, age of onset, duration of attacks, mental status, physical condition or previous medication. The vast majority of patients had been having ten or more seizures per month regularly. Medication previous to this study had consisted of phenobarbital in doses of 3 grains (0.2 gm.) or less daily.

The effect of treatment by phenobarbital or dilantin sodium was evaluated on the basis of effect on seizures, salutary effects, effects on the general condition of the patient, and untoward effects. The therapeutic response was graded as follows:—

Group 1. Complete control of, or marked reduction in, the number of seizures, with absence of untoward effects or only slight and easily managed untoward effects.

Group 2. Moderate reduction in the number of seizures with salutary effects or easily controlled untoward effects.

Group 3. No appreciable reduction in the number of seizures or increased number of seizures, with or without untoward effects; or marked untoward effects which could be managed only by terminating treatment and which overshadowed any anticonvulsant and/or salutary effects.

Group 4. Indeterminate, no definite favourable or unfavourable effects being noted during the period of observation.

Our study divided itself into the following three phases: (1) treatment with phenobarbital alone, (2) treatment with dilantin sodium alone and (3) treatment with a combination of phenobarbital and dilantin sodium.

### PHENOBARBITAL IN EPILEPSY

The 100 patients, representing the total number of cases included in our complete study, were given phenobarbital in gradually increasing doses either until the optimal anticonvulsant effect was obtained or until untoward effects contra-indicated further increases or demanded reduction in dosage. Thirty-seven of the 100 patients derived marked benefit from the larger doses of phenobarbital alone and are classed as P 1 (P refers to phenobarbital and the numeral 1 to group 1 in the classification previously indicated). During the period of increased phenobarbital dosage, the maximal and optimal doses of phenobarbital ranged from  $3\frac{1}{2}$  to  $11\frac{1}{2}$  grains (0.2 to 0.7 gm.) a day. Twenty-eight patients are taking 6 grains (0.4 gm.) or more of phenobarbital a day and twelve are receiving 9 grains (0.6 gm.) or more of phenobarbital a day. Twenty-seven of the thirty-seven patients have been on the larger doses of phenobarbital for from eleven to fifteen months and ten for from three to ten months. Only a few patients experienced untoward effects, which have been slight, transient and easily managed. Salutary effects have been common, consisting of increased activity, alertness, desire and willingness to work, and greater interest in surroundings.

### DILANTIN SODIUM IN EPILEPSY

Fifty-six patients who were not greatly benefited by large doses of phenobarbital were given dilantin sodium in gradually increasing doses, ranging from 3 to  $13\frac{1}{2}$  grains (0.2 to 0.9 gm., or two to nine capsules). The criteria used for changing medication from phenobarbital to dilantin sodium were (1) complete failure of large doses of phenobarbital to lessen frequency of

seizures, (2) only slight to moderate reduction in the number of seizures and (3) untoward effects associated with large doses of phenobarbital, which either prevented raising phenobarbital to the anticonvulsant level or which overshadowed any favourable anticonvulsant effects.

Forty-five of the fifty-six patients have been followed for from two to eight and one-half months while taking dilantin sodium and eleven for from three weeks to two months. The length of time these patients had been receiving the larger doses of phenobarbital varied from three weeks to six and one-half months.

Evaluation of the results obtained with this group of patients is summarized as follows:—

Twelve, or 21.4 per cent, obtained excellent improvement on dilantin sodium with regard to both anticonvulsant and salutary effects (group 1). Of these twelve patients only two did equally well on phenobarbital.

Seventeen patients, or 30.3 per cent, showed moderate improvement on dilantin sodium (group 2). Of these seventeen patients, eleven did equally well on phenobarbital and six were definitely worse on phenobarbital.

Totalling the number of patients in groups 1 and 2, we find that twenty-nine, or 51.7 per cent, were much improved on dilantin sodium. This includes thirteen patients who did as well on phenobarbital.

Twenty-seven patients, or 48.2 per cent, did poorly on dilantin sodium (group 3). Of these twenty-seven patients, four did moderately well on phenobarbital, and twenty-three did as poorly on phenobarbital.

Whatever results have been obtained with dilantin sodium have been obtained in a group of patients all but two of whom were selected on the basis of failure to respond satisfactorily to large doses of phenobarbital. The results with dilantin sodium impress us as especially significant because we are inclined to believe that any anticonvulsant drug is unlikely to show up to its best advantage in many institutional patients of this type.

There was no correlation between results with dilantin sodium and dosage, for some patients taking as little as  $4\frac{1}{2}$  grains (0.3 gm. or three capsules) of dilantin sodium did very well, while others receiving as much as  $13\frac{1}{2}$  grains (nine capsules) did not do well. The optimal dose varied from 3 to  $10\frac{1}{2}$  grains (0.2 to 0.7 gm., or two to seven capsules). Likewise there was no correlation between the size of the dose of phenobarbital and the results obtained. The optimal dose of phenobarbital varied between 3 and 11 grains.

While, to be sure, most patients in this series experienced toxic effects from the larger doses of phenobarbital or from dilantin sodium at some time, it should be kept in mind that, in the very nature of this investigation, unless an appreciable anticonvulsant effect was produced by a non-toxic dose, it was necessary to increase medication steadily to the point of toxicity.

Lethargy, ataxia, anorexia, nystagmus and tremor were toxic effects common to phenobarbital and dilantin sodium; whereas epigastric distress, ocular pain, diplopia and hyperplasia of the gums were related solely to dilantin sodium. Benzedrine sulphate was found effective in controlling apathy and lethargy, and sodium bicarbonate in controlling nausea and vomiting. The other untoward effects were controlled by decreasing the dose of the drug. A distinct advantage of dilantin sodium is the lack of sedative effects except in toxic doses, which is in marked contrast to the effects of phenobarbital in the larger therapeutic doses. None of our patients had dermatitis while on dilantin sodium, and no serious untoward effects were associated with dilantin sodium therapy.

From experience gained during the course of this study, we believe that untoward effects could often have been considerably lessened had we increased the doses of phenobarbital and dilantin sodium more slowly than was done and temporarily reduced the doses more often during periods of inactivity. During the first part of the period in which we used dilantin sodium we gave some patients as much as nine capsules a day ( $13\frac{1}{2}$  grains), since we did not know what the limit of dosage should be. Untoward effects were common and almost invariable when more than six capsules

Can bend knees to about 90 degrees and stretch them out. Can sit up alone, using his arms to help. Wheels himself in chair with comfort.

*Case 9.*—Male, aged 14. Advanced case. Could not walk, chiefly due to contractures of legs. Arms very weak. Could just use wheeled chair. Could not get into bath. Full sexual development. After five months' treatment he wheels himself about in his chair freely. All muscles in arms much stronger. Can get into bath.

*Case 10.*—Male, aged 9. Early case. Younger brother affected. Getting worse in spite of massage for last year. Stumbled often when running. Stairs difficult. Calves typical. After three months' treatment and massage calves much softer. He appears better to me, though his mother is dubious.

*Case 11.*—Male, aged 22. Advanced case. Great weakness of arms and shoulder girdle. Contractures of thighs. Leg muscles not greatly affected. Normal sexual development. After nine weeks' treatment legs stronger, arms very much stronger. For the next four months treatment was stopped, and both arms and legs were much weaker.

*Case 12.*—Male, aged 8. Early case. Slight improvement in walking reported in a month.

*Case 13.*—Male, aged 30. Advanced case. Condition first noticed nineteen years ago. Hardly any change in last three years. Can just stand and just shave. Sexual development normal. No effect from six weeks' treatment.

*Case 14.*—Male, aged 14. Advanced case. Mentally deficient. Full sexual development. No change with four months' treatment.

*Case 15.*—Male, aged 10. Advanced case. Bed-ridden. Treatment and massage had no effect in a month.

*Case 16.*—Male, aged 18. Very advanced case. Gross wasting of all muscles. Could not move or feed himself. Sexual development normal. Six weeks' treatment had no effect.

*Case 17.*—Male, aged 17. Advanced case. Bed-ridden. Could just feed himself. Sexual development normal. Six weeks' treatment had no effect.

*Case 18.*—Male, aged 10. Very last stages. Died after a month's treatment.

#### AMYOTROPHIC LATERAL SCLEROSIS

*Case 19.*—Male, aged 49. Six years ago whole of right hand suddenly became numb and paralysed, with great wasting. Arm not affected. Apparently diagnosed as brachial neuritis. Right hand has slowly improved since. Six months ago left hand started to feel weak and to waste and legs felt tired, the condition slowly getting worse. Amyotrophic lateral sclerosis was diagnosed by a consulting physician and his own doctor. On examination he appeared to be a typical case. There was gross wasting of all muscles of the right hand. The left hand had some wasting of the thenar muscles and the interossei but no fibrillation. There was extensive fibrillation of all the muscles of both legs and feet. All reflexes were normal. There were no sensory changes. Two months after beginning treatment there was no longer any feeling of tiredness in his legs, and his hands if anything were stronger. The left thenar muscles appeared less wasted. Fibrillation was worse in the legs. A month later there was definitely more muscle both in the left hand and the right, and the fibrillation in the legs had decreased. After seven months' treatment, 'he has forgotten his left hand was ever weak'. His legs feel normal. On examination his left hand appears normal, his right much stronger and with an increase in muscle. There was no fibrillation in his right leg or foot, and very little in his left.

*Case 20.*—Female, aged 65. Six months' history of progressive weakness and stiffness of legs and weak hands. On examination could just walk across room. Legs spastic, extensor response mild fibrillation. Hands slightly wasted, worse after a month's rather

uncertain treatment; but after another two months' treatment is reported to be improving.

*Case 21.*—Female, aged 45. Treatment was started in the last stages of bulbar paralysis, and the patient died six weeks later.

*Case 22.*—Female, aged 38. Treatment was started in the last stages of bulbar paralysis, and the patient died four weeks later.

#### TABES DORSALIS

*Cases 23 and 24.*—Two cases of tabes dorsalis, one blind and both bed-ridden, were treated for eight weeks for very severe lightning pains and abdominal crises. Neither improved.

#### PERONEAL MUSCULAR ATROPHY

*Case 25.*—Male, aged 18. His maternal uncle died of peroneal muscular atrophy. The patient developed symptoms when he was 12, which have progressed very slowly, neither hands nor feet being very affected. His sexual development is normal. Two months' treatment has had no effect. The progress of the disease is too slow to know if it has been checked or can be improved.

#### AMYOTONIA CONGENITA

*Case 26.*—Female, aged 2½. There had been extreme muscular weakness since birth. The child could just raise her arms and draw up her legs but could not roll over or raise her head. There was gross kyphosis. After three months' treatment and massage she could kick her legs in the air and her arms were much stronger. She could raise her head and could roll over. Vitamin E was then stopped, and her improvement appeared to be slower.

#### DISCUSSION

In the group of the myopathies—chiefly children—the results of treatment with vitamin E were remarkable. Every patient improved who was treated for more than six weeks, except case 14, who was mentally deficient. When it is remembered that these cases should have got worse or at least remained the same, such definite improvement in 12 cases out of 13 must mean that this treatment promises success in a disease which has always, until now, been hopeless. The slowness, however, of the recovery and therefore the necessity for prolonged treatment must be emphasized. Recovery has continued in case 1 for eighteen months and in no case has shown any signs of stopping. How far it can go is as yet unknown, but there seems to be no reason why patients in an early stage should not recover completely provided that they continue to be treated. The diagnosis, however, should be definite before treatment is begun; otherwise an apparently normal child may continue to be treated to guard against a relapse of a disease he may never have had. This danger of a relapse is shown in case 11.

Even bed-ridden patients show improvement. Since these children often have a long period of growth still before them, it seems possible that they may recover enough to lead comparatively normal lives. Since much of the disability in advanced cases may be due to contractures, these should be dealt with surgically at the beginning of treatment so that the recovering muscles can function normally.

No ill effects or sexual stimulation have been seen during treatment.

Not enough patients with amyotrophic lateral sclerosis have been treated for the results to be definite, but on the whole I think they are promising. Case 19, in whom the disease is arrested and who feels normal again, has no obvious involvement of upper neurones. Case 20 has been treated for three months, and is reported to be improving. The two patients who died had advanced bulbar involvement before treatment began.

The two cases of tabes (23 and 24) were too advanced for the negative results to be of any value, but I still believe vitamin E will be found of value in this condition. The man with peroneal muscular atrophy

(case 25) has not been treated long enough for any conclusions to be drawn. The small girl with amyotonia congenita (case 26) appeared to have been greatly improved.

It appears reasonable to suggest that in all degenerations of the muscular or nervous systems, such as disseminated sclerosis, a large supply of vitamin E should be of value; for, though a deficiency may not be the cause, yet a sick cell should have an abundance of what is necessary for its life. It also may be that in children who have a diet rich in vitamin E the anterior-horn cells would be more resistant to infantile paralysis; hence, at least during epidemics, the vitamin should be used as a protection.

The clinical results reported here strongly confirm the deductions which Einarson and Ringsted made from their laboratory work. The discovery of the importance of vitamin E in the treatment of muscular and nervous diseases appears to be revolutionary. It opens up new lines of thought and treatment in many diseases. It appears indeed to be one of the great advances in general medicine of the century.

#### SUMMARY

The laboratory work of Einarson and Ringsted is discussed, and the reasons are given for their suggestion that the muscular dystrophies, amyotrophic lateral sclerosis, and tabes dorsalis are deficiency diseases due to lack of vitamin E.

Normal human diets may be poor in vitamin E.

The results of giving vitamin E for muscular dystrophy and amyotrophic lateral sclerosis support the contention that these are deficiency diseases and curable.

### Medical Aspects of the Use of Food

By MAJOR-GENERAL SIR ROBERT McCARRISON,  
C.I.E., M.D., D.S.C., LL.D., F.R.C.P.

(Abstracted from the *British Medical Journal*,  
Vol. I, 15th June, 1940, p. 984)

THE medical aspects of the use of food are manifold, and include such matters as food allergy, food poisoning, microbic and parasitic agents conveyed to man in food, and the treatment of disease by food. I shall confine myself to the relation of food as a whole to the preservation of health, the constituents of a properly constituted diet, the relation of such constituents to the structure and functions of the living body, and the effects of the inadequate supply or utilization of these essentials in causing disease.

Food may be defined as anything which when taken into the alimentary tract provides, on digestion, materials for the energy requirements, growth, maintenance, repair, and regulation of the vital activities of the body. The materials are many: proteins, fats, carbohydrates, minerals, vitamins, pigments, blood-forming substances, extractives, and flavouring matters. The food must also contain a certain amount of roughage to stimulate intestinal movements, and there is something, again, in the freshness of food which gives it a health-promoting influence. No single food-stuff contains all these properties. Even milk, which is the nearest approach to a complete food, lacks one and may lack more of them. A properly constituted diet is such a combination as contains them all in proper quantity and proportion.

#### NATURAL FOODSTUFFS

In order to learn what a properly constituted diet is we may consider the diet of the peoples of India, as it was among them that most of my own work was done. With the exception of the races whose staple article of food is rice—the nutritive value of which is usually debased by various treatments before use—the Indian peoples have national diets composed of the unsophisticated foodstuffs which their fields and pastures provide. Some of the peoples of Northern India are unsurpassed for perfection of physique, powers of endurance, and resistance to disease. Others,

particularly the rice-eating races of the west and south, are of poor physique, low powers of endurance, and subject to much disease. Maladies such as tuberculosis, leprosy, dysentery, and many others are more common in the south and east than in the north. McCay came to the conclusion that food was the all-important determining influence, and the conclusion has been confirmed by the results of my own experiments.

The best diet was found to be one similar to that used by certain hardy, agile, vigorous races of Northern India—a diet composed of freshly ground whole-wheat flour made into cakes of unleavened bread, milk, butter, pulses, fresh green leaf and root vegetables, and fruit, with meat occasionally. Many other experiments were made which showed that when previously healthy animals were fed on improperly constituted diets, such as are habitually used by human beings, they developed many of the diseases from which these human beings tend to suffer—diseases of the bony framework of the body, of the skin and membranes, of the glands, of the gastro-intestinal tract, of the lungs, of the nerves. All these were produced in animals under experimental conditions by feeding them on faulty human diets.

A properly constituted diet is one made up of whole cereal grains, milk and its products, pulses, green leaf and root vegetables, fruit, with eggs or meat, or both, on occasion. The dependence of health on a diet composed of these natural foodstuffs or others of like nutritive value is the essence of the whole matter of food in relation to health and of food deficiency in relation to disease. It relieves the layman, or for that matter the doctor, of all or nearly all anxiety as to whether the food contains this or that constituent. It provides both for essential constituents of food already known and for those not yet known. There is, however, this proviso—that the foodstuffs must be produced on soils that are not themselves lacking in essential mineral and other substances, nor themselves rich in substances harmful to the body. Another proviso is that, owing to lack of sunshine at certain seasons of the year in this country, and to the sparse distribution of vitamin D among foodstuffs, it is necessary to add cod-liver oil or halibut-liver oil to the list given above.

For many years it was thought that proteins, minerals, fats, and carbohydrates sufficed for the growth, maintenance, repair, and energy requirements of the body. It is now known they do not suffice, and with new analysis and methods of investigation many other essential constituents of food have been found. Nevertheless, this older knowledge showed the fundamental relations of energy-yielding constituents to vital processes, also the importance of the protein factor in nutrition, and this older knowledge still stands.

#### THE VITAMINS

For some years following the discovery of vitamins and of their deficiency in the food as the cause of the maladies now known as the deficiency diseases, certain limiting terms—anti-this and anti-that—were attached to them. But further research showed that they had much else to do besides the prevention of these diseases. It is this 'much else' that concerns us, for these maladies result from the complete or almost complete absence of the respective vitamins from the food, a contingency rarely met with in this country. It is not with complete but with partial deficiency that we are chiefly concerned. This partial deficiency is relatively common, certainly among the poorer classes, and it is becoming generally recognized that much sub-normal health and development and even incidence of disease are associated with it.

It is well, therefore, to have a working knowledge of the functions of the more important vitamins and minerals and of the effects on the body of their insufficient supply or utilization. For just as the knowledgeable gardener knows when his plants are not thriving for want of some nutrient, so should the knowledgeable parent know when her children are not thriving for the same reason. It is extraordinary how quickly one's powers of observation grow in this respect. I find myself saying of this or that child or

young person: You need lime, you iron, you vitamin B<sub>1</sub>, you vitamin A, you vitamin C, and you all of them.

*Vitamin A* is essential to growth and development of the young. It maintains the normal structure of mucous membranes, protecting them against infection. It controls the content of visual purple in the retina and has important relations to the enamel-forming organs of the teeth and to the structure of the blood, bone marrow, certain glands, and the nervous system. Its deficiency gives rise to poor growth of the body, eye affections, night blindness, dry or scaly skin, enamel-poor teeth, and to inflammatory states of mucous or other membranes. Rich sources of the pre-formed vitamin are animal fats, cod-liver oil, milk, butter, cream, liver, egg, and herring. Rich sources of its precursor—carotene—from which it is formed in the body itself, are carrots and fresh green vegetables.

*Vitamin B* is a complex of many vitamins. Vitamin B<sub>1</sub>—now known as aneurin or thiamin—is necessary for the structural and functional efficiency of the nervous system; consequently its adequate supply is essential to all neuro-muscular activities, including those of the heart, the stomach, and the bowels. The structural and functional efficiency of the adrenal gland depends largely upon it. It is related in a specific way to carbohydrate metabolism and is essential to growth. When absent from or very deficient in the diet the disease known as beri-beri arises. Its insufficient consumption or utilization may give rise to anorexia, poor growth, lack of vigour, fretfulness or nervousness, cardiac and bowel irregularities, and neuritis. The chief sources of vitamin B<sub>1</sub> are yeast, marmite, whole cereal grains, egg yolk, liver, fresh green vegetables, and tomatoes. The body, in the course of its chemical activities, uses up the vitamin and does not store it to any extent; its constant and liberal replacement is therefore necessary. The chief cause of its insufficiency in the diets of our people is the almost universal use of white flour, from which it is lacking, in preference to whole-meal flour, in which it is abundantly present, and the excessive consumption of vitaminless sugar.

The other fractions of the vitamin B complex may be grouped together. Their functions include the activation of combustion processes, the promotion of growth, blood-forming activities, and a very important contribution to the maintenance of health of the skin, the mucous membranes, the gastro-intestinal tract, liver, heart, nervous system, and mind. One or more fractions are concerned in preventing pellagra; another appears to have something to do with the prevention of cataract; and a third has blood-forming functions. Deficiency may give rise to buccal, lingual, and gastro-intestinal ailments and to anæmia. The chief sources of the complex are yeast, liver, kidney, muscle meat, egg, milk, and green vegetables.

*Vitamin C* (ascorbic acid) has an important part to play in the chemistry of oxidation-reduction processes. It maintains the structural integrity of the cement substance which holds the cells of the body together. Consequently it has a close concern with the structural integrity of the capillaries, bones, teeth, gastro-intestinal tract, and mucous membranes. Its absence from the diet gives rise to scurvy. Its insufficient supply may cause hæmorrhage into, or easy bruising of, exposed parts of the body, sallowness and unhealthiness of the skin, imperfections of the teeth, fragile bones, unhealthy gums, and gastro-intestinal disorder. Rich sources of the vitamin are parsley, chillies, orange and lemon juice, green leaf vegetables, and potatoes.

*Vitamin D* (calciferol) controls the absorption and utilization of calcium and phosphorus. Its adequate supply is therefore of the utmost importance to the normal structure of the bones and teeth. Its deficiency gives rise to rickets, dental disease, and to slow healing of fractures. It is sparsely distributed among foodstuffs, occurring in considerable quantities only in fish oils, egg, liver, milk, and butter, and therefore it is deficient in the diet of many people.

*Vitamin E* is the so-called 'anti-sterility vitamin', but it has other relations besides those to reproduction.

It is indispensable to growth and to bodily functions generally. Research tends to connect it with the pituitary body, that master-gland of the endocrine system. Its chief source is wheat-germ oil.

The other vitamins I must pass by with the general remark that between them they contribute a considerable share to the health of the skin, the efficiency of the functions of reproduction and lactation, the maintenance of the normal composition of the blood, the prevention of hæmorrhage, and the promotion of growth.

#### MINERAL CONSTITUENTS

The mineral constituents of food consist of some twenty elements, of which eleven are known to be essential to vital processes. In general their functions are to provide building materials for the fabric of the body and to regulate various functions. Some enter into the composition of all cells; others form the major part of the skeleton and teeth. In fulfilment of their regulating functions they have various parts to play: all are concerned in controlling the normal exchanges of body fluids and the permeability of the cell membranes; some maintain and regulate the neutrality of the blood, others the normal contractility of the muscles and excitability of the nerves; some enter into the composition of the digestive juices, others take part in the transport of oxygen from the lungs to the tissues and of carbon dioxide from the tissues to the lungs, thus making oxidation process possible. Indeed, the more the mineral constituents of food are studied the more important is their rôle in nutrition found to be.

From the point of view of dietary construction four of these mineral elements—calcium, phosphorus, iron, and iodine—are of outstanding importance, not only because of their own functions but because they are those most likely to be present in the average diet in insufficient quantities. In the diet the amounts of these minerals should be adjusted with the same care as is given to those of proteins, carbohydrates, fats, and vitamins, and in estimating the quantities of essential components in any diet the calculations should always include these four elements. By making provision for their ample supply no serious deficiency of any other mineral essential is likely to arise.

*Calcium* is a chief constituent of the bones and teeth. It controls the contractility of muscle, and the rhythmic beat of the heart depends to a great extent upon it. It maintains the normal response of the nerves to stimuli, preventing their hyper-irritability, preserves the clotting power of the blood, and sustains the capillary circulation. Calcium is made use of in the body to the extent of about 0.68 gramme daily, but to allow a fair margin the food should provide at least one gramme a day, and even more for expectant mothers and growing children. The insufficient supply of calcium is one of the commonest of all food faults in this country. It is difficult for the growing child under modern conditions to obtain enough calcium unless the diet contains at least a pint of milk a day. The diet of pregnant women is often dangerously low in calcium. Recent researches in America have shown that such women need 1.6 grammes daily; often they do not receive one-half of this amount. Deficiency leads, in growing children, to imperfect building of bones and teeth, to rickets and all its attendant consequences, and to malformation or mal-alignment of the vertebræ. Not infrequently the normal calcium content of the blood, on which so many bodily activities rely, is being maintained at the expense of decalcification elsewhere—of teeth, alveoli, and bones. Want of calcium leads also to nervous excitability and to tetany, to impaired muscular activity, and to disturbance of cardiac rhythm and of the neutrality of the blood. Foods rich in calcium are (weight for weight and in descending order of richness) cheese, turnip-top greens, black treacle, almonds, water-cress, dried figs, egg yolk, milk, beans, lentils, oatmeal, turnips, whole wheat, and green leafy vegetables.

*Phosphorus* is an essential component of the nuclei of all cells, and therefore plays a conspicuous part in

all cellular activities. It should be provided in the diet to the extent of 1.5 grammes daily, and increased during pregnancy. Deficiency may lead to stunting of growth, poor bone formation, softening of bone, a type of rickets, tooth decay, disturbance of neutrality of blood, and depression of vital processes generally. Foods rich in phosphorus are cheese, egg yolk, oatmeal, lean meat, chocolate, almonds, nuts, dried peas and beans, whole wheat, liver, milk, fresh beans, spinach, brussels sprouts, currants, raisins, and potatoes.

*Iron* is also concerned in the control of all cellular activities. It is a component of haemoglobin, the carrier of oxygen from the lungs to the tissue cells. The diet should contain at least 15 milligrammes of iron daily, increased to 20 during pregnancy. It is estimated that the iron content of the average diet in England is rarely more than 100 milligrammes, frequently as low as 5. In these circumstances anaemia is likely to arise. Foods rich in iron are lentils, egg yolk, liver, dried peas and beans, black treacle, oatmeal, whole wheat, dried currants, almonds, turnip-top greens, spinach, dried prunes, dates, figs, and raisins.

*Iodine* is an essential constituent of the thyroid gland and of its active principle, thyroxine. In normal circumstances the daily requirements of iodine are about one-thousandth of a milligramme. Growing children and pregnant and lactating women need more of it than others. Its deficiency or inadequate absorption or utilization gives rise to goitre and its tragic sequel, cretinism, in which bodily and mental development is gravely retarded. Foods rich in iodine are sea foods, cod-liver oil, eggs, goat's milk, fresh vegetables, and some condiments.

#### THE FUNCTION OF PROTEINS

Apart from water, proteins are the most abundant constituents of living cells. Their chief rôle in the body is to provide materials for its growth and for the repair of its tissues. Their continuous supply is, therefore, necessary, and this supply must be of the right kind, to furnish the requisite amino-acids, derivatives of proteins, from which the various tissues are built up. Besides their function as providers of building materials they also furnish a certain amount of energy. They are the source from which the body elaborates some enzymes for ferments, such as those concerned in the digestive processes, and catalytic agents needed for the speeding up of chemical processes.

The daily requirement of the body for proteins is approximately one gramme per kilogramme of normal body weight. More than this is an undesirable excess. Sources of them among animal foods are milk, meat, glandular organs, eggs, and fish; and among vegetable foods, legumes, whole cereal grains, seeds, nuts, and green vegetables. Those derived from animal sources are, in general, more suited to the needs of the human body than those derived from vegetable, but it is not necessary that the protein requirements of the body should be derived mainly from animal sources; it is sufficient if one-third is so derived. Nor is it necessary that 'good' proteins as distinct from second-class should be derived from meat. Those of milk are among the best of all proteins and well able to leaven the whole lump of those derived from vegetable foods. For this reason, among others, the use of milk and cheese as articles of diet should be greatly extended. Much greater use should also be made of the better-class vegetable proteins, such as those of the soya bean and whole wheat, and much less use of the flesh of animals. Apart from every other consideration, the use of meat as the main source of proteins is as uneconomical as it is unnecessary—but where flavour is, there will desire be also.

Insufficient ingestion, absorption, or assimilation of proteins, or of proteins of the right kind, will tend to degradation of vital processes—a degradation manifested in stunting of growth, poor physique, lack of energy, resource, and initiative, digestive disturbances, and impaired action of glandular organs. To these may be added a lowered resistance to infection. Severe degrees of protein starvation, associated as they often are with want of food in general, may give rise to a condition

known as 'malnutritional oedema', 'war oedema', or 'famine oedema', in which the body, in part or in whole, becomes water-logged.

#### PROTECTIVE FOODS

It will have been noted how frequently the names of certain foodstuffs—such as milk, green and root vegetables, and whole cereal grains—recur in the lists I have given to those rich in vitamins, minerals, and proteins. These are the protective foods, so called because they are rich in those substances which protect the body or its constituent parts against disturbance of structure or of function, or of both—that is to say, against disease. It is these foodstuffs which must be brought within the financial reach of everyone in the country and used by everyone if health is to be maintained. The last war resulted in a great increase in knowledge of the relation of food to nutrition and health; the present war already demonstrates the need to apply it—a need which day by day becomes more urgent.

Many factors interfere with the adequate supply or utilization of essential nutrients. Poverty, ignorance, indifference, habit, soil deficiencies, sophistication of natural foodstuffs, bad cooking, fads and fancies—all may interfere with adequate supply. Gastro-intestinal disorder and other bodily conditions may interfere with adequate utilization. In the presence of gastro-intestinal disorder defective utilization becomes dominant. Inadequate supply may itself impair appetite and set up gastro-intestinal disorder, thus interfering with utilization and establishing a vicious circle. It is rare that we have to deal only with a single deficiency in the diet. It is more usual for deficiencies to be multiple, and more usual still for multiple deficiencies—whether of vitamins or minerals or both—to be associated with the excessive richness of the food in carbohydrates. Thus the manifestations of ill-health resulting from the faulty food are compounded of the several effects of varying degrees of vitamin and mineral deficiency on the one hand and of carbohydrate excess on the other. Nor is this all, for infection by microbic agents usually contributes to the general morbidity.

#### DIETETIC MALNUTRITION

Malnutrition produced by faulty food should be spoken of as 'dietetic malnutrition'. It is widespread in its distribution, and is preventable only by readjusting our ways of life—social, agricultural, and economic—so as to ensure for everyone a diet that will satisfy physiological needs. Owing to the substitution of artificial feeding for mother's milk infants become subject to gastro-intestinal and pulmonary disease, to which they frequently succumb. Fretfulness, restlessness, anaemia, imperfect calcification and growth are other symptoms of malnutrition in infants. In early childhood malformation of the bones, dental defects, and abnormalities of the pharynx are alarmingly common and are consequences of dietetic malnutrition and faulty nurture. Consequent on malnutrition, children of this age have a lowered resistance to infections, are poorly grown, under height and weight, and have nervous systems that lack stability.

During adolescence the lowered resistance of the malnourished fosters the occurrence of tuberculosis. Girls reach womanhood with deformed pelvis which make child-bearing difficult or precarious, while faulty nutrition during pregnancy is a serious menace to both mother and child. Middle life and advancing age is for many a period of physiological decay and long suffering caused by chronic illness.

So from infancy and childhood through adolescence to adult life, dietetic malnutrition, aided often by infection, leaves its trail of morbidity, and this although the food faults may not be extreme. So long as they are sufficient in degree to impair the function of nutrition they will, sooner or later, directly or indirectly, give rise to disease. The constant drip will wear away the stone; the constant imperfection of nutrition, though this be relatively slight, will wear away the body. This dietetically caused imperfection of the

function of nutrition and the ailments resulting from it can be prevented by the use of a diet into which milk and its products, fresh green vegetables, root vegetables, particularly potatoes, and whole cereal grains, either in the form of oatmeal or of wholemeal bread, or both, largely enter. Thus we arrive, though by another path, at the same conclusion to which Professor J. C. Drummond's historical survey had led us.

## Clinical Studies in Non-Dysenteric Intestinal Amœbiasis

By JAMES J. SAPERO

(Abstracted from the *American Journal of Tropical Medicine*, Vol. XIX, November 1939, p. 497)

DIVERSE opinions are held regarding the pathogenic rôle of *Entamoeba histolytica* in cases of intestinal amœbiasis which present neither a present nor past history of dysentery. Certain clinicians tend to attach clinical significance only to the dysenteric manifestations of the organism; others attribute to *E. histolytica* a wide range of protean symptomatology. Although the viewpoints of the majority are at neither of these two extremes, there is a considerable lack of agreement as regards both the nature and the frequency of symptoms in amœbic infections and their clinical importance when dysentery is absent.

Dobell in his monograph states that probably less than 10 per cent of persons who become infected with *E. histolytica* ever suffer to any appreciable extent from their parasitism. Faust believes that 90 to 95 per cent of persons harbouring the organism are apparently symptomless carriers. More recently, Wenrich, Stabler, and Arneth noted little evidence of pathogenicity in carriers found in an examination of college students, and observed that a control group seemed to have as many or more signs of ill health than those in their series who were carriers of *E. histolytica*.

Findings contrary to these have been reported by other workers. Craig, who had had wide experience, states that about 65 per cent of carriers have had symptoms referable to their infection, and that these symptoms disappeared after the eradication of the parasite. Philpitschenko reports that one-half of 400 apparently healthy carriers found in a survey of Leningrad food handlers had various intestinal disorders. Johnstone and his co-workers found that 52 out of 92 infections among a prison group were associated with notable gastro-intestinal upsets.

In addition to the discrepancies in the frequency with which symptomatology is associated with *E. histolytica* infections, it is to be noted that agreement is also lacking regarding the nature of the symptoms. Certain observers have incriminated the organism as the causative agent of symptoms far remote from the gastro-intestinal tract. Boyers, in an analysis of 1,961 complaints presented by persons found to be infected, believes his results show symptomatology referable to many other systems of the body. Craig, although mainly emphasizing the gastro-intestinal manifestations, notes that frequently nervous and circulatory disorders are attributed to *E. histolytica*. Arthritis, iritis, Hodgkin's disease and other conditions have been suspected of being caused by the organism, but no convincing ætiological relationship has been demonstrated in such cases and those claims have not at present gained any acceptance.

Many features lend particular importance to the problem of non-dysenteric amœbic infections. Primarily to be considered is the concept that *E. histolytica* is an obligate tissue parasite and that in every individual harbouring the organism there is a process of invasion and repair accompanied by more or less injury, the amount of disease, in all probability, being dependent on host resistance. As reliable estimates place the incidence of the organism to be about 10 per cent in the United States, it becomes important to reach some agreement on what proportion of the cases of amœbiasis shows evidence of injury.

### Analysis of signs and symptoms

**Physical signs.**—One of the most striking findings was the presence of abdominal tenderness. No less than 29 out of 46 gave this sign. The most prominent localization was at McBurney's point. In several instances this sign was so marked that had the individual complained concurrently of the symptoms encountered in appendicitis, operation would have appeared advisable. Circulatory abnormalities were not observed.

**Nature of symptoms.**—An analysis was made of 47 cases in which there was no ætiological factor other than the parasitic infection which would adequately explain the syndrome. To these were added seven cases in the control group who, although admitted for treatment for some unrelated condition, were found to be suffering concurrently with symptoms referable to their *E. histolytica* infections.

*Subjective complaints and objective signs in 54 hospital cases harbouring E. histolytica in which no other ætiological factor would adequately explain the syndrome*

Past history:—			
Dysentery	..	..	0
Appendicitis	..	..	24
Present history:—			
Nausea	..	..	20
Vomiting	..	..	6
Distention or flatulence	..	..	18
Heartburn	..	..	12
Abdominal pain	..	..	50
Epigastric	..	..	13
Umbilical	..	..	9
Right lower quadrant	..	..	14
Left lower quadrant	..	..	5
Generalized	..	..	9
Bowel movements, normal	..	..	28
Bowel movements, abnormal	..	..	26
Diarrhœa	..	..	9
Constipation	..	..	12
Diarrhœa and constipation	..	..	5
Headaches	..	..	16
Fatigability	..	..	14
Nervousness	..	..	10
Loss of weight	..	..	7
Physical signs:—			
Tenderness, abdominal	..	..	37
Epigastric	..	..	7
Cæcum	..	..	18
Ascending colon	..	..	7
Transverse colon	..	..	8
Descending colon or sigmoid	..	..	10

Almost one-half had at some recent time come under observation for appendicitis. Occasionally, upper gastro-intestinal complaints occurred to the exclusion of all other complaints. Pain was the most frequent symptom. The bowel movements were normal in over one-half of the cases. Constipation was a more frequent complaint than diarrhœa, this latter symptom occurring in but a small proportion of the cases. Nervous and circulatory disorders occurred but almost always in association with and subordinate to the gastro-intestinal complaints. Tenderness in various regions of the colon was elicited in 37 of the 54 cases and again the sign was commonly localized over the cæcum.

*Tentative admission diagnoses on 47 cases in which later clinical study revealed no adequate cause to explain the syndrome other than the presence of E. histolytica*

	Number of cases
Appendicitis, subacute or chronic	18
Peptic ulcer or chronic gastritis	10
Enteritis, chronic	7
Gall-bladder disease	4
Gastro-enteritis, acute	3
Appendicitis, acute	3
Renal colic	2
<b>TOTAL</b>	<b>47</b>

The tentative admission diagnoses made in 47 cases demonstrate the wide variation of conditions simulated by amoebic infections. The large number of cases thought to be appendicitis is consistent with other observations recorded in this series. Of those cases which came to operation, only those were included in which the pathological report of the appendix revealed no evidence of disease. It is to be noted that the larger number of cases were considered subacute or chronic manifestations of appendicitis, most of which were discharged without operation.

The most frequent was pain, being presented by 34 out of 47 cases. In three of the cases the complaint was mainly of weakness and in one the chief symptom noted by the patient was headache.

*Chief complaint in 47 cases harbouring E. histolytica in which there was no adequate cause to explain the syndrome other than the presence of the organism*

Pain .. .. .	34
Epigastric .. .. .	11
Umbilical .. .. .	5
Right lower quadrant .. .. .	8
Generalized .. .. .	8
Lumbar .. .. .	2
Nausea .. .. .	1
Constipation .. .. .	4
Diarrhoea .. .. .	3
Alternating constipation and diarrhoea .. .. .	1
Headache .. .. .	1
Weakness .. .. .	3

*Results of treatment.*—Carbarsone in 0.25 gramme capsules administered twice daily for a period of 10 days was given as a routine. The follow-up examinations were made between six and twelve months after treatment. Approximately three-fourths obtained relief following carbarsone administration. Although but few cases are included in which no treatment was given, it is of interest that the results were exactly opposite, the majority stating either that their symptoms had persisted or had become aggravated.

#### COMMENT

Judging from the rarity with which diagnoses of non-dysenteric phases of amoebiasis are made in medical practice, and considering the prevalence of *E. histolytica*, one would come to the conclusion that clinical manifestations of the organism without dysentery are rarely of such severity as to require medical assistance. In the present investigation, however, quite the contrary proved to be so. Even in what may be presumed to be a highly resistant group, some of the infected individuals presented complaints which could not be regarded as unimportant. In the hospital study an impressive number of cases proved to be of amoebic origin and, had not the presence of the parasite been demonstrated, the final diagnoses in these cases would have fallen in that large and unsatisfactory group in which neither the true cause nor the nature of the disorder is known.

The most striking feature of the cases studied in the investigation was the dissimilarity of their clinical manifestations as compared to the symptomatology encountered in amoebic dysentery. Whereas the presence of dysentery, or blood and mucus in the stools immediately brings to mind the possibility of an amoebic process, the same organism is capable of producing disorders which give but scant clues to the nature of the disease. This observation becomes of greater importance in view of the fact that the largest proportion of amoebic infections are of this latter type. This was demonstrated in a recent naval survey in which only 4.6 cases of dysentery were found for each 1,000 individuals harbouring *E. histolytica*. Thus, despite the less serious nature of the non-dysenteric cases of intestinal amoebiasis as compared with those presenting dysentery, the difficulties in their diagnosis

and their prevalence constitute a problem of some importance in clinical medicine.

It appears that a large number of apparently obscure gastro-intestinal cases which seek relief in hospitals and clinics are actually cases of amoebiasis and that frequently these cases are not being diagnosed. The lack of recognition of the non-dysenteric syndromes is due to the fact that a positive diagnosis is dependent on the demonstration of the organism in the stool examination. It is known that rarely should the organism be reported in any less than 5 per cent of routine stool examinations, yet too often hospital laboratory reports fail to reveal any such incidence of infection. Where this is so, the infections cannot be diagnosed and this situation has led to a false impression regarding the clinical importance of non-dysenteric manifestations of *E. histolytica*.

Certain clinical aspects of these cases are characteristic enough to bring to mind the possibility of an amoebic infection and lead to an intensive search for the parasite by stool examination. From the clinician's standpoint, a clear understanding that blood and mucus need not be associated with amoebic infections is of fundamental importance. Usually the non-dysenteric case is first suspected of being some well-defined and common gastro-intestinal entity, but a study shows so much to be atypical that the anticipated diagnosis cannot be reached. It is this very atypicalness which should suggest amoebiasis, and with abdominal pain as a prominent complaint, and when the symptoms are characterized by chronicity and recurrency, these features all become especially suggestive of amoebiasis.

Of special interest in the present investigation was the common occurrence of a syndrome simulating subacute or chronic appendicitis. Appendicitis was particularly apt to come under consideration in the disorders encountered in these groups, but the frequency with which the various attending physicians were led to consider the possibility of disease of the appendix was a striking feature of the investigation and one which indicated the organism to have an important rôle in such syndromes. The possibility of a large proportion of the non-dysenteric cases suffering from an amoebic typhlitis suggests itself. Many of the cases harbouring the organism were subjected to operation. In none of the infections were ill-effects noted as a result of operation, and in a few, serious results undoubtedly would have followed had operation been withheld. The significant fact was that in many cases the signs were too mild to indicate surgery, while in others there was a return of like symptoms after operation, these facts suggesting the advisability of anti-amoebic therapy in connection with other indicated treatment in these cases.

#### SUMMARY

In the present clinical investigation only cases of intestinal amoebiasis in which there was neither a present nor a past history of dysentery were studied. The cases comprised both symptomless carriers of *E. histolytica* and infected individuals with complaints of varying severity. Control observations were made whenever feasible. Only those symptoms and signs were ascribed to *E. histolytica* after other possible causes had been ruled out. In all, 216 cases of non-dysenteric amoebiasis were studied, of which 100 were found to have symptoms.

1. A study of the occurrence of symptomatology in a selected group of 106 apparently healthy men harbouring *E. histolytica* showed 46 or 43.4 per cent to have symptoms. A control group of 108 cases negative for intestinal protozoa revealed but 8 or 7.4 per cent to have complaints. Of the 106 cases of amoebiasis only 13.2 per cent of the complaints were of any appreciable severity.

2. Of 236 individuals harbouring various intestinal protozoal species, but not *E. histolytica*, the percentage with symptoms was similar to that found in the non-parasitized group, with the exception of *Dientamoeba fragilis* in which 27.3 per cent of 44 cases presented

symptoms. Similarly, some of the flagellates presented higher percentages than the control. An explanation of this apparent pathogenicity was offered.

3. A study of the blood findings in 61 cases of apparently healthy carriers of *E. histolytica* showed no significant differences from the results obtained in a control group of an equal number of individuals not harbouring the parasite.

4. Despite the apparent trivial nature of the complaints presented by most of the cases in an ambulatory group, it was found by a study of various hospitalized groups that a considerable number of non-dysenteric amoebic infections are severe enough to require hospitalization. In 47 such cases the disease picture was so obscure that only the finding of the parasite in the stool led to the proper diagnosis, and

in these, specific anti-amoebic treatment gave good results where other methods had failed.

5. A study of the nature of complaints revealed these to be primarily referable to the gastro-intestinal tract, yet without blood and mucus in the stools and usually without bowel abnormalities which might suggest an amoebic process. Complaints referable to both upper and lower gastro-intestinal tracts appeared with equal frequency. Complaints referable to other systems were seldom encountered. Chronicity, recurrence and mildness of the symptoms were characteristic features.

6. A symptom-complex simulating subacute or chronic appendicitis was the most commonly observed syndrome in this series of non-dysenteric cases of amoebiasis.

## Reviews

**THE BRITISH ENCYCLOPÆDIA OF MEDICAL PRACTICE INCLUDING MEDICINE, SURGERY, OBSTETRICS, GYNÆCOLOGY AND OTHER SPECIAL SUBJECTS. SURVEYS AND ABSTRACTS. 1939.** Under the General Editorship of Sir Humphry Rolleston, Bt., G.C.V.O., K.C.B., M.D., D.Sc., D.C.L., LL.D. Pp. xiii plus 605 plus 50. Illustrated

and

**CUMULATIVE SUPPLEMENT. 1939. Pp. 170.** Published by Butterworth and Company (Publishers), Limited, London. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price of these two volumes inclusively is Rs. 18-8

THE publishers of the *British Encyclopædia of Medical Practice* have always expressed their intention of keeping this ambitious publication alive by issuing supplementary volumes year by year. That they have kept this promise in the trying circumstances of the year 1940 is very much to their credit. Two supplementary volumes have been issued.

*Surveys and Abstracts, 1939.* This volume consists of twenty-five critical surveys with such general headings as General Medicine, Diseases of the Blood-forming Organs, Pharmacological Aspects of the Endocrines, and Tropical Medicine, and some more specific ones, such as Q-Fever, Contact Lenses, and Acute Rheumatism. The writers are all well-recognized authorities on their own subjects. There follows a short section on drugs; some Modern Drugs by Dr. P. Hamil and the Pharmacology of the Sulphonamide Drugs by the publishing editor, Dr. Clark. The rest of the volume consists of abstracts from the literature arranged under headings which more or less correspond to the headings in the twelve volumes of the encyclopædia.

The majority of the critical surveys are excellent, but in a few instances the writer didn't seem to know quite what he was really setting out to do and the result was a short résumé of a very wide subject, which didn't hold well together or give the reader any information that he could not have obtained from the original article in the earlier volumes.

The abstracts are taken from a wide range of medical journals, including British and British Empire journals, American, and European other than British. These for the most part are well chosen and well arranged, but there are a number of isolated extracts which, divorced from their context, appear, to the reviewer, to be more or less meaningless, e.g., Methylene Blue Reaction, and Formol-gel and Takata-Ara Reactions.

*The Cumulative Supplement.* If the above volume is a little uncertain in its purpose, there is no uncertainty about the purpose and value of this cumulative supplement. The headings followed are those

of the original encyclopædia and in each the volume and key numbers of the original articles are given in the margin. Whenever a subject has been adequately dealt with in *Surveys and Abstracts* this fact is noted, but in other instances a short note is given which is strictly supplementary to the original article and which brings the subject up to date. Not only are these short articles clearer in their purpose, but they are in most instances much more balanced and relevant contributions to their various subjects than those provided in the other volume. We sincerely hope that the supplement will meet with the success that it deserves and that the publishers will be able to keep to their original purpose of issuing this cumulative volume each year.

**HÆMORRHOIDS AND THEIR TREATMENT: THE VARICOSE SYNDROME OF THE RECTUM.**—By Kasper Blond, M.D. (Vienna). Translated by E. Stanley Lee, M.S., F.R.C.S. 1940. John Wright and Sons Ltd., Bristol. Simpkin Marshall Ltd., London. Pp. viii plus 140, with 49 illustrations, many in colour. Price, 15s.

THIS is a monograph of outstanding merit and one which will meet with a cordial welcome. For the English translation much credit is due to Mr. Stanley Lee. The injection treatment of hæmorrhoids will cause no surprise or comment anywhere. But the author's conception of ætiology and treatment of fistula and pruritis will be new to many readers. The concept of the portal system, and its rôle in the formation of hæmorrhoids, will be not merely new but startling to many of us. The author has described under the heading of 'Varicose Syndrome of the Rectum' a number of conditions such as pruritis, anal fissure and fistula, etc., which are generally regarded as separate entities. The author is of opinion that all pathological conditions which impede the portal venous return may thus play a part in the development of hæmorrhoids and allied lesions. There is considerable evidence in support of the author's concept.

The printing, get-up and illustrations are excellent. We strongly commend this book to the notice of the general practitioner.

P. N. R.

**DISEASES OF THE URETHRA AND PENIS.**—By E. D'Arcy McCrea, M.D., M.Ch. (Dub.), F.R.C.S.I., F.R.C.S. (Eng.). 1940. John Wright and Sons Ltd., Bristol. Simpkin Marshall Ltd., London. Pp. viii plus 306, with 181 illustrations, many in colour. Price, 21s.

THE author explains in the preface that this volume represents an attempt to give in some detail an account of present-day knowledge of diseases of the urethra and penis and to provide an easy reference to the literature on the subject.

There are altogether sixteen chapters in this book, with clear descriptions of regional anatomy, malformation, injuries, diseases and new growths of the penis and urethra. This book may rightly be regarded as an important monograph and will be much appreciated by the general practitioner. The printing, get-up and illustrations are excellent.

P. N. R.

**A HANDBOOK OF RADIOGRAPHY.**—By J. A. Ross, M.A. (Camb.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), D.M.R.E. (L'pool). 1940. H. K. Lewis and Company, Limited, London. Pp. viii plus 126, with 67 illustrations. Price, 7s. 6d.

THIS small book was read with great interest by the reviewer; it gives in clear and simple language all that should be known about radiography accompanied by simple line illustrations.

The descriptions of the technique are adequate, and the printing, get-up and illustrations are excellent.

The book will prove extremely valuable to both the radiologist and radiographer.

E. H. W. F.

**A MIRROR FOR SURGEONS: SELECTED READINGS IN SURGERY.**—By Sir D'Arcy Power, K.B.E., F.R.C.S. 1939. Little, Brown and Company, Boston (34, Beacon Street, Boston, Massachusetts). Pp. xii plus 230. Price, \$2.00

THIS is a contribution to the history of medicine of a kind we are beginning to associate with the name of Sir D'Arcy Power.

The book contains vignettes of twenty-two well-known surgeons ranging over the years 1307 to 1924. The first date being the birth of Master John Arderne, 'the first British surgeon', and the second the date of Sir William MacEwen's death.

Each section begins with a few lines indicating the upbringing and family life of the surgeon concerned, and this is followed by one or more quotations from the surgeon's own writings on his chief contributions to surgical practice.

The book makes an interesting and valuable contribution to the history of medicine, and reading it serves to pass a few hours pleasantly and profitably.

We notice it is published in the United States of America although the author is one of the leaders of British surgery. By publication overseas the book has lost nothing from the point of view of production for the binding, printing and kind of paper used are most appropriate for the contents of the book.

**SEX KNOWLEDGE FOR BOYS. VOLUME ONE AND SEX KNOWLEDGE FOR GIRLS. VOLUME TWO.**—By A. P. Pillay, O.B.E., M.B., B.S. Published by D. B. Taraporevala Sons and Company, Hornby Road, Fort, Bombay. Volume I:—Pp. vi plus 72, with 5 illustrations. Price, Re. 1-8. Volume II:—Pp. iv plus 66, with 5 illustrations. Price, Re. 1-8.

MANY parents look with disfavour and sometimes harshness on any signs of sex knowledge on the part of their children. It is now, however, being increasingly recognized that some form of sex education should be given to children, in view of the evil results of early inhibitions and repressions during the most impressionable period of puberty. Hence the presentation of the facts of sex to the young in a popular style will meet an important need.

These two volumes of 'facts of life' series provide simple and common sense information about sex for boys and girls. Starting with the reproduction of plants, birds and mammals the author finally tells as much about human sex life as a growing child should know. The physical and psychic problems of sex, masturbation, the hygiene of sex, etc., have been dealt with concisely in a practical manner with a summary following each section. Many of the facts and illustrations are common in both books. There is a glossary at the end of each.

R. C.

**A HANDBOOK OF MALARIA CONTROL.**—By R. Svensson, D.S.O., M.C., M.B., B.Ch. With a Foreword by Sir Malcolm Watson, LL.D., M.D., C.M., D.P.H., F.R.F.P.S. Published by the Shell Group of Oil Companies for The Ross Institute of Tropical Hygiene, Keppel Street, Gower Street, London, W.C.1. Pp. viii plus 73. Illustrated.

MUCH patient labour has been usefully expended in the compilation of this small handy treatise, which it is hoped will satisfy the need of a simple compact reference book on certain aspects of malaria control work for the use of planters, engineers, and other laymen who have to undertake antimalaria work in the tropics. Although the book is not primarily intended for medical men, nevertheless, they will also find it useful at times.

The book is divided into 11 chapters and 11 appendices. Such useful subjects as collection, preservation and dissection of mosquitoes, bionomics of carrier species, etc., have not been overlooked.

D. N. R.

**MEDICAL RESEARCH COUNCIL. SPECIAL REPORTS SERIES, NO. 238. 'THE STRUCTURE OF TEETH AS SHOWN BY X-RAY EXAMINATION'.**—By J. Thewlis. 1940. Published by His Majesty's Stationery Office, London. Pp. 82. Illustrated. Price, 2s. 6d.

'ONE of the main problems of dental research is that of caries, and it is becoming increasingly apparent that liability to this disease is related to defective structure of the teeth. The nature of the structural defects concerned is not precisely known, although certain manifestations of such defects are recognizable both by the naked eye and microscopically.

It is not unreasonable to assume that these defects may be related to the submicroscopic structure of a tooth, of which something has been learned by the use of the x-ray diffraction technique used by Mr. Thewlis. This method has been successfully applied for a long time in various technical branches of science, but has nevertheless been little used in biology. That it has definite biological applications, however, may be seen from the present report, in which the nature, size and arrangement of the crystalline particles in teeth are shown to have been ascertained by its use.

Optical methods have also been employed in the investigation, but apart from x-ray diffraction chief use has been made of the radiographic method, perhaps more familiar than the others to the majority of readers. The radiographic method, however, has been adapted to the special needs of the work and has been so developed as to make possible the quantitative determination of the degree of calcification in different regions of the enamel and dentine in a given tooth, or indeed in any calcified tissue. It has been usual to control estimates of the degree of calcification in teeth by histological methods, the accuracy of the results of which cannot be guaranteed. This highly specialized and applied study of the problem by Mr. Thewlis has yielded valuable and unquestionable information more exact than histological examination could possibly provide.'

**MEDICAL RESEARCH COUNCIL. SPECIAL REPORTS SERIES, NO. 241. 'DENTAL DISEASE IN THE ISLAND OF LEWIS'.**—By J. D. King. 1940. Published by His Majesty's Stationery Office, London. Pp. 63. Price, 1s.

THE superiority of the teeth of the average country child in Lewis, as regards both sound formation and freedom from decay, has been placed beyond dispute by the evidence here presented. From a general standpoint, chief interest naturally attaches to the reasons for this enviable quality. Here, however, the data are less adequate as a basis for firm conclusions: the possible factors are complex, and points relating to mode of life are difficult to ascertain with completeness and accuracy. Nevertheless, all the positive indications support the viewpoint that only differences in diet

can explain the facts, and no other differences of a relevant kind have been found. These indications include the consumption of a relatively high proportion of fat-soluble vitamins and mineral salts, the nutritional factors which have been experimentally proved to be essential for the proper development and calcification of the teeth. In other respects, such as the amount of carbohydrate and the physical consistency of the food, the diets of the rural and urban children in Lewis did not seem to be notably different.

The more favourable diet of the country children is due to the inclusion of a greater proportion of natural produce, and a lesser dependence on bought foodstuffs poor in protective factors. This in turn is related to distance from the shopping centre and to difficulties of transport. It is therefore conceivable that, under the impact of changing conditions, the local advantage may already be waning. The evidence stands, however, to show once again that dental disease is to an important extent preventable by correct nutrition, and that means of diminishing this evil are therefore within the scope of public administrative action.

The value of such a study and the application of its findings to conditions in India are obvious.

**MEDICAL RESEARCH COUNCIL. SPECIAL REPORTS SERIES, NO. 242. 'STUDIES IN NUTRITION: AN INQUIRY INTO THE DIET OF FAMILIES IN THE HIGHLANDS AND ISLANDS OF SCOTLAND'.**—By E. P. Cathcart, A. M. T. Murray and J. B. Beveridge. 1940. Published by His Majesty's Stationery Office, London. Pp. 37. Illustrated. Price, 9d.

'Among the basic data for research on human nutrition, and for application of scientific knowledge to its practical problems, it is clearly necessary to have definite information as to the actual diet of the people: this can be obtained only by careful and laborious studies of samples of the population. Professor E. P. Cathcart of the University of Glasgow, with assistance by Mrs. A. M. T. Murray and others, has made a number of surveys of this kind in different parts of Great Britain.

The present report deals with a study made in the Highlands and Islands of Scotland.

The method used in the survey was to select a number of families and ascertain the food intake of each during a period of one week. The original studies in the Highlands were made in summer, but duplicate studies of some of the same families were made in winter; this was done partly to reveal any seasonal variations, and partly as a check on the reliability of a single week's observations as an index of the diet as a whole. As on a previous occasion, the investigators found from the evidence obtained in this way that their method was sound, although there were naturally some differences between foods consumed in summer and winter respectively.

As already indicated, the diet can be considered from the standpoint of fundamental constitution (protein, fat, carbohydrate, minerals and vitamins) and energy value (expressed in calories), or it may be considered with regard to the actual food commodities which make up the diet. In this report the results of both methods of analysis are given.

**THE DIAGNOSIS AND TREATMENT OF DIABETES.**—By W. Willson Ingram, M.C., M.D., F.R.A.C.P. Third Edition. 1940. Angus and Robertson Limited, Sydney. Pp. ix plus 150. Price, 6s. 6d.

This book has been designed primarily for the use of general practitioners and gives a simple outline of those facts regarding diabetes, a knowledge of which is essential for the successful treatment of the disease.

The book has been written in a very simple and clear style and should prove to be very useful to both the practitioner and the medical student. The text is quite up to date.

A new chapter has been added on the new insulin compound—protamine zinc insulin—and a new outline

of diet has been added for those patients who are on this modified insulin.

A short chapter has also been added on the management and treatment of diabetic children.

The book contains valuable information and should prove useful to those for whom it is intended.

J. P. B.

**THE DIABETIC A. B. C. A PRACTICAL BOOK FOR PATIENTS AND NURSES.**—By R. D. Lawrence, M.A., M.D., F.R.C.P. (Lond.). Seventh Edition. 1940. H. K. Lewis and Company, Limited, London. Pp. vii plus 64. Price, 3s. 6d.

LITTLE comment is necessary on the seventh edition of Dr. Lawrence's practical book for patients and nurses, the predecessor of which we had the pleasure of reviewing a little over a year ago. No radical changes appear to have been made in the present edition except that a few new diabetic recipes have been added.

We hope the book will continue to be as useful and popular as its predecessor.

J. P. B.

**PRACTICAL HANDBOOK OF THE PATHOLOGY OF THE SKIN: AN INTRODUCTION TO THE HISTOLOGY, PATHOLOGY, BACTERIOLOGY AND MYCOLOGY OF THE SKIN WITH SPECIAL REFERENCE TO TECHNIQUE.**—By J. M. H. Macleod, M.A., M.D., F.R.C.P. (Lond.), and I. Muende, M.B., B.S., B.Sc. (Lond.). Second Edition. 1940. H. K. Lewis and Company, Limited, London. Pp. xix plus 415, with 27 coloured and 125 black-and-white illustrations. Price, 42s.

THIS book is accurately described in its title and sub-title (given above) for that is exactly what it is.

The unusually long period of 37 years has passed since the appearance of the first edition under the authorship of Dr. Macleod alone. That the same author was sufficiently experienced to produce a valuable book so long ago and that he has been actively engaged upon the study of dermatology ever since is sufficient evidence that the present edition must be a valuable book.

Considering the many advances that have been made in pathology and biochemistry since 1903 the character of the book is changed to a remarkable small degree and it contains only a few more pages than its predecessor despite the fact that the number of illustrations has been considerably increased. At the same time there is a definite addition to the amount of the text, which is masked by the fact that the pages of the new edition are about 20 per cent larger than those of the old one.

If we may select a section for special comment without in any way indicating that the rest of the book is not also excellent, we feel that the portion dealing with mycology is particularly useful, because it gives a short and clear summary of the essentials of what is a most confusing and unwieldy subject for a beginner to acquire a working knowledge of, from the books that are usually available. This makes the book of special value to tropical dermatologists, such a large proportion of whose cases are caused primarily by a fungus of some kind, and it is sure of a ready sale in the tropics.

P. A. M.

**THE CONTENT OF CELLS AND PROTEINS IN THE NORMAL CEREBRO-SPINAL FLUID: THE DIAGNOSTIC IMPORTANCE OF DEMONSTRATING SMALL PATHOLOGICAL CHANGES IN THE CELLS AND PROTEINS—THE TECHNIQUE OF THE INVESTIGATION.**—By A. V. Neel, M.D. Oxford University Press, London, Humphrey Milford. Pp. 141. Price, 7s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

THIS is the report of studies carried out in Copenhagen by the author. It is remarkable how poor and inaccurate are our normal data for many of the examinations that form part of our daily practice.

# Quinine salts in MALARIA

---

The "short Quinine treatment" for Malaria has been tried out in many affected districts over a period of years, and its efficacy has been well established. Satisfactory clinical reports and an entire absence of hostile criticism is evidence that it has won the approval of responsible medical authorities throughout the world.

The 4th General Report of the LEAGUE of NATIONS MALARIA COMMISSION, published as recently as December 1937, strongly recommends it after a most careful review of all the known methods of combating this world-wide scourge.

**TREATMENT.** A daily dose of 15 to 18 grains of Quinine Hydrochloride for 5 to 7 days. After treatments are omitted, but an eventual relapse is treated in the same way.

It is important for the patient to be at rest during treatment, and the daily dose should be given in 3 parts.

In subtertian cases it is advisable to give not less than 18 grains of Quinine Hydrochloride daily during 7 days for adults; the dosage for children should be reduced proportionately.

Quinine should always be administered orally, unless coma or vomiting in serious cases of subtertian malaria should necessitate intramuscular or intravenous injection.

Quinine still ranks first in current practice by reason of its clinical effectiveness and almost complete absence of toxicity, coupled with the widespread knowledge of its use and dosage.

Howards & Sons, Ltd., guarantee the uniformity of their Quinine in original packages of tablets, etc., both as regards accuracy of dosage and conformity with the official standards shown on the label.

# Persistent Antisepsis for normal skins . .

Recently investigations have shown that the dried film left on the hands after treatment with 30% 'Dettol' renders them insusceptible to infection by Hæmolytic Streptococci for at least two hours (vide 'British Medical Journal', 21st October, 1933, page 723). 'Dettol' can be employed at high concentration, except on sensitive skins. The Rideal-Walker test proves it three times more potent than phenol. A two per cent. solution very rapidly kills Hæmolytic Streptococci and B. coli even in the presence of pus.

*Non-poisonous*

*Non-staining*

*Pleasant aroma*

Studies of this kind are very important and should be fully reported wherever possible. This book should find a place in the libraries of all medical teaching institutions.

**A SYNOPSIS OF THE BRITISH PHARMACOPŒIA, 1932, AND OF THE POISON LAWS OF GREAT BRITAIN, NORTHERN IRELAND AND THE IRISH FREE STATE, INCLUDING THE 1936 POISONS LIST AND RULES.**—By H. Wippell Gadd. Thirteenth Edition. 1936. Baillière, Tindall and Cox, London. Pp. 200. Price, 3s. 6d.

THIS well-known *Synopsis* has been brought up to date by two synopses of the 1936 and 1940 addenda to the *British Pharmacopœia* 1932.

**THE PRACTITIONER'S POCKET-BOOK.**—By D. S. Davies, D.M. (Oxon.), F.R.C.S. (Edn.). 1939. John Bale Medical Publications Limited, London. Pp. 266. Price, 7s. 6d.

THIS is the sort of book a physician might keep in his car. It is a pocket-book size, but there is already a fair demand on the physician's pocket. The descriptions are incredibly concise, and frequently very

apposite. For example, there are six lines on the treatment of cholera; they include instructions in giving intravenous saline and the terse remark 'never give morphine', amongst other good advice. (We cannot however agree that the incubation period is 2 to 8 days.)

Other subjects simply will not compress and the result of the attempt is rather disastrous. However, on the whole, the balance is in favour of the book if it is kept out of the hands of the student.

**IRVING'S ANATOMY MNEMONICS.**—By Alastair G. Smith, L.R.C.P. & S. (Edn.). Fourth Edition. 1939. E. and S. Livingstone, Edinburgh. Pp. 133. Price, 1s. 6d. Postage, 1d.

'To the simple-minded, to the crammers for exams, and to those whose stumbling feet find the anatomical pathway difficult, this little book is offered in the hope rather than the belief that they may find some help from it.'

So writes the author, and many will agree that mnemonics are a great assistance to the examinee.

This book which has now reached its fourth edition, will form a useful Christmas card to send to a medical student, as it is very cheap and will easily go into an ordinary envelope.

## Abstracts from Reports

### PUBLIC HEALTH COMMISSIONER'S PRELIMINARY REPORT FOR 1939

PUBLICATION of a preliminary report has been found advisable owing to unavoidable delay in preparing the full report, which contains a great deal of statistical and other material relating to the wide variety of health activities of the whole sub-continent of India.

In 1938, as the result of a widespread dissemination of infection following the Hardwar festival in April, all the provinces in Northern India and the Central Provinces suffered severely from cholera. The extent to which the incidence of cholera decreased may be judged from the figures for cholera deaths in the Punjab and Sind, in which provinces there were respectively 19 and 3 deaths in 1939 as against 5,760 and 343 in 1938. In other provinces, too, cholera prevailed in a relatively milder form.

It is reported that the incidence of plague also decreased in 1939 and that, in regard to smallpox, although the majority of the provinces reported epidemic prevalence of the disease, Bengal and Sind experienced only mild outbreaks.

In the field of public health administration, the most important event was the second meeting of the Central Advisory Board of Health in January 1939. This board, which consists of representatives of the Central and Provincial Governments and of certain Indian States, was inaugurated in June 1937 for the purpose of providing a forum for the discussion and formulation of public health policy. Within the short period of its existence it has already given proof of its usefulness.

The problems associated with the health of the mother and child are of supreme importance to every country and, in India, the high rates of child and maternal mortality place this branch of health work in the forefront of the national health programme. A special committee appointed by the board reviewed the whole question and submitted a report, which has been approved by the board and which should provide for many years a sound basis for the orderly development of maternity and child-welfare work in this country.

Another important question is that of co-ordinating the activities of the civil, military and railway health authorities in matters of common concern, in order to avoid unnecessary overlapping of effort. For this purpose the board suggested the formation of local committees representing all three interests for the

study of common health problems and for the formulation of suitable methods of solving these problems. Encouraging reports have been received regarding the development of such co-operation in many places.

The important part that festivals and large gatherings of pilgrims play in the spread of cholera is a subject of great concern to the health authorities. While an improvement of the sanitation of the villages and towns through which the pilgrims pass is the most effective means of prevention, its realization must be slow, in view of the cost involved.

In the circumstances, the most practical method of minimizing the spread of cholera appears to be the provision of mass protection through anti-cholera inoculation. The possibilities of introducing a system of compulsory inoculation among pilgrims was investigated in 1939 by a special committee and their report will shortly be presented to the board for its consideration.

Control of the purity of food supplies is an important function of health administrations, and one of the means of achieving this end is by the enforcement of the Food Adulteration Act. A committee was appointed by the board to report on the question of food adulteration in India and this committee held two meetings in 1939.

The problem has three aspects: (a) standards of purity for different articles of food and the standardization of the technique employed in food analysis; (b) food legislation and (c) administration.

In regard to the first the present position in India is very unsatisfactory. For the same article of food different provinces have different standards. This anomaly impedes the free flow of inter-provincial trade and causes considerable inconvenience to traders. The question of food standards has, therefore, been studied by the committee and its recommendations, which are calculated to relieve the existing complicated situation, will shortly be submitted to the board for its consideration.

The modernization of food legislation in India and the application of the provisions of such legislation by suitable administrative action are equally important aspects of the food adulteration problem.

Mention may also be made of other directions in which it has been sought to secure uniformity of policy between the different Governments in the improvement of health conditions. Common lines of policy have been recommended by the board regarding the expansion

of health services, co-ordination of effort between the medical and public health departments and the teaching of hygiene in medical schools and colleges.

Such subjects as nutrition and quinine policy have also been discussed by the board.

This brief review of some of the important subjects discussed and the recommendation made by the board, indicates that the wish expressed by His Excellency the Viceroy at the inaugural meeting of the Board in June 1937 is being increasingly fulfilled, namely, that the Board, 'in its capacity as an advisory body in organic union with the Central Government, will be capable of bringing to a common denomination the varied opinions of Governments throughout the sub-continent in matters pertaining to Public Health'.

**Malaria.**—That malaria is undoubtedly the most important public health problem in India is shown by the fact that many millions of cases occur every year and that, of the annual total of over 6,000,000 deaths, about 20 to 25 per cent are attributable to this cause.

Except for areas 5,000 feet above sea level and a few widely separated regions—namely, a portion of the Brahmaputra Valley in Assam, Eastern Bengal and two strips of territory on the east coast of Madras Presidency—the remaining parts of India are subject to outbreaks of malaria of varying intensities. This wide distribution of the disease and the liability of large tracts to periodical epidemic outbreaks make malaria the most important health problem in India.

The malaria problem in India may be classified under three heads—urban, industrial and rural. In large cities, such as Bombay and Delhi, it has been shown that a considerable measure of success in the control of mosquito breeding and of the incidence of the disease can be achieved by properly directed measures. As regards industrial malaria, control measures are being successfully carried out on many tea and coffee estates and rubber plantations and in mines, sugar factories, cotton mills and other industrial concerns in different parts of India, mainly through the activities of the Indian Branch of the Ross Institute.

Malaria control is also being carried out on railway systems, the Bengal-Nagpur and Eastern Bengal Railways employing special officers for the purpose. Among the anti-malarial measures adopted by the railway authorities, an important method is that of spraying employees' quarters with insecticides in order to kill adult mosquitoes.

The problem of rural malaria is the most difficult of solution, because the village communities are widely scattered and are very poor. The general policy adopted by the provincial authorities is to try and provide an adequate supply of quinine and of cinchona febrifuge, to popularize the use of these drugs as far as possible by means of propaganda and teaching in the schools, and to provide for distribution by special staffs, travelling dispensaries and other agencies in localities visited by regional epidemics.

Experiments are being conducted over a period of five years and are designed to devise and test out methods of control under rural conditions, in order that they may subsequently be applied over more extended tracts of the country.

**Leprosy.**—A conservative estimate of the incidence of leprosy in India places the figure in the neighbourhood of 1,000,000 persons affected, although the number of infectious cases may be only a quarter of this figure. While leprosy in India is essentially a rural problem, the commingling of the rural and urban populations that increased facilities for transport has rendered possible, has tended in recent years to produce a rise in the incidence of leprosy in towns.

The prevalence of the disease is highest along the eastern coast of the peninsula and in the western parts of Bengal. From this area the disease gradually diminishes in incidence to the north and west, until a fairly wide area of comparative freedom from leprosy is reached, comprising the northern half of Bombay Presidency, Gujerat, Rajputana, the western portion of the United Provinces, the Punjab, the North-West Frontier Province, Sind and Baluchistan.

Antileprosy work in India is shared by official and voluntary organizations. The principal voluntary organizations are the Indian Council of the British Empire Leprosy Relief Association with its provincial branches, and the Mission to Lepers. There is considerable co-ordination of effort between the provincial health authorities and the provincial branches of the British Empire Leprosy Relief Association. Antileprosy work has included surveys to determine the extent of the incidence of leprosy and of the types of cases present in particular localities, the provision of treatment centres, training of medical officers in the diagnosis and treatment of the disease, and propaganda. Laboratory and field research into various problems has also formed an important part of the work.

**Tuberculosis.**—Although the organized campaign against tuberculosis in India received a great impetus in 1929 when it was decided to devote the King George Thanksgiving Fund of Rs. 9,50,000 to antituberculosis work, the necessity for a widening and intensification of the campaign against the disease was recognized by Her Excellency the Marchioness of Linlithgow soon after her arrival in India. As a result, Her Excellency made an appeal on behalf of the King-Emperor for funds to place the antituberculosis organization in this country on a sound and lasting basis.

The response was wide and generous and a sum of Rs. 79,00,000 was collected. In February 1939, Her Excellency's objective was achieved by the formation of the Tuberculosis Association of India which incorporated the King George Thanksgiving (Anti-Tuberculosis) Fund. Of the total amount collected 5 per cent was retained by the central organization, the remaining 95 per cent being returned to the provinces. Provincial and state branches of the association were established during the year.

**Yellow fever.**—As regards yellow fever, the greatest source of danger is air traffic passing through the infected regions of Africa. Air traffic from Africa to India passes through the Anglo-Egyptian Sudan northwards to Europe and eastwards to India. The Sudan occupies, therefore, a central position and constitutes the main line of defence against the advance of yellow fever to Europe and Asia. The Government of India have taken additional precautions to prevent the entry of infection into this country. Under the Government rules, any person who has been in a yellow fever area is forbidden to enter British India until nine days have elapsed from the last date on which he was possibly exposed to infection, unless he has previously been inoculated against the disease or protected by a previous attack. Further, the entry into India of any aircraft which has alighted in or started from a yellow fever infected area is prohibited, unless the aircraft has been disinfected by the health authorities at Alexandria or Cairo and has a certificate to that effect.

**Dietary habits.**—A point of special importance to India is that, at a meeting of a special committee of the Technical Commission in August 1938, it was decided that collaboration should be extended to the Far Eastern countries in order to collect further information regarding the dietary habits, the incidence of diseases connected with dietary habits and the value of local foods. Dr. W. R. Aykroyd, Director of the Nutrition Research Laboratories, Coonoor, was present at the meeting and it has since been decided that the Coonoor Laboratory should act as a liaison centre between the Technical Commission and the various institutions engaged in nutrition work in Eastern countries.

**Epidemic dropsy.**—Epidemic dropsy is a disease which is widely prevalent in north-eastern India, for instance, in Assam, Bengal, Bihar, Orissa and the eastern parts of the United Provinces. The cause of the disease was for long a mystery in spite of considerable research done on the subject. Recently, however, it has been shown through epidemiological studies and the results of human feeding experiments, that the accidental contamination of mustard seed with the seed of a weed, *Argemone mexicana*, which grows wild in the fields where the mustard plant is grown, seems to be associated with the production of this disease.

20 units per c.c. 5 c.c. vials.

40 units per c.c. 5 c.c. vials

## PROTAMINE INSULIN (with Zinc) SUSPENSION—BOOTS

may be used alone or with Insulin according to the needs of individual patients. Cases of Diabetes of moderate severity can usually be controlled by one injection of Protamine Insulin (with Zinc) Suspension—Boots a day, given before breakfast.

40 units per c.c. 5 c.c. vials

## JECOCIN

(Medicated Cod Liver Oil)

JECOCIN is prepared with Vitamin-tested Cod Liver Oil, Creosote, Chloroform, Cinnamon Oil, and contains the powerful non-toxic antiseptic Amyl-meta-Cresol. It has nutritive, demulcent, expectorant, and antiseptic properties. Excellent results have been obtained in the treatment of infections of the lungs and bronchi; particularly in chronic bronchitis, bronchiectasis, tuberculosis, and chronic coughs of a similar nature.

**THE MEDICO-LEGAL POST-MORTEM IN INDIA.** By D. P. Lambert, M.D., Ch.B., D.T.M. & H. (Univ., Edin.). With a Foreword by Sydney Smith, M.D., F.R.C.P. Rs. 3-12. (1937.)

**THE MICROSCOPICAL STUDY OF DRUGS.** By Lilian A. Kay, B.Pharm., Ph.C. Rs. 7-14. (1938.)

**THE ORIGIN OF CANCER.** By J. P. Lockhart-Mummery, M.A., M.B., B.C. (Cantab.), F.R.C.S. (Eng.). With 29 Illustrations. Rs. 7-14. (1934.)

**THE PHYSIOLOGY OF HUMAN PERSPIRATION.** By Yas Kuno, Professor of Physiology, Manchuria Medical College, Mukden. With 38 Illustrations. Rs. 9-6. (1934.)

**THE PREVENTION OF CANCER.** By Sampson Handley, M.S. (Lond.), F.R.C.S. (Eng.), Senior Surgeon to The Middlesex Hospital. As. 14. (1936.)

**THE PRINCIPLES OF CONTRACEPTION.** A Handbook for General Practitioners. By Joan Malleson, M.B., B.S. Rs. 3-6. (1935.)

**THE PRINCIPLES OF SURGICAL DRESSING.** An Introduction to Practical Surgery. By Lieut.-Colonel R. C. McWatters, M.B., F.R.C.S., Civil Surgeon, Naini Tal. Rs. 3-8. (1928.)

**THE SURGERY OF PAIN.** By Rene Leriche, M.D. (Lyon.), LL.D. (Glasgow), F.R.C.S. (Eng.) (Hon. Causa), etc., Professor of Clinical Surgery, University of Strasbourg. Translated and Edited by Archibald Young, B.Sc., M.B., C.M., F.R.F.P.S.G., F.A.C.S. (Hon.), M.D., Strasbourg (Hon. Causa). Rs. 15-12. (1939.)

**THE SURGERY OF THE SYMPATHETIC NERVOUS SYSTEM.** By George E. Gask, C.M.G., D.S.O., F.R.C.S. (Eng.), and J. Paterson Ross, M.S. (Lond.), F.R.C.S. (Eng.). Second Edition. Illustrated. Rs. 12. (1937.)

**TROPICAL GYNÆCOLOGY (Clinical Lectures).** By V. B. Green-Armytage, M.D., F.R.C.P., Lieut.-Colonel, I.M.S. Illustrated. Rs. 3-8. (1928.)

**TROPICAL HYGIENE.** For Europeans and Indians. By The Late Surgeon-General Sir Pardey Lukis, K.C.S.I., Knight of Grace of the Order of St. John, and Colonel R. J. Blackham, C.B., C.M.G., C.I.E., D.S.O., M.D., M.R.C.P.E., F.R.F.P.S., D.P.H., Knight of Grace of the Order of St. John. Revised and Enlarged by Lieut.-Colonel A. D. Stewart, M.B., F.R.C.S.E., D.P.H., D.T.M. & H., I.M.S. Fourth Edition. Illustrated. Rs. 5. (1931.)

**TROPICAL HYGIENE AND SANITATION.** A Course of Study and Reference Book for Sanitary Inspectors in the Tropics. By H. Jordan, A.R.San.I. With Notes on Communicable Diseases and their Prevention by J. P. Mitchell, M.D., and Medical Entomology by G. H. E. Hopkins, M.A. (Cantab.). Rs. 3-12. (1939.)

**UROLOGY IN WOMEN.** A Handbook of Urinary Diseases in the Female Sex. By E. Catherine Lewis, M.S. (Lond.), F.R.C.S. (Eng.). Second Edition. Illustrated. Rs. 4-8. (1936.)

**VACCINE THERAPY.** In Acute and Chronic Respiratory Infections. By Henry T. Gillett, M.D. (Lond.). With a Foreword by W. H. Wynn, M.D., F.R.C.P. With 9 Charts. Rs. 3-12. (1933.)

**THACKER, SPINK & CO. (1933), LTD.**  
Post Box 54, CALCUTTA

**Endemic fluorosis.**—On a report in April 1936 from the Health Officer of Nellore district in Madras Presidency, regarding the wide prevalence of a disease characterized by a definite train of symptoms such as stiffness and pain in the spinal region and in various joints, a detailed study of this condition was carried out by the health authorities of that province and it was shown to be one of chronic fluorine intoxication resulting from the continued use of water containing fluorides. The problem is twofold, namely, the prevalence of a comparatively wide geographical area of a dental condition, commonly known as 'mottled enamel', and the occurrence in a restricted area, of severe manifestations of chronic fluorine intoxication involving the spine, joints and ligaments to which the name of endemic fluorosis has been given.

**Nutrition research.**—There has been a growing interest in problems of nutrition among the public and an increasing desire to apply the knowledge to the practical question of improving the existing diets within the means of the people.

This emphasis on the immediate application of the available information for the benefit of the country has largely influenced the direction in which nutrition research has developed in India in recent years. The Nutrition Research Laboratories at Coonoor, maintained by the Indian Research Fund Association, have taken a prominent part in these investigations. Rice as the staple food of a large section of the population received considerable attention in 1939.

Work on other foodstuffs included the determination of the vitamin-A content of a large number of samples of fish oils. Shark liver oil has been found to be exceptionally potent and this substance has considerable possibilities as a cheap source of vitamin A.

The vitamin-C content of the *amla* or Indian gooseberry, a very rich source of this vitamin, has been extensively studied by chemical and biological methods, special attention being given to the effect of storage and various methods of preparation and conservation.

**Increasing interest in rural health.**—There are signs of a growing interest both among the authorities and the people, in problems of public health. A welcome feature of this awakening to the seriousness of the existing situation is an increased interest in the welfare of the rural population. The expansion of medical relief, the provision of safe water-supplies, experiments to evolve a cheap system of night-soil conservancy and the provision of skilled attendance at childbirth are some of the directions in which provincial health authorities are earnestly endeavouring to make progress.

The Provincial Governments have increasingly interested themselves in improved agricultural practice and animal husbandry, the consolidation of agricultural holdings and the provision of better village communications and of other amenities designed to build up a corporate life in the rural areas.

#### ANNUAL REPORT OF THE ALL-INDIA INSTITUTE OF HYGIENE AND PUBLIC HEALTH, CALCUTTA, 1939

The annual report of the All-India Institute of Hygiene and Public Health for the year 1939 reviews modern trends in the training of public health officers. These trends are based upon the marked amplification that has occurred in the past 20 years in the concept of public health, originally limited to the prevention of infectious diseases and in the control of environment.

Current thought is increasingly, throughout the world, attaching a much wider significance to the functions of public health. These now imply a study and control of *all* factors which affect the health of the community. Medical measures alone are insufficient to ensure that the community has or attains a normal standard of health.

The physical effects of occupation and of housing, the nutritive value of the food available; social customs, the educated consciousness of the community to attain a normal standard of health; economic

factors; these are some of the considerations which have to be studied in addition to the application of purely medical measures. Even the previous negative outlook of the purely medical measures is now becoming increasingly superseded by positive measures for the maintenance of health.

The function of investigation and training in public health is described as 'the development of the most efficient and practicable methods of scientific medical protection through organized community effort and the provision of opportunity for students to train themselves in the principles and application of those principles and methods'.

For the provision of opportunity to the students to train themselves and for a study of all the factors covered by the term public health, the necessity for the inauguration of 'controlled areas (to permit exemplification of methods) of a size sufficient to provide quality and quantitative facilities for students' self-participation' is emphasized. 'The principles determining the controlled community fields in public health correspond exactly to those governing the provision of a teaching hospital to a medical college presenting investigative facilities and quality and quantity standards for students' self-participation'.

Research in public health has been defined as 'the development of the most efficient and practicable methods of scientific medical protection through organized community effort'. Here again the necessity for controlled community areas is emphasized and the deficiency in the present organization of the institute in this respect is pointed out. 'The absence of controlled community fields places the institute under the same disabilities as would be faced by a department of clinical medicine in undertaking research in the absence of a teaching hospital. . . . The result has been that it has not been possible for the institute to discharge its chief function of making contribution towards the demonstration of the *utilization* of scientific knowledge in the advancement of community health.'

Having defined the primary function and scope of an institute of hygiene and public health in the matter of teaching and research, the report goes on to mention the deficiencies in the present organization of the institute and the curriculum and training. Special regard has been paid to the definite requirements of this country in determining the line of re-organization.

'Public health is organized community effort for medical protection, and, as such, is social medicine, the utilization of which must be different under varying social-economic conditions even although the principles derived chiefly from medical biology are universally similar. Consequently, it is essential that organization for instruction and research must vary from country to country during the levelling up process. Malaria must be afforded an importance in India that would be uncalled for in England. Health insurance cannot be given the same prominence in China as in Germany.'

An account is given of the progress made in the introduction of reforms in the training of public health officers and mention is made of the proposals under consideration for bringing the All-India Institute up to a standard comparable with similar institutions in other and more advanced countries.

The report goes on to say: 'The D.P.H. training should be one of the first educational fields to demonstrate the greater demand for local qualifications in the light of local variabilities in administrative practices. This recognition will be accorded shortly after the students are given adequate practice locally under Indian community conditions'.

#### APPENDIX TO THE REPORT OF THE CHEMICAL EXAMINER TO GOVERNMENT, PUNJAB, FOR THE YEAR 1939

[As usual, Lieut.-Colonel Thomas has an interesting appendix to his report which we think will be of more value to our readers than a résumé of the activities of the department therefore we reproduce it in full.]

## APPENDIX—

*Chemical warfare*

With the rapid progress made by modern aircraft in speed, range, carrying capacity and ceiling height, a war amongst so-called civilized nations can directly affect their civilian population, in other words, the civilian as well as the soldier must be prepared to face courageously and intelligently the shock of military attack.

The nature of such an aerial attack may be by any or all the three following types of bombs:—

- (1) High explosive.
- (2) Incendiary.
- (3) Gas.

In reviewing the effects of an aerial bombardment on a civilian population, our most recent and reliable knowledge is from the civil war in Spain which ended in 1939. No detailed information is so far obtainable of the Russian air attacks on the Finnish towns or of the German aerial bombardment of the Polish towns except that gas is not being used. Gas was not used in Spain nor is it being used in China, but there is proof that gas was employed latterly in Abyssinia in order to expedite operations before the setting in of the seasonal rains.

I cannot, therefore, do better than quote freely from a pamphlet on 'Lessons from Barcelona' by a Major MacRoberts who was present at some of the bombardments on that city.

*High explosives*

'The type of high explosives which has been used with most devastating effect in Spain is a percussion bomb bursting on impact. Made of light metal in weight from 100-250 kilograms, it has no serious crater effects; in many instances the craters were but a few inches in depth, but the blast effect has been such as to demolish the walls of a building in a lessening degree to a radius of as much as sixty yards from the point of explosion.

On the other hand, the important, and from our point of view, the vital fact to remember is that the pressure waves—the blast—only radiates over the surface of the ground from a percussion bomb. There are no violent underground tremors—no seismic effects. The damage is all above ground, hence the supreme importance of underground shelters. Underground we are safe, and a seven-foot deep trench in our backyard is just as effective, and probably more so, than a great strongly constructed basement shelter, because in any form of cellar or basement accommodation there is the additional factor to be taken into consideration of the ability of the roof of the basement to support the weight of the total collapse of the building overhead, and under the very worst conditions the total concentration of a load may reach a maximum of two tons per square yard.

The other type of high explosive bomb which has been used with varying success in Spain is what is known as the armour-piercing delay-action bomb. It must be admitted that the direct hit of an armour-piercing bomb presents an almost unanswerable problem. But there again is one of its chief drawbacks against its general use. It must be a direct hit—a miss is as good as a mile; it is so entirely local in its effect. And unless there is a direct hit on a shelter there is none of the terrifying blast effect which is connected with the percussion bomb.

Let it suffice for us to say that although there is no protection from the direct hit of a missile of this type unless there is overhead protection of at least twenty feet of solid earth and rubble, or fifteen feet of concrete, nevertheless there are so many factors militating against its general employment in attack against a civil population that it may be assumed that it would only be used in any great numbers against targets of supreme military importance.

The effectiveness of an armour-piercing bomb lies in its penetrability, and to achieve this its stream-lined shape, its sharp-pointed highly-tempered nose cap, its rather complicated delayed action fuse, and its great

weight of solid steel which may vary between 1,000-2,000 lb., all combine to make it a most costly projectile to manufacture.

The armour-piercing bomb relies for its power of penetrability on its great weight alone. The force of gravity draws it down to tear its way through any obstruction save the most heavily protected armour or earth-works. It is like a projectile hurled from a 15-inch naval gun. It is, in fact, almost the same type of armour-piercing shell. The armour-piercing bomb is equipped with a delayed action fuse which is usually placed in its base. The fuse ignites the explosive charge after the resistance of the earth has brought the huge weight of metal to a final halt. By means of its shape and pointed nose it is enabled to bury itself deep in the ground to a depth of ten feet or more according to the material resistance offered by earth or concrete. The explosion then occurs, and a great yawning crater varying from ten feet to fifteen feet in depth is hollowed out at the point of impact—a mass of debris being thrown up in all directions, i.e., the "splinter" effect referred to in textbooks. It will be seen, therefore, what a problem our engineers are faced with in constructing underground shelters which will withstand the shock of a direct hit from such a force. And yet again, if we study its effects it will be seen that there are very definite limiting factors. I placed the greatest importance on its entire absence of lateral blast effect—for unlike the percussion bomb, which radiates over the surface, the blast of an armour-piercing bomb is smothered or muffled by its own crater effect'.

Casualties in such cases are due to—

(1) People being trapped by falling masonry or injured in resulting fires.

(2) *Blast*.—Casualties are picked up dead, without apparent wounds, and only showing blood-stained fluid trickling from the mouth or nose. Post mortem the lungs are found to be torn.

(3) *Flying glass or fragments of the bomb*.—During the Dussehra bomb explosion of 1924, I myself was present at a post-mortem examination on one of the victims. A tiny fragment from the casing of the Mill's bomb was found in the body but this small fragment which had been projected with such velocity had completely reduced the whole liver to pulp resulting in immediate death.

*Incendiary bombs*

Modern chemistry has brought incendiary technique to a new stage. As a result of the invention of aluminothermy incendiary bombs have attained such an importance that they appear to be very dangerous weapons for bombarding towns, petrol tanks, gasometers, stores, ammunition dumps, etc., taking also into consideration the fact that a bomber can carry large quantities of such bombs. Some years ago there was a wave of incendiarism in Lahore. Some students made various attempts to burn letter-boxes. Phosphorus dissolved in carbon bisulphide was the combustible chemical generally used. The Thermit and Electron-Thermit incendiary bombs in contrast to phosphorus burn independently of the oxygen contained in the air. These bombs have the property of what is known as 'sub-surface persistence' and can burn at an initial temperature of 3,000°C. Such bombs are usually small, weighing from 2-4 lb., so a big bomber can carry upwards of 2,000 such bombs which can be scattered indiscriminately over cities and start numerous fires. An efficient Fire Brigade is the best protection.

Casualties in such cases are due to—

- (1) Burns.
- (2) Shock.
- (3) Sepsis.

It has been reported from Spain that shock caused the greatest number of fatalities in such cases and that the most successful treatment against shock was blood transfusion. As blood donors women were better volunteers than men in the proportion of 4 to 1.

The recent book on the treatment of wounds caused by high explosives and burns is 'Medical Organization and Surgical Practice in Air Raids' by Mitchiner and Cowell, published in 1939 by J. & A. Churchill, price

# Elastoplast Technique in Modern Surgery

## ABDOMINAL POST-OPERATIVE DRESSING

A sterile dressing is applied to the abdominal wound followed by a piece of an 'Elastoplast' bandage, sufficiently wide to cover completely the sterile dressing and sufficiently long to stretch from one side of the abdomen to the other.

Piece of 'Elastoplast' Bandage showing centre portion rendered NON-adhesive by dabbing with cotton-wool.

Section showing 'Elastoplast' applied over a sterile dressing.

Section showing 'Elastoplast' cut up centre and turned back for examination and re-dressing of wound. Fix with clip or safety-pin.

The centre of the 'Elastoplast' is dabbed with cotton wool, thus rendering it non-adhesive, to an extent that will just cover the sterile dressing. This is then applied to the abdomen with the required tension, so that the non-adhesive portion covers the dressing.

When it is desirable to change the dressing the following procedure is necessary:—

The centre is slit up with a pair of dressings scissors; the sterile dressing is changed and the cut ends are folded back over the dressing and fastened with a clip or safety-

pin. For subsequent dressings it is then only necessary to unfasten the clip or safety-pin for the wound to be examined and re-dressed.

Where frequent change of dressing is required, an improved method is illustrated below.

Completed Dressing.

Dressing opened for inspection.

(1) Rods. (2) Strips of 'Elastoplast' folded round the rods, so that the adhesive surface does not come in contact with dressing. (3) Rubber bands. (4) Dressing.

# For successful Radiography

ILFORD X-RAY FILM is coated with an emulsion which combines speed to X-Ray, speed to Intensifying Screens, excellent contrast, freedom from fog, and quick fixing to a degree hitherto unknown.

The same film may be used with or without Intensifying Screens, and radiographs of excellent quality, full of detail, are obtainable.

The greatest care is taken in the coating and preparation of the film to ensure complete freedom from mechanical defects, while the risk of abrasion is removed by the use of super coating.

Ilford X-Ray Film is supplied on both nitrate and acetate bases.

## ILFORD X-RAY FILM (Double Coated)

FOR EXTREMITY WORK, the finest results are obtained from

ILFEX Double-Wrapped X-Ray Film. Supplied only on Acetate (Safety) Clear Blue Base.

MADE BY ILFORD LIMITED · ILFORD · LONDON

Full and fresh stocks maintained by:—

ILFORD-SELO (INDIA), LTD., Bombay, Calcutta, Lahore and Madras.

## THE STANDARD BOOK FOR INDIAN TREATMENT AND DIETARY **DIABETES** and ITS MODERN TREATMENT

By  
J. P. BOSE, M.B. (Cal.), F.C.S. (Lond.)

Third Edition

Thoroughly Revised and brought up to date.

Price Rs. 7-8.

*Contents.*—Antiquity of diabetes—Insulin and its later modifications—Incidence of diabetes and mortality and some of the common etiological factors—Carbohydrate metabolism—Pathology of diabetes—Symptoms of diabetes—Diagnosis of diabetes mellitus—Blood sugar and blood lipoids—Principles of dietetics and their application in the treatment of diabetes—Insulin treatment—Some of the dangers and complications of diabetes and their treatment—Diabetes in children—Glycosuria and life insurance—Author's simplified method for estimation of sugar in blood—Examination of urine—Protamine zinc insulin—Tables of food values and average weight, etc.—General index.

## THACKER SPINK, CALCUTTA

half a guinea. (Reviewed in the July 1939 issue of the *Indian Medical Gazette*, p. 442.)

#### Gas

From about 3,000 chemical poisons which were closely examined both before and during the Great War by the belligerent states with regard to their suitability as fighting materials, *i.e.*, for use in open country, only about 20 were considered to be of any practical use. The reason for this small number lies in the very high requirements exacted of these materials, such as immunity against the oxygen of the air, atmospheric and terrestrial humidity, indifference towards the material of the projectile, resistance to detonation, intensity of the physiological effect, large volumetric weight in gaseous form, etc., to which may be added special properties, according to the application (defensive or offensive materials). These explanations will, at the same time, explode the myth of the existence of new secret discoveries exerting a more deadly effect. It may happen that one or the other material may still be found to be suitable. Yet the demands which must necessarily be made on its properties will naturally limit the probability that it would be more effective than those already known (Kinttoff).

The object of poison gases is to disable or kill the opponent. Therefore, their effect is directed to various parts or organs of the human body according to which they are classified as follows:—

- (1) Eye irritants.
- (2) Nose and throat irritants.
- (3) Lung irritants.
- (4) Vesicants or blister gases.

The lung irritants and the vesicants are the most important groups. Phosgene is a typical example of a lung irritant and mustard gas is a true vesicant.

An excellent book by Lieut.-Colonel Bilderbeck, *R.M.S.*, called *A. R. P. Instructors' Manual*, price Rs. 2-4-0 and published at the *Times of India Press*, Bombay, gives all the symptoms, treatment, etc., of poisoning due to the war gases together with such information as is useful to us in India. I am recommending this book to anyone who is interested in this subject.

#### Conclusions

The odds are that gas is not likely to be used against civilians, even untrained civilians, as so much more material damage can be done by high explosives and incendiary bombs. The providing of respirators does not appear necessary at present. Equally effective protection can be obtained by remaining quietly indoors. During the Great War the French and Belgium peasants in the forward areas were not supplied with respirators. When a gas attack was made they left their fields and shut themselves up in their houses and suffered little, yet they must have been in a much higher concentration of gas than any civilian population is ever likely to be.

In an air raid it is certain that if poison gas were used, the initial attack would consist of high explosive bombs. Such an attack would have the effect of loosening the fabric of a building above ground and thus permit the infiltration of poison-gas in a subsequent attack.

As a famous instructor has stated at one of the Home Office A. R. P. Schools: 'If you want to get at the sardines you have first to open up the tin'. A high explosive bomb is only a high explosive shell in a different form, for whereas one is propelled from a gun, the other is dropped from the sky, and every soldier knows that the only protection from shell-fire is in a trench.

Public psychology is an increasingly determining factor in modern warfare. The threat of air attacks against the civil population constitutes an important psychological weapon which an unscrupulous enemy may employ.

If the present war continues or spreads to other countries, the subject of chemical warfare will be dealt in much greater detail in our next year's report.

### ANNUAL REPORT OF THE CHEMICAL EXAMINER TO GOVERNMENT, UNITED PROVINCES AND CENTRAL PROVINCES, FOR THE YEAR 1939

ONE THOUSAND SIX HUNDRED AND FIFTEEN medico-legal cases and 5,613 articles were examined during the year under report as against 1,524 cases and 4,970 articles in 1938.

The total number of human poisoning cases examined under this head was 413. Poison was detected in 60.5 per cent of cases as against 67.0 for 1938.

Dhatura was again the most commonly used poison. It was detected in 37.5 per cent of the cases.

Opium, arsenic, mercury-salts, aconite, nux vomica (strychnine), cyanides and alcohol came in order of frequency forming 23.5, 18.6, 3.7, 3.0, 2.3, 1.9 and 1.1 per cent respectively of the detected poisons. In 2.3 per cent of cases unidentifiable organic poisons were found. This shows the need for research on the indigenous vegetable poisons. Bones and ashes of five persons were received and examined during the year. Arsenic was found in four of the cases.

Thirty-six cases of animal poisoning were examined compared with 23 cases for the preceding year. The percentage of detection was 66.6 compared with 65.2 for the year 1938. Arsenic was detected in 14 of these cases. Kancr came next in order of frequency.

One thousand one hundred and sixty-two stains were examined comprising 853 blood stains and 309 blood and semen stains (sodomy and rape cases). There has been a considerable increase in the number of murder cases during the latter part of this year.

### CHEMICAL EXAMINER'S DEPARTMENT, GOVERNMENT OF MADRAS: REPORT FOR 1939

THE total number of articles examined in the chemical examiner's department increased from 8,913 to 9,392.

Four hundred and fifty-eight cases of human poisoning were examined as against 467 in the previous year and poison was detected in 54.6 per cent of the cases. Some of the cases described below show how an ignorant or a mistaken use of certain drugs, some of which are regarded as medicinal, ended in disastrous results and they should serve as a warning to the general public.

A religious mendicant sucked perchloride of mercury mistaking it for alum and died of the effects of poisoning. Another gave a paste containing datura to a husband and wife to enable them to travel without fatigue. The husband, who ate a large quantity of the substance, lost consciousness and when he regained consciousness the next day, he found that his wife had been throttled to death. A shopkeeper sold denatured spirit to a woman mistaking it for 'omam water' (caraway water). The ignorant woman administered it to her child with fatal result. Two children were given the bark of *Holarrhena antidysenterica* Wall (*Kurchi* or *Coness*) as a purgative with fatal results to both. A young man accepted a bet and ate yellow oleander kernels. He was removed to a hospital in a collapsing condition where he recovered. Another was given toddy with mercury by a quack, to cure him of an evil habit. He became seriously ill, but recovered under hospital treatment. Investigation of a suspected case of poisoning of a hysterical young girl of twenty resulted in the discovery that she had been beaten to death by a magician who had offered to drive the devil out of her.

There was a slight reduction from 26 to 23 in the number of animal poisoning cases. Poison was detected in 56.5 per cent of the cases. Arsenic and oleander account for the largest number.

The number of stains examined increased from 979 to 993. Blood was detected in 91.8 per cent of the blood-stain cases. The examination of such cases has been of great assistance in the investigation of crimes and prosecution of criminals.

Miscellaneous medico-legal cases involving the examination of firearms, bullets, bones and tissues, counterfeit coins, re-used stamps, documents, etc., increased from 99 to 136. One of the noteworthy cases is that of a village officer who was entrusted with the

duty of conducting an election to a *panchayat* board and who was alleged to have tampered with the notice of election by altering the day and date of election. An examination of the document under the microscope and in ordinary and ultraviolet light, proved that the allegation was true.

One hundred and twenty-five cases were examined for Government departments, as against 214 in the previous year.

#### REPORT OF THE EUROPEAN MENTAL HOSPITAL AT RANCHI FOR THE YEAR 1939. BY MAJOR MOORE TAYLOR, M.D., D.P.H., I.M.S., MEDICAL SUPERINTENDENT

THE condition of every patient on admission is thoroughly investigated, the routine consisting of a complete physical, pathological and psychological examination. This is followed by dental and ear, nose and throat, and where indicated, ophthalmic examination. Thereafter treatment is prescribed, and all patients are given the benefit of whatever special treatment is indicated. The treatments now in common use are cardiazol shock-therapy, prolonged narcosis, malariotherapy, pyretotherapy, hydrotherapy, occupational therapy, in addition to whatever physical, medicinal or endocrine therapy may be called for in individual cases. Shock-therapy is expensive, highly specialized and takes three or four months to complete in any one case, but its results are encouraging, and in the present state of our knowledge it offers the only hope of cure or amelioration in certain cases of schizophrenia. In spite of the difficulties and dangers of the treatment it has justified itself as a form of therapy. Treatment by prolonged narcosis is found particularly useful in states of excitement and especially in the manic-depressive psychoses. Hydrotherapy is an important form of treatment in many types of mental disorder and is used extensively in this hospital. The detailed technique of all methods of treatment has been dealt with in previous annual reports of the hospital, and repetition is, therefore, unnecessary.

Occupational therapy continues to be one of the main features of the hospital. The average number of patients employed in useful tasks in the hospital represents over 80 per cent of the population. All nursing sisters are now fully qualified to supervise this treatment, either in the occupational therapy department or in the wards. The crafts taught on the female side include crochet, tapestry, painting, leather work, embroidery, quilting, plain sewing and mending, dress-making, tailoring, basket-work, raffiawork, knitting of all types, bead-work, etc.; and on the male side carpentry, book-binding, upholstery, cloth-weaving, rug and mat making, basket-work, paper bag making, decorative paper work, picture-framing, metal work, etc. Most of the articles made in the department are utilized in the hospital but any surplus stock is sold to the public. During 1939 the female occupational department undertook all the tailoring and dressmaking required in the hospital and in addition sold goods to the value of Rs. 396-7-0, an increase of Rs. 97-3-6 compared with last year, while in the male section all manufacture of furniture, repairs to hospital furniture and plant were executed, and goods sold to the value of Rs. 423, an increase of Rs. 57 compared with last year.

Classes in physical drill, folk-dancing and games are held daily, and the patients, assisted by the staff, staged a number of excellent concerts during the year. Parties attended the cinema at Ranchi whenever suitable films were shown. The usual social evenings and dances continue, and a full Christmas programme was brought to a close with the usual fancy dress ball. The cricket, football and hockey teams played a number of friendly matches on the hospital grounds, and also at Ranchi, some of which they won.

In the treatment of mental illness it is extremely important that as far as possible, the patient should not feel that his (or her) liberty is being unduly interfered with. There are no locked doors in the hospital, and patients are allowed to write and receive

as many letters as they wish, and it is a rarity for any letter written by a patient to be withheld, indeed, most of the correspondence remains uncensored.

Voluntary boarders who elect to manage their own affairs are permitted to do so.

During the year a thorough investigation into the dietary scale was carried out, and a report was submitted to the managing committee. The aim has been to set up a standard by which each patient should receive his physiological proportion of calories and vitamins at the least possible cost, and to provide a certain amount of variety. It has to be conceded that the dietary, considering all circumstances, is an excellent one—and perhaps more elaborate than that which can be obtained by many of those who have to pay the rates and taxes. The answer to this is (1) that diet is one of the most important methods of treatment, (2) the better the diet the greater is the hope of recovery and (3) the higher the recovery rate, the less will be the contribution charges payable by Governments. Nevertheless the average *per capita* cost under diet for the year 1939 has been reduced to Rs. 280 per annum.

It is gratifying to be able to report that all uniforms of ward-boys and ayahs, and all garments and clothing for both male and female patients have been made in the female occupational department. In former years a substantial part of this work had to be undertaken outside the hospital. This is the first year that the entire requirements have been met within the hospital, and for this, the credit must go to Sister Haagensen, who has held charge of the female section of the occupational department throughout the year under report.

#### ANNUAL REPORT OF THE PUBLIC HEALTH DEPARTMENT IN THE CENTRAL PROVINCES AND BERAR FOR THE YEAR 1938

THE state of public health during the year was unsatisfactory. The death rate was higher by 7.95 per mille than the mean of the previous five years and exceeded that of the previous year by 8.44 per mille. The infant mortality rate was 19.60 higher than in 1937 and exceeded the mean of the five previous years by 12.07. The increase in mortality occurred under all heads with the exception of plague, smallpox and injuries.

Owing to the serious outbreak of cholera, the ordinary routine public health and medical relief work of travelling dispensaries and even of stationary rural dispensaries was greatly disorganized as all efforts were concentrated on the suppression of cholera. This was reflected by a general deterioration in health. The chief causes of increase in mortality compared to the previous year were: cholera (44,225), malaria (34,662), respiratory diseases (8,619), diarrhoea (7,896), and other fevers (5,383).

The urban and rural death and infant mortality rates exceeded those for 1937 by 7.69, 8.53, and 20.12 and 10.53 respectively.

Four tuberculosis clinics, one each at Nagpur, Jubbulpore, Amraoti and Raipur, were established during 1938. Five thousand, two hundred and seventy-seven patients attended at these clinics. Of these, 1,365 were found positive to tuberculosis. Total number of sputum examined was 3,000, of which 632 were found positive. Four thousand and eighty x-ray examinations were made and only 1,593 gave positive signs; 1,515 pneumothorax operations were performed. Number of deaths amongst patients who attended the clinics was 59. One thousand and eighty-two patients ceased to attend. Two thousand five hundred and ninety-one cases were visited and advised at their homes.

Guinea worm is specially prevalent in Damoh subdivision of Saugor district which abounds in step wells. Efforts to get these wells converted into draw wells have so far failed.

*Leprosy*.—The number of deaths from this cause was 1,579; 255 more than last year. The disease is prevalent all over the province.

# **New Facts about the Power of BOVRIL**

---

## **Remarkable Experiments at an English University**

As long ago as 1911, the late SIR WILLIAM THOMPSON of Dublin established that Bovril has a unique power of ministering to nutrition. During last year a series of remarkable experiments were conducted at an English University which provided physiological explanation and proof. A group of medical students volunteered to undergo scientific dietetic tests, so that accurate studies might be made of the effect of certain beef preparations. One of the substances investigated was Bovril. As a result of these experiments\* Bovril was proved to be "The most effective stimulant." Briefly, it was shown that Bovril increased the supply of gastric juices where there was a deficiency and restored it to normal. It is an accepted medical fact that a lowering of the essential gastric activity is found in people of sedentary habits and poor muscular development. Bovril helps to rectify this and, by facilitating the digestion of proteins, enables full nourishment to be gained.

\**B.M.J.*, 1937 August 28. Page 412.

## *As Development Proceeds*

The needs of the growing infant call for increased amounts of mineral elements ; these, with small variations in the proportions of fat, protein and soluble sugars, form the *raison d'être* for the use of Allenburys No. 2 Humanised Milk Food instead of Allenburys Milk Food No. 1 from the beginning of the fourth month.

*Descriptive literature will  
be sent on request.*

**ALLEN & HANBURY LTD.**  
(Incorporated in England)

Clive Buildings, CALCUTTA  
and at 37, Lombard Street, London, E.C.3

During the year, two more leprosy clinics were established at Bhandara and Arni (in Yeotmal district), making a total of 37 centres. The number of sub-centres remained the same, *viz.*, 51.

Systematic resurvey and active propaganda was carried out, resulting in the discovery of 409 new cases which were brought under treatment.

There are in the province 11 assistant surgeons and 18 assistant medical officers and 16 private medical practitioners, who have received special training in leprosy at the School of Tropical Medicine, Calcutta.

During the course of their tours sub-assistant health officers of Chanda, Bilaspur, and Drug came across 255 cases of yaws. All these cases have been brought under treatment.

There were 6,539 deaths from child birth, of which 953 were registered in municipal and other towns and 5,586 in rural areas. This corresponds to one maternal death to every 84 urban and 107 rural births, including still births. The general, urban and rural maternal death rates are 9.64, 11.86 and 9.34 per 1,000 births, including still births, respectively.

### TRIENNIAL REPORT ON THE WORKING OF THE HOSPITALS AND DISPENSARIES IN ORISSA FOR THE YEARS 1936, 1937 AND 1938

THE Province of Orissa was created on the 1st April, 1936. The province had, on the day of her creation, 176 hospitals and dispensaries which are by no means considered sufficient for the medical needs of the province. During an inspection of hospitals and dispensaries in the province it was noticed that many of them under the management of local bodies were not in as an efficient condition as they should be, especially those in the agency area. As regards hospitals, it may be said that most of them are poorly equipped and medical, nursing, and menial staff are inadequate for the number of patients each hospital has to deal with. There is a further deterioration in these respects in many institutions as payments of contributions by local bodies are often in arrears and do not suffice to meet the expanding demands. The progress in effecting improvements of the hospitals and dispensaries was slow owing to requisite funds not being always forthcoming. Local bodies, as proprietors of class III hospitals and dispensaries, have placed the management of the institutions with managing committees constituted with local members with the idea that they should endeavour to make the institutions self-supporting by raising local subscriptions and to relieve the boards thereby of a large proportion of the recurring expenditure which they could utilize in extending medical relief to other areas. With a few honourable exceptions, these committees function in name only and evince little interest in the institutions. They also do not appear to realize the civic responsibility for improving the institutions under their management so as to render better medical facilities to the poor for whom the institutions are primarily meant. Such being the state of affairs in the management of hospitals and dispensaries under the local committees, they have not been able to create public feeling for regular contributions towards the upkeep of the dispensaries, thus defeating the purpose for which such committees were established.

Since the formation of the province a great impetus has been given to the progress of medical work in the province as a whole. There have been visible signs of greater activity in almost every direction and in all that concerns the welfare of the medical institutions in the province. There has been a general awakening amongst all who are interested in medical work which, it is hoped, will lead to better results in future. The popularity of the scientific and modern system of medicine, especially in the agency area the inhabitants of which are somewhat averse to medical treatment, has been kept always in view and measures are being taken in that direction. All such improvements which have been possible during this short period are due to the wise liberality of Government, who have not only

contributed in a large measure to ameliorating the sufferings of the poor people but have also stimulated public interest and benevolence.

### THE PREMANANDA FREE CHARITABLE OUT-DOOR LEPRO DISPENSARIES, CALCUTTA. ANNUAL REPORT FOR 1939

During the year 905 new patients were admitted at Maniktola and 260 at Kalighat. This is an increase of 274 on last year.

The total number of patients who attended for treatment during the year was at Maniktola 1,405 ordinary patients and 200 street beggars, who are classified separately, and at Kalighat 533, and 71 beggars.

These made 33,967 attendances at Maniktola and 11,152 at Kalighat. Last year's figures were 27,438 and 12,039.

Of these patients 633 (Maniktola) and 294 (Kalighat) attended sufficiently regularly to justify re-examination at the end of the year. The following results were obtained:—disease arrested 110; much improved 416; slightly improved 278; the same 118; worse 5.

One of the members of the dispensary staff is employed as part-time visitor to the homes of patients who have discontinued treatment, to explain to them the serious nature of the disease, to persuade them to return to treatment and take the necessary precautions against the spread of the disease. He paid 411 visits; 80 patients were traced, and of these 49 returned to treatment; 48 were found to have given wrong addresses; 2 had died; and of the rest no trace could be found.

We have appointed three whole-time clinical assistants in place of two whole-time and two part-time workers.

We have recently produced a pamphlet in Bengali containing instructions to patients on admission, explaining the nature of the disease, the principles of treatment and precautions to be taken. This will meet a long-felt need. A Hindi translation is being prepared.

In our report last year we announced our intention of rebuilding the Maniktola Dispensary. The plans had to be adapted to the very limited ground available. They provide for a large treatment room and smaller dressing room on the ground floor, and laboratory, office and store on the first floor. The expense has been met in part from the building fund, and in part by an anonymous donation from England, and the equipment of the laboratory by a grant of Rs. 2,000 from the Government.

The commencement of the building operations in November was the occasion for the outburst of opposition from certain neighbours; this led to police court proceedings which held up the building for another three months. Happily the efforts to obstruct the work proved futile and now the building is well in hand and should be finished by the end of April 1940. These new quarters will very much add to the efficiency of the Maniktola Dispensary.

Our next task must be to improve the premises at Kalighat.

The Calcutta Corporation without any warning reduced their grant from (1938-39) Rs. 8,000 to Rs. 5,000. We were therefore faced with a very serious situation. The situation was saved by the generosity of of the Trustees of the Crichton Trust who gave us a donation of Rs. 2,500 and by other kind friends. This has enabled us to pay our way in the current year, 1939-40, but, our mounting expenditure, due to the increasing work and the improvements introduced, will make it difficult to meet our bills in the coming year, unless the Corporation restore the grant in full.

Our first need is for a gradually expanding income that will meet the needs of the normal development of the work.

Our second need is for a capital sum to meet the cost of new premises at Kalighat.

Our third need is for friends who will co-operate in the struggle against this terrible disease. We are always grateful for gifts in kind, especially of bandages and cotton-wool which we use in large quantities, and of

food and cigarettes, which we give to our poorest patients, when the time for the Christmas feast draws near.

We hope that many who read this report will send their subscription to the Secretary, Premananda Out-Door Leper Dispensaries, 42, Cornwallis Street, Calcutta.

#### MEDICO-LEGAL SOCIETY, BIHAR, 1939-40

[WE have received the first annual report of the Medico-Legal Society, Bihar. It appears that this society was founded in April 1939. We give below an abstract from an appeal to join the society issued by the President, the Chief Justice of Bihar, as it expresses our own opinions on the subject. It would be an advantage to other provinces of India if they followed the lead given by Bihar and formed similar societies.—EDITOR, I. M. G.]

A Medico-Legal Society has been started with a view to promoting medico-legal knowledge in all its aspects. It will consist of qualified members of the legal and the medical professions and such other persons as may be interested in the objects of the society. The need for such a society is obvious. Lawyers have often very little knowledge about the human system and frequently cannot fully appreciate the medical reports which are at times difficult and complicated and the medical men have an equally meagre idea about the legal problems arising out of their reports. The result is that a clear understanding of the problems becomes difficult. To promote justice a better understanding between the two professions is necessary not only for members of the two professions but also for the judiciary. The idea is to provide a common platform for all those who are interested in the problem to meet together, read papers on medico-legal subjects and discuss questions arising therefrom.

### 'DOPING' IN ATHLETIC CONTESTS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—It was with the greatest interest that I read Colonel Phipson's paper on 'doping' in athletic contests, in the August number of the *Indian Medical Gazette*. It is a subject towards the medical aspect of which very little attention has been paid; and yet, in view of the considerable increase in the practice of 'doping', it is a matter of the greatest importance that its effects should be fully understood, and its dangers realized. Colonel Phipson's warning in this respect is therefore timely, and should be widely appreciated. It is, indeed, surprising, that the matter has been hitherto so neglected, not only in view of its practical importance, but also on account of its undoubted novelty and attraction as a field of research.

What is 'doping'? If we confine its meaning to the use of drugs which are toxic, injurious, or dangerous, such as cocaine, benzedrine, or cardiazol, then there is no doubt that the practice should be stopped, medical grounds alone being sufficient warrant. In horse-racing, the Jockey Club deal with cases of 'doping' with the utmost severity, though this, of course, is more on account of the large sums of money involved, than any particular consideration for the horse. If, however, we use the term in its widest sense, to include any means adopted to increase one's athletic performance above its normal standard, it becomes increasingly difficult to decide where to draw the line. In this connection the paths of ethics and medicine may diverge, or coincide; and what in one case may be a comparatively harmless procedure, may, under different circumstances, be quite the reverse, either ethically, medically, or both.

Many sporting writers refer, in the words of Colonel Phipson, to the 'lofty standard of ethics, which, we presume, characterized the Olympic contests in the

golden days of Ancient Greece'. I wonder if this presumption is altogether justified. One cannot be too sure that there were not occasions when a 'swift' drachma or two were made by 'gingering up an outsider', or by 'nobbling' the favourite, which amounts ethically to the same thing.

Should one consider 'training', the usual preparation of an athlete for a contest, as 'doping'? Some of the lengths to which trainers go nowadays may well be considered to transcend the bounds of ethics, as judged by the highest standards. From the medical point of view, there is no doubt that judicious and intelligent training is advisable, to prepare the body for the approaching strain on its resources. But the over-trained athlete is a common occurrence. The Harvard crew, which won the Grand Challenge Cup at Henley in 1914, were said to have been trained to the pitch of hysteria, and some of the members burst into tears at the conclusion of the final.

When the Olympic Games took place in London in 1908, the Marathon race from Windsor to London was held on one of the hottest days of the year. Dorando, an Italian, was the first to enter the White City stadium; he was obviously exhausted, and as he neared the finishing line he collapsed. Some of his compatriots rushed on to the track, and threw a bucket of water over him. This partially revived him, and he attempted to get to his feet. In the meantime the next competitor, Hayes, an American, was entering the stadium. In the excitement that ensued, the Italian's friends lifted him up and pushed him forward, with the result that the gallant Dorando managed to stagger past the winning post before collapsing again. The Americans immediately lodged a protest on the grounds of unfair assistance, and the Italian was disqualified. This nearly finished him altogether, and he was carried to the dressing room practically unconscious. He was examined by the official medical officer who stated that his heart (presumably his apex beat) was displaced half an inch. His condition gave rise to the gravest anxiety, and he showed no signs of improvement until he was informed that Queen Alexandra had given him a special gold cup as a reward for his gallant effort, after which he slowly recovered. The point is this; the pluck and endurance which had carried him through that gruelling 26 miles would not have failed him in sight of victory, except as a result of complete and utter physical exhaustion. In this case, the 'dope' was merely a bucket of water externally applied, but the final effort made following its stimulating effect, might well have had an even more serious effect than it did.

Public opinion, I am afraid, is not altogether a reliable guide. A competitor might openly, and in full view of the spectators, swallow a couple of benzedrine tablets, without exciting much comment. But let his trainer approach him with a few cubic centimetres of glucose solution in a syringe, and in all probability the Riot Act would have to be read.

'Doping' should undoubtedly include psychological stimulation. The shouts of his supporters, or a man's own determination, which spur him on to further effort in spite of his fatigue, are just as dangerous in this respect, as a drug which diminishes the feeling of fatigue; and what of the Christian Scientist (I have recently seen one in action), who refuses to acknowledge the symptoms of fatigue! Propaganda and the 'war of nerves' are 'dopes' very much employed, especially in boxing, both as a support and encouragement, and also as a means of demoralizing or intimidating the opposition. Descamps, manager of Carpentier, was an adept at this form of ringside strategy. An interesting article by Gene Tunney, ex-heavyweight champion of the world, recently appeared. It was entitled 'Courage is a business', and in it Tunney endeavoured to show that the business side of professional boxing can not only get a man into the ring in spite of his 'funk', but can actually overcome it, and develop in him a true fearless courage; and he cites examples among many famous boxers to prove his contention.

With regard to some of the other means of 'doping' carbohydrates, in some form, have long been used, to

# HEADACHE IS DISABLING

Headache may be as disabling as a grave illness. In migraine particularly, the headache is of all degrees of intensity, at times so severe as completely to incapacitate the sufferer. It is noteworthy how quickly the patient can obtain relief with Veganin. Composed of minimum doses of acetylsalicylic acid, phenacetin and codeine, Veganin affords striking proof of the superior analgesic potency of this synergistic alliance over that of its components administered separately. Recurrent painful conditions, such as migraine and dysmenorrhœa, yield with impressive promptness to the efficacy of Veganin.

## VEGANIN TABLETS

Supplied in tubes of 10 and 20. Veganin is not advertised to the public.

*A trial supply to Physicians on request.*

**MARTIN & HARRIS LTD.,** Mercantile Buildings, Lall Bazar, Calcutta.

Also at Bombay, Madras, Karachi and Rangoon.

Prepared by **WILLIAM R. WARNER & CO. LTD.,** LONDON, ENGLAND.

# THE IMPORTANCE OF PRECISION POLISHING

In order to obtain uniformity of calibre and complete roundness of strand along its entire length, A. & H. Catgut is polished by automatic machinery.

Hand polishing of individual strands fails to obtain this desirable precision and uniformity in the production of surgical catgut strands.

One of the modern advantages incorporated in the production of A. & H. Catgut.

The entire product  
manufactured in  
England.

*A descriptive booklet will  
be sent on application.*

Precision Automatic Polishing, in one operation, of twelve catgut strands, each 10 feet in length.

and at 37 Lombard Street, London, E.C. 3

defer exhaustion and to furnish a source of energy. I agree with Colonel Phipson, however, that it should be administered during the period of exertion. 'Premedication' with glucose is not likely to be of much use, unless the glycogen reserves of the body had already been depleted. The method would therefore appear to be of most use in long distance events, or other endurance contests. Some years ago, a South African farmer, Norton, arrived in England, and proceeded to break various long distance running records, such as London-Bath and London-Brighton. According to the press, he was considerably aided in this by a 'magic drink', which he took at intervals during his running. This drink turned out to be a solution of sugar in lemonade, and it is a fact, that this man, who was, I think, over 40 at the time, did put up some remarkable performances on the road.

The cutting down of the salt intake in an athlete's diet is generally done in an attempt to reduce weight. Surplus fat is in most cases undesirable and an unnecessary burden to an athlete. But 'wasting' can be carried too far, and, if persisted in, may have definitely harmful effects. The practice is particularly common among jockeys and boxers, whose weight has to be kept within certain limits. The method usually adopted is 'sweating' (Turkish baths, violent exercise in sweaters, etc.), and 'drying-out' (limiting the fluid intake). Jockeys and boxers both start young, and a deliberate and persistent refusal to allow the body to develop along its normal lines is bound to have an ill effect after a time. One of the most celebrated jockeys of all time, Fred Archer, is said to have ruined his health by continued wasting. The so-called classic races of England are run at 9 stone, but to be of general use throughout the season a jockey has to be able to ride at about 8 stone. He may have commenced his actual racing career at about 14, well within the weight limit then, of course. But while his skill and experience are growing, so also is his body, and when, after a few years, he is on the threshold of becoming a successful jockey, he is faced with the necessity of wasting for the rest of his career. Boxers, especially among the lighter weights, also start at an early age, and as they grow and develop they have to choose between entering a higher weight, with its tougher opposition, or wasting to remain in the same class; and many a boxer has fallen between the two stools. It is interesting to note that Jimmy Wilde and Gordon Richards, strong men of the ring and turf, respectively, never had to waste, and there is little doubt that their long and highly successful careers were due, in no small measure, to this fact.

'Oxygen-priming' under practical conditions is not of great value, as very little delay between its administration and the start of the race would be sufficient to restore the oxygen balance to normal. However, I did once see it put to an effective use, as follows: While holding a short service commission in the Navy, I was one of a batch of 'young doctors' sent to do a gas course. At the end of our training we were 'invited' to hold a quarter-mile race in gas masks. The field numbered about 20, and included several tough young midshipmen. However, as we lined up to receive our final instructions, one intelligent surgeon-lieutenant hooked his finger in the chin-piece of his mask, and got in about six good gulps of fresh unfiltered Hampshire air. Letting go at the 'Off', he streaked down the course and won in a canter. As he told me afterwards, he was clear of the field before he ever needed a breath!

I think everybody agrees that the disadvantages of alcohol far outweigh its potentialities as a source of energy. Nevertheless, it has its uses, and may be employed to allay an initial nervousness. For instance, the machine-like precision of the professional billiard player becomes almost subconscious as a result of constant practice. A 'quick one' before an important match might quite conceivably give him the initial confidence to get quickly into his stride, an important factor in these days of 2-hour sessions and 1,000 breaks! There is also the story of the long jumper who had developed a 'taking-off board complex', and was inches

short in consequence. Just before a contest someone gave him a nip of whisky, with the result that he forgot all about the board, and did a perfect take-off.

Artificial sunlight has become increasingly popular in recent years, but it is not without real danger. Cases have been reported of otherwise unexplained 'lighting-up' of foci of infection, particularly tuberculous, through injudicious use of 'artificial sunlight' lamps.

Benzedrine, as its stimulating properties became known to the public, began to be used fairly frequently, and at one Wimbledon was said to have been employed by certain players, not only to lessen the sense of fatigue, but also to speed up their sense of anticipation. The drug has, of course, since been brought under the scope of the Dangerous Drugs Act, which has fortunately made it less easily accessible.

The administration of hormones, such as testicular extracts, to normal healthy athletes might not prove an altogether unmixed blessing, particularly to trainers responsible for their teams. The effects, psychological and physical, might well spread beyond the immediate end in view. Some of the oestrous-producing substances used to alter the date of menstruation in women athletes have certain disadvantages. The results of their administration are often unreliable, and gastrointestinal disturbances are common. Also one cannot be altogether happy about disturbing the menstrual cycle in a woman whose pelvic physiology has hitherto functioned normally. It is surprising how little many of the women athletes of to-day worry about their 'periods'. Aerobic and tap dancing, and similar athletic features of modern stage technique, call for a considerable degree of physical fitness in their exponents, to carry them through a long run of repeated performances. Yet the young lady of the chorus rarely takes, or is allowed, a day off, on account of being 'unwell'. As a matter of convenience, the use of internally worn sanitary appliances has been widely adopted by women athletes, but the medical profession is still divided in its opinion as to their desirability.

With the temporary cessation of international athletics, the question of 'doping' can perhaps be relegated in favour of more pressing affairs. When, however, the present craze for mutual destruction has passed, and we can once more devote our attention to more healthy pursuits, there is no reason to suppose that the intensity of sport, especially as regards record-breaking and international contests, will not become as great as before. The question of 'doping' will then once again come to the fore, and the matter will have to be taken up. I would suggest an investigation by a committee of medical men (the profession has always included famous athletes in all branches of sport), who would lay their findings and recommendations before the various national and international athletic bodies. These in turn could then consider the necessity of legislation and control.

Yours, etc.,

W. J. MOODY, M.A., M.B.,  
F.R.C.S. (Ed.),  
MAJOR, I.M.S.

BRITISH LEGATION,  
KABUL,

### HONORARY APPOINTMENTS

#### To be Honorary Surgeons to the King

COLONEL F. F. S. SMITH, V.R.S., 8th November, 1939, vice Major-General E. W. C. Bradfield, C.I.E., O.B.E.

Colonel E. G. Kennedy, 24th November, 1939, vice

Colonel S. G. S. Houghton, C.I.E., O.B.E.

Colonel R. H. Candy, C.I.E., 24th January, 1940, vice Colonel W. E. R. Williams, O.B.E.

*To be Honorary Surgeon to the Viceroy and Governor-General*

Colonel J. S. S. Martin, *vice* Colonel F. F. S. Smith, vacated 21st September, 1940.

**APPOINTMENTS AND TRANSFERS**

On reversion from foreign service under the Indian Research Fund Association, Major Jaswant Singh, an officer of the Medical Research Department, is appointed to officiate as Assistant Director, Malaria Institute of India, *vice* Major M. K. Afridi reverted temporarily to military employment.

On return from leave Major R. A. Wesson has been posted as Civil Surgeon, Meerut.

The services of Major V. Srinivasan, Civil Surgeon, Bilaspur, and Captain F. C. Leach, Civil Surgeon, Raipur, have been placed at the disposal of the Government of India Defence Department for military duty, with effect from 3rd September, 1940, and 1st September, 1940, respectively.

Captain T. M. Williams, Assistant to the Civil Surgeon, Poona, reverted to military duty, with effect from 8th September, 1940, forenoon.

The services of the undermentioned officers of the Indian Medical Service (Civil) are placed temporarily at the disposal of His Excellency the Commander-in-Chief, with effect from the dates stated against their names:—

Captain C. L. Greening. Dated 1st May, 1940.  
Major J. R. Dogra. Dated 2nd May, 1940.  
Captain T. Sommerville. Dated 2nd May, 1940.  
Captain I. J. Franklen-Evans. Dated 3rd May, 1940.  
Captain R. Passmore. Dated 6th May, 1940.

*Appointment*

The undermentioned officer retires with gratuity and is granted an emergency commission from the same date:—

Captain K. N. Rao. (Short Service Commission.) Dated 1st July, 1940.

**INDIAN LAND FORCES. INDIAN MEDICAL SERVICE  
(Emergency Commissions)**

*To be Lieutenants (on probation)*

**LEAVE**

Lieutenant-Colonel C. J. Lodge-Patch, M.C., Medical Superintendent, Punjab Mental Hospital, Lahore, who was on leave *ex-India* till the 18th October, 1940, has been granted, by the High Commissioner for India, a further extension of his leave by 4 months from the 19th October, 1940, to the 18th February, 1941.

Lieutenant-Colonel M. Das, M.C., Superintendent, Alipore Central Jail, is allowed leave on average pay for 1 month from the 17th October, 1940.

Major B. M. Rao, Medical Officer, Meshed, an officiating Agency Surgeon, is granted leave for 2 months, with effect from the forenoon of the 9th September, 1940.

**RETIREMENT**

Lieutenant-Colonel N. K. Bal, M.C. Dated 10th September, 1940.

**PROMOTION**

*Major to be Lieutenant-Colonel*

J. L. Donnelly. Dated 25th September, 1940.

The seniority of the undermentioned officers in their present rank is antedated to the dates specified:—

Captain B. N. Bhandari. Dated 21st May, 1934.  
Captain B. L. Kapur. Dated 22nd May, 1934.  
Captain A. K. Dev. Dated 31st May, 1934.  
Captain M. Akram. Dated 2nd June, 1934.  
Captain M. S. Chadha. Dated 19th June, 1934.

## Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors *ask for them at the time of submitting their manuscripts*.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

*Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.*

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

### MORE NOTES ON CLINICAL HEART DISEASE

By GERARD KELLY, F.R.C.P.(I.)

MAJOR, I.M.S.

*Professor of Clinical Medicine, Medical College Hospitals, Calcutta*

#### *Some manifestations of elevated venous pressure in heart failure*

FIGURATIVELY speaking, the systemic veins may be regarded as a reservoir filled from the periphery by blood from the capillaries and emptied by the cardiac pump. Normally, the intake and emptying mechanisms are in dynamic equilibrium. The height of the venous pressure is a gauge of the fullness of the reservoir. When, in ordinary or in acute congestive failure, the right heart fails to empty the systemic veins, the venous pressure rises. This rise of venous pressure is reflected in the venous reservoir formed by the systemic and portal venous system behind the failing right ventricle.

*Engorgement of the liver.*—The hepatic veins enter the inferior vena cava at a considerable angle close to its point of entry into the right auricle. The blood flow in the hepatic vein is a feeble stream as compared with that in the inferior vena cava. The liver itself is a vascular sponge. In the early stages of failure of the right heart to empty the systemic veins, the liver holds back a considerable volume of the venous return. Storage of water within the liver cells is probable. Thus, enlargement of the liver may precede the rise and persist after the fall of venous pressure. In young people the liver capsule is more distensible and so as a rule in them liver engorgement is proportionately more marked than are the other signs of right-heart failure.

Engorgement of the liver is an almost invariable consequence of failure of the right heart. Very rarely right-sided failure, including liver engorgement, may occur in left-sided failure without the intervention of pulmonary engorgement, *i.e.*, in the absence of the usual evidence of left-sided heart failure, a phenomenon which, Harrison asserts, speaks against the idea that the overworked chamber is always the one to fail first. Most usually, however, liver engorgement is conspicuously absent in isolated left ventricular failure. We have the impression that the liver is sometimes slightly congested in peripheral circulatory failure of toxic origin. The remaining causes of liver engorgement are relatively infrequent. Occasionally, liver engorgement may afford early evidence of effusion into the pericardial sac, which by resting on the diaphragm about the vena caval hiatus may exert compression especially of the mouths of the hepatic veins,

which, as stated above, open into the inferior vena cava. Liver engorgement is disproportionately prominent in adhesive pericarditis because adhesions more readily kink the trunks and pinch the mouths of the hepatic veins than of the inferior vena cava. On rare occasions, a tumour mass may obstruct the proximal inferior vena cava or the hepatic veins themselves may become thrombosed.

A rare but interesting result of the increased venous pressure of right-heart failure is phleboscrosis of the hepatic veins, which is the analogue of sclerosis of the pulmonary artery in pulmonary hypertension. Cardiac cirrhosis accompanies some cases of hepatic phleboscrosis.

When right-heart failure is ushered in acutely, as for example by auricular fibrillation, hepatic pain and its associations may raise a suspicion of an acute abdomen. This suspicion may be heightened by the supervention of congestive vomiting. The pain is due to stretching of the liver capsule. Its localization is the right upper quadrant or the epigastrium: we shall refer presently to those cases in which pain and tenderness are localized in the epigastrium. The radiation of the pain is to the back, to the right scapula, and to the right shoulder (phrenic shoulder pain). A sharp or colicky character of the pain, local tenderness and rigidity, tympanites and the absence of any notable liver enlargement may further obstruct diagnosis. In the shock stage of coronary thrombosis such upper abdominal manifestations are not hepatic in origin: they occur reflexly from the sudden injury to the heart muscle or they are reflections of an attendant pericarditis, whilst the vomiting is probably due to a reflex from the heart through the afferent vagal fibres. The pain of acute engorgement, however, is usually of a continuous aching distressing type and is located in the right hypochondrium. It soon responds to digitalis and salyrgan. Provided the liver is not already cirrhotic, we initiate treatment with morphine gr.  $\frac{1}{4}$ . Leeching is a time-honoured remedy in these cases.

In chronic congestive failure the main burden of the patient's complaints is very often 'dyspepsia' or indigestion. In these cases congestion of the liver, of the stomach, of the intestines and of the pancreas produces slowness of digestion, anorexia, nausea, belching of gas, bloating of the stomach, a sensation of tension in the epigastrium and hypochondria, constipation, occasional bouts of diarrhoea, and rarely vomiting or bilious attacks. The patient may wonder where all the 'wind' comes from: 'vicarious respiration' is one answer, but not the correct one. In the tropics the possibility of a complicating amebiasis should not be overlooked.

The influence of the time factor in the production of the signs of right-heart failure is indicated by the following observations. The acute heart failure of diphtheria and of coronary

thrombosis may be attended within the course of a few hours by conspicuous liver engorgement and by but little or no œdema : the latter takes some days to develop. The practitioner should regard vomiting in diphtheria as an urgent symptom of impending circulatory collapse. Rapid and extreme liver engorgement in coronary thrombosis is, in Libman's opinion, highly suggestive of thrombosis of the right coronary artery. Septal infarction due to either right or left coronary thrombosis is commonly associated with high grade right-heart failure : an acquired interventricular septal defect murmur and liver engorgement may be prominent features of septal infarction, as in a recent case of ours. In an attack of paroxysmal tachycardia, the classical example of acute cardiac dilatation, downward bulging of the liver is detectable within a few minutes : with the abrupt fall of heart rate that marks the offset of the attack, the cardiac dilatation magically vanishes in a moment or two, while recession of the swollen liver is more gradual. A passing reference to acute heart failure is made elsewhere.

In his routine examination of the abdomen in a heart case the examiner should deliberately search for three important abdominal signs, namely, (1) enlargement of the liver, (2) enlargement of the spleen, and (3) ascites. He should invariably employ bimanual palpation for the detection of (1) and (2). In his quest for an enlarged liver, he should commence palpation in the right lower abdominal quadrant into which a Reidel's lobe may rarely wander. The swelling of the liver in engorgement is general and mostly downwards. Usually, the larger right lobe will be encountered projecting further down than the much smaller left lobe. Sometimes the engorged liver imparts to the palpating hand a definite impression that it is swollen, that its surface is convex and that its elasticity is increased. Ordinarily, the engorged liver feels smooth and firm; its lower border is rounded and feels thickened. In long-standing engorgement, the liver may convey the impression of hardness and its edge may feel sharp or obtuse. Tenderness at least of the liver edge is a usual finding, even in the absence of any complaint of pain. As a rule, tenderness is general over the hepatic region, *i.e.*, below the right costal margin and the epigastrium. Occasionally, pain and tenderness are localized over a small area in the epigastrium, and if in addition there is any suggestion of jaundice a misdiagnosis of gall-bladder disease is very likely. The degree of enlargement of the liver may be great or slight : generally the liver size waxes and wanes with the advance and retreat of failure. The associated *defense musculaire*, however, often prevents definition of the size of the engorged liver by palpation. In long-standing engorgement of the liver caused by heart disease, the overlying muscular rigidity usually disappears and little or no tenderness is

elicited on palpation. Confirmation of liver enlargement in heart failure should be sought by percussion of the liver in the middle line from the umbilicus to the ensiform cartilage.

In minor grades of failure, designated insufficiency of the right heart with early engorgement of the liver, the examiner may observe that as he exerts increasing pressure over the sub-hepatic area the cervical veins on both sides of the neck become more evidently engorged. Compression of the engorged liver empties it, as if it were a sponge, driving the blood via the inferior vena cava into the dilated right auricle with consequent visible and palpable cervical vein engorgement, which subsides when pressure is released, thereby permitting once more full expansion of the liver and descent of the diaphragm. This phenomenon, described in 1885 by William Pasteur of London, is called the hepato-jugular reflux. Expansile pulsation of the liver, especially of the left lobe, documents the advanced right-heart failure of long-standing mitral stenosis or of high-grade tricuspid disease. When one hand is applied over the liver anteriorly and the other is pressed into the right loin, this liver pulse gives the impression of an accordion expanding and contracting. 'When once the liver has begun to pulsate, it probably always continues to do so till death'—Mackenzie. Much more commonly the pulsation felt over the liver is not truly expansile, but is transmitted from the heart, particularly in cases of right ventricular enlargement or of aortic incompetence.

The engorged liver of right-heart failure commonly pushes the diaphragm upwards with some degree of resultant collapse of the right lung base. This is clinically evidenced by right basal dullness and deficient breath sounds and vocal vibrations. Such pulmonary collapse is distinguished from a pleural effusion by the fact that the upper level of dullness is not higher in the axilla than behind, and that in the prone position or in deep inspiration the increased dullness is notably lessened or become imperceptible. More appropriate to the occasion is the recognition of a right hydrothorax, in that hydrothorax is not only a further sign of congestive failure but is predominantly right sided.

In ordinary right-heart failure, the liver engorgement roughly parallels the rise of pressure observable in the cervical veins, except in the congested subject who is already suffering from cirrhosis of the liver. Venous pressure may be roughly measured by inspection of the cervical veins when these are easily observable. The retreat of the liver lags behind the decline of venous engorgement. In the first attack of congestion in the average case, digitalis and salyrgan produce a remarkably rapid retraction of the liver beneath the false ribs. In subsequent attacks of congestive failure the recession of the swollen liver under the same treatment is increasingly sluggish, the dyspepsia becomes more intractable and a sub-icteric tint

of the conjunctivæ develops. In protracted right-heart failure, the size of the liver may not decrease, in spite of marked subsidence of the signs of increased venous pressure. Peripheral œdema and transudation into serous cavities are usual but by no means invariable or proportionate accompaniments of liver engorgement in congestive failure.

The main causes of painful enlargement of the liver are congestion of the liver, amœbic abscess of the liver and cancer of the liver. Evidence of increased venous pressure, e.g., cervical vein engorgement, will be found *only* in the liver engorgement of heart disease: other cardiac symptoms and signs will of course be present here as well. In liver abscess, the signs of sepsis (spiky temperature chart, rigors, sweats, wasting, anæmia and leucocytosis: the latter may be comparatively slight or even absent) will point to the correct interpretation of the liver and right basal signs: any jaundice is latent: frank jaundice should suggest a complicating epidemic catarrhal jaundice, for example, as in a recent case of ours: the stools may show *Entamoeba histolytica* cysts: a previous history of dysentery or diarrhœa is sometimes helpful: radiography of the liver and a therapeutic test (emetine) are other useful diagnostic aids. Many years ago I was invited to see a 'liver abscess' prior to operation: the patient, an elderly golf caddy, was in fact a case of slow auricular fibrillation with congestive failure due to arteriosclerotic heart disease complicated by a benign tertian malarial relapse. Digitalis and quinine operated upon him instead in a most dramatic manner: digitalis and quinidine, by the way, we sometimes use with much success in selected cardiac cases.

The liver engorgement of advanced congestive failure in mitral disease or in Hanot's hepatic asystole, has in rare instances been regarded as carcinoma of the liver. However, in cancer of the liver, the liver enlargement is not only painful and tender but is also stony hard and irregular: jaundice and ascites are common accidents rather than essential signs: the spleen is very seldom enlarged in the absence of portal thrombosis: a blood-stained pleural effusion may be discoverable: the left supra-clavicular glands may be palpable: cachexia and perhaps pyrexia are present: there may be evidence of a primary growth elsewhere or an operation may have been performed for the removal of a growth within the past five years.

Other causes of painful enlargement are ascending cholangitis, associated with stone, especially in the common bile duct, pyelphlebitis (portal pyæmia) due to septic appendix, suppurating hydatid cyst, and hepatic necrosis.

*Splenomegaly.*—The spleen is the example *par excellence* of a blood depôt. Thus, in acute or recent congestive failure slight splenic enlargement may be detected as a result of

venous engorgement, whereas chronic congestive failure tends to empty the splenic reservoir, thereby leading to splenic atrophy with connective tissue hyperplasia and clinical diminution in the size of the spleen. Cardiac cirrhosis may rarely cause clinically-evident enlargement of the spleen due to portal obstruction, as in ordinary cirrhosis of the liver. Rarely have we been able to palpate the spleen in the circulatory failure of typhoid fever in the absence of enlargement due to other causes. In the absence of malaria, kala-azar, blackwater fever, undulant fever and the tropical splenomegalies, splenic enlargement is an important sign of subacute bacterial endocarditis. Enlargement of the spleen due to acute infections, such as typhoid, typhus, pneumonia, septicæmia or streptococcal fever, subacute bacterial endocarditis, and active rheumatic fever, as a rule being slight and soft, easily escapes detection. In endocarditis lenta (slow but all too sure), however, although the spleen is usually only just palpable, it may become very large from the impact of a constant stream of small emboli on the infected organ. In chronic compression of the heart, enlargement of the spleen is, equally with the attendant ascites, liver enlargement, cyanosis, peripheral œdema, hydrothorax, pulmonary œdema, varicose veins and hæmorrhoids, an expression of the prevailing venous stasis. In blood diseases, the size of the spleen may aid diagnosis: in leukæmia the spleen may seem almost to fill the abdomen: in splenic anæmia, acholuric jaundice and polycythæmia vera the spleen extends perhaps to the level of the iliac crest and to the middle line in front: in pernicious anæmia and in secondary anæmia, splenic enlargement is slight. Polycythæmia hypertonica (Gaisboeck's disease) is either polycythæmia vera with secondary hypertension or of hypertensive heart failure with secondary polycythæmia. Thrombo-phlebitic splenomegaly is commonly diagnosed as Banti's disease. Pulsation of the spleen and aneurysms of the spleen are distinct rarities. Very occasionally a well-marked continuous murmur is heard in splenic enlargements associated with venous engorgement. Splenic friction in acute leukæmia may be slight or gross. We found kala-azar complicated by a left pleuro-pneumonia in a recent case of 'fever with enlarged spleen, splenic friction and liver enlargement'. Palpability and not increased percussion dullness of the spleen is the test of splenic enlargement. The phrenico-colic ligament or rather the shorter gastro-splenic omentum in the adult, it will be remembered, makes the enlarged spleen pass forward and downwards. In children the spleen may enlarge directly downwards. Splenomegaly, especially in the tropics, is of little assistance in the diagnosis of heart disease.

*Ascites.*—Ascites may be defined as a collection of free serous fluid in the peritoneal cavity so that the abdomen becomes converted into a bag of fluid. Its main mechanisms are stasis in

the portal system and inflammation or irritation of the peritoneum. Thus, ascites is either a transudate or an exudate. Indeed the main differential diagnosis of ascites lies between cirrhosis of the liver and chronic peritonitis: they are sometimes found combined in a single case. The causes of ascites in order of frequency are said by Cabot to be, (1) cirrhosis of the liver, (2) heart disease, (3) renal disease (nephritis and nephrotic œdema), and (4) tuberculous peritonitis, especially in children. In the tropics severe anæmias and lymphatic obstruction (filariasis) are important factors. In diseases of the heart, the mechanism of ascites is venous engorgement due to right-heart failure or to failure arising from chronic compression of the heart. The clinical manifestations of chronic compression of the heart are produced by venous stasis and a reduced arterial circulation. Beck has assembled a diagnostic triad which the practitioner may find helpful in the diagnosis of chronic compression of the heart. It consists of—(1) ascites and liver engorgement, (2) high venous pressure, and (3) a *small quiet heart*. In this syndrome the cervical veins stand out like goose quills and pulsus paradoxus is frequently present. Not unreasonably, Beck regards as a confusing mass of medical verbiage such terms as adhesive pericarditis, concretis pericardii, symphysis cardiaca, pericarditic pseudo-cirrhosis of the liver, mediastino-pericarditis, Pick's disease, Concato's disease, and polyserositis. The compressing agent in chronic compression of the heart may be fluid (sterile or infected), scar tissue, neoplasm, or a combination of several of these lesions. [In acute compression of the heart, as for example when a myocardial infarct or contusion ruptures, the liver has not had time to enlarge. Its diagnostic triad however is (1) low arterial pressure, (2) high venous pressure, and (3) a small quiet heart.] In protracted right-heart failure of rheumatic, arteriosclerotic or rarely syphilitic origin, recurrent ascites may figure so prominently that chronic compression is simulated. The term hepatic heart failure or asystole hepatique was used by Hanot to describe a series of congestive failures characterized by considerable liver engorgement over months or years, with recurrent ascites and without notable deterioration in the general health notwithstanding these morbid phenomena. Clinical cardiac cirrhosis is rare: its diagnostic criteria are preponderant ascites, a small liver, supernormal venous pressure and a palpable spleen. 'The sudden onset of ascites or of hæmatemesis and their recurrence, accompanied by considerable splenic enlargement, might suggest the presence of portal thrombosis'.—Rolleston. Cirrhosis of the liver, however, would be a safer diagnosis. Horder has stated that ascites arising insidiously in a woman in whom there are no other symptoms or signs for example of heart, kidney or liver disease, is generally due to ovarian adenoma.

The clinical signs of ascites are shifting dullness, fluid thrill and signs of portal-peripheral anastomosis. When testing for shifting dullness, the examiner should wait a few moments after the patient has rolled over on to his side, to permit the fluid to seep through the mesenteric and intestinal folds: it does not run over the sharply projecting spinal column as over a waterfall. Tympanites is especially common in heart failure. It commonly masks ascites. Its presence in high degree should lead to a more careful search for free fluid in the peritoneal cavity.

The tempo of accumulation of cardiac ascites is the most rapid of all forms of ascites, just as that of tuberculous ascites is usually the slowest. If the quantity of ascitic fluid is large and its accumulation has been rapid, the abdomen is more or less globular, the umbilical region is prominent and there is a tight sensation of the belly, sometimes amounting to actual pain, due to the stretching of the abdominal wall. If the quantity of ascitic fluid is large and its accumulation has been gradual, then bulging of the flanks is more prominent, the lower ribs are pushed outwards and upwards and the epigastric angle is widened. Hæmorrhagic ascitic fluid usually means cancer. The chemical characters however of ascitic fluid are of little help in the differential diagnosis of ascites. Never omit to make a rectal examination for small collections of fluid and secondary deposits from gastric cancer in the recto-vesical peritoneum and a vaginal examination. The knee-elbow position, for the detection of small collections of fluid, is a gymnastic exercise ill-borne by cardiacs: it should be omitted.

*Cardiac hydrothorax*.—Hydrothorax is defined as a collection of clear fluid in the pleural cavity, the result of passive transudation from the capillaries. The essential mechanism of cardiac hydrothorax is engorgement of the pleural venous system (the pleural sacs have both a systemic and a pulmonary venous drainage, i.e., the superior vena cava and the pulmonary veins) with resultant increased hydrostatic pressure in the capillaries—capillary hypertension. A further factor is the lowered colloid osmotic pressure of the plasma by reason of the relative permeability to protein of the capillaries of the serous cavities. Hence in heart failure, osmotic factors associated with increased capillary permeability co-operate with capillary hypertension in the production of effusions into serous cavities as potently as does the mechanical factor of gravity in the production of œdema of the ankles and lower limbs. The combination of pulmonary and systemic congestion, i.e., of left- and right-heart failure, is most favourable to the development of cardiac hydrothorax, whereas systemic venous engorgement alone determines the occurrence of peripheral œdema. Evan Bedford has found that left ventricular stress and failure with regular rhythm favours the development of left hydrothorax and that

left ventricular failure with auricular fibrillation predisposes to right hydrothorax. The classical domain, however, of hydrothorax is right-heart failure. The theories advanced to explain the right-sided predominance of cardiac hydrothorax are at least sufficiently numerous. We have tapped a right-sided cardiac hydrothorax twelve times: this patient now has considerable ascites as well but no radiological evidence as yet of fluid in his left pleural cavity.

Although hydrothorax may herald the other signs of failure in the systemic circulation, it is more commonly masked by the gross manifestations of congestive failure. The physician should, however, make a deliberate clinical and radiological search for evidence of hydrothorax supervening in any case of congestive failure that suddenly manifests distressing oppressive dyspnoea, more evident cyanosis and a general accentuation of the signs of right-heart failure. Such a sudden worsening of the clinical status in congestive failure may be ascribed in the main to the reduced vital capacity, the interference with the pulmonary ventilation and the increased intrapleural pressure attendant upon the sudden development of cardiac hydrothorax. Further, elevation of the venous pressure is caused by the increased intrapleural pressure. The cardinal signs of hydrothorax are those of a pleural effusion—namely, (1) percussion dullness, (2) displacement of the heart, (3) annulled vocal fremitus, (4) diminished and altered or absent breath sounds—*minus* friction sounds and fever.

As transudations take place into the pleural cavity, absolute and toneless percussion dullness may be detected at the extreme base, together with a correspondingly increased sense of resistance. The dullness gradually extends upwards and slight variation of the dullness with the position of the patient may be demonstrable. The prevailing intrapleural pressure is negative, more so on the right side than on the left. Immediately fluid accumulates in the pleural cavity the lung on that side collapses. The elastic traction exerted on the mediastinum by the lung on the affected side is thus removed, leaving unopposed the traction of the sound lung with consequent mediastinal shift to the opposite side. The contents of the middle mediastinum, it will be remembered, are almost totally the heart and its coverings. Hence, when fluid is poured out into a pleural cavity, the heart is invariably and instantly displaced to the opposite side, in the absence of fixation of the heart by adhesions and of consolidation or of fluid at the opposite base: approximately one case of hydrothorax in three is bilateral. Enlargement of the heart and the possibility of an associated hydropericardium must be borne in mind in the assessment of cardiac displacement. In the latter case, the apex beat (*i.e.*, the point on the surface of the chest, furthest downwards and outwards, at which the impulse can be distinctly felt) is generally pushed upwards and to the

left, and lies, when it is palpable at all, distinctly within the left border of cardiac dullness and not, as in cardiac enlargement, in close relationship with it. Absence of vocal fremitus ranks third in importance and is due to the interposition of fluid which is a poor conductor of the laryngeal vibrations to the chest wall. Routine auscultation in congestive failure commonly reveals persistent moist sounds at the bases. Diminished breath sounds and diminution of the whispered voice sound at a base in congestive failure should suggest basal collapse and attendant bronchitis consequent upon hydrothorax. A collection of 500 c.cm. or over will yield the signs described. We must not forget that hæmorrhagic infarction of the lung is a common and often repeated complication of advanced congestive failure and that it more commonly involves the lower and middle lobes of the right lung, because the right pulmonary artery affords a wider entrance for pleural emboli from the right heart and from the deep pelvic veins which latter may suffer thrombosis in cases long confined to bed.

The removal even of 500 c.cm. in cardiac hydrothorax gives the patient remarkable relief and facilitates the action of digitalis and salyrgan, much as a timely venesection may do. The character of the transudate may approximate that of an exudate.

As Evan Bedford has remarked on his paper on left ventricular failure (1939) radiological study will occasionally reveal an interlobar or encapsulated hydrothorax (hydrothorax saccatus interlobaris) due to transudation from the visceral pleura consequent upon pulmonary congestion.

*Oliguria.*—Oliguria, remarks Fishberg, is a cardinal manifestation of systemic venous stasis. In our wards the urinary output curve is shown on the temperature chart of the heart case. It depicts the progress of right-heart failure. If a patient with right-heart failure states that his urine is abundant this should excite a suspicion of complicating diabetes mellitus. Horder states, 'Both chronic nephritis and dilatation of the heart may lead to a scanty, albuminous urine. But in the case of chronic nephritis the scanty urine is usually pale, pigment elimination being diminished, is free from or has but a small deposit, the amount of albumin is always considerable, and renal casts are present. Whereas in dilatation of the heart the scanty urine is high-coloured, contains a large uratic deposit, the amount of albumin is very variable, and renal casts are absent'. Unfortunately, many heart cases are renal cases as well. In acute heart failure, *e.g.*, in coronary thrombosis, oliguria bespeaks systemic hypotension and may proceed to anuria.

#### Remarks

The manifestations of increased venous pressure dominate the clinical picture of right-heart

failure, which in its pure form is not accompanied by pulmonary congestion. Dyspnoea may be caused by associated hydrothorax, ascites, and severe liver engorgement. Dyspnoea, however, is an almost invariable symptom in right-sided failure because, as we have stated elsewhere (Kelly, 1939), its causes, e.g., left-heart failure, etc., essentially implicate the pulmonary circuit. Armstrong has recently described a case of heart failure restricted to the right ventricle. Evan Bedford and Harrison hold the view that unilateral hypertrophy, dilatation and failure not only may occur but usually do occur. Venesection has no place in the treatment of primary right-heart failure, or of acute right ventricular failure due to pulmonary embolism. Congestive failure is associated with cardiac enlargement except in chronic compression of the heart. The presence of marked chronic passive congestion of the liver, lungs and other viscera and of extensive myocardial lesions often render it quite unnecessary to invoke toxæmia or exhaustion to explain the advent of heart failure in subacute bacterial endocarditis.

#### *Jaundice in heart disease*

In clinical heart disease jaundice may be either latent or frank. We have already referred to latent jaundice in second and subsequent attacks of right-heart failure. Latent jaundice is evidenced by a subicteric tint of the conjunctiva and skin, or is altogether masked by attendant cyanosis. The cause of latent jaundice here, as in subacute bacterial endocarditis, is increased blood destruction, due in the first case to prolonged anoxæmia and to *Strepto. viridans* in the second case. Frank jaundice is not common in heart disease. It suggests three possibilities, that (1) severe right-heart failure has superimposed congestion upon an already damaged liver, that (2) the case is one of severe and long-standing right-heart failure due to marked mitral or tricuspid stenosis, or that (3) pulmonary infarction is now complicating congestive failure. The latter complication is suggested by an abrupt worsening of the clinical status of the patient: there is a sudden increase in heart failure and cyanosis with a sudden onset of jaundice or a sudden accentuation of any existing jaundice, or jaundice appears two or three days after the lung infarction. The coloration of frank jaundice in heart disease is less deep than that of obstructive jaundice. Cyanotic icterus connotes yellowing of the conjunctiva and facial skin *plus* cyanosis of the lips and ears: this facies is of grave import. The unusual distribution of jaundice in congestive failure was first indicated by Meakins who reported that in a case of congestive failure he observed that the œdematous lower part of the body was free from jaundice whereas the upper part was markedly jaundiced and free from œdema. This observation holds also of course for cyanotic icterus. Page later reported two

cases of congestive heart failure with hemiplegia wherein the paralysed side was œdematous, and the sound side was icteric. Ottenburg (1932) explains this strange phenomenon by the low solubility of bilirubin which is held in the blood adsorbed to protein because of the lower protein content of the œdema fluid. According to Ottenburg two or more of the following factors are responsible for the production of jaundice in congestive failure—

- (1) Increased production of bilirubin especially in the lungs, spleen and liver due to the destruction of red cells, as a result of the slowed circulation and prolonged anoxæmia.
- (2) Profound depression of the excretory function of the intact liver cells for bilirubin as the direct result of lack of oxygen.
- (3) Actual atrophy of the liver cells at the centres of the lobules as a secondary result of anoxæmia.
- (4) Slowing of the circulation so that only a small fraction of the usual amount of blood passes through the liver to be cleared of its bilirubin.

Two special points emerge from the fact that anoxæmia constitutes the essential mechanism of cardiac jaundice.

(1) Failure not only of the right heart but also of the left heart seems to afford the most favourable circumstances for its production.

(2) Cardiac jaundice is a clear indication for oxygen therapy.

#### ACUTE HEART FAILURE

In general, the clinical picture of ordinary backward or congestive failure is dominated by upstream manifestations, i.e., by congestion behind the failing left and/or right chambers, rather than by inadequate output of the failing chamber. Acute heart failure is compounded of peripheral circulatory failure (shock) and of congestive cardiac failure; for example, in coronary infarction the sudden injury to the heart not only disables the cardiac pump but also initiates peripheral circulatory failure of hæmatogenic type (secondary shock). In general, the clinical picture of acute heart failure is dominated by downstream manifestations, i.e., by forward failure or by signs of acute circulatory collapse due to an inadequate blood supply to the tissues. Thus, in acute heart failure, whilst the downstream features of peripheral circulatory failure declare themselves, the upstream symptoms and signs of congestive right- and left-heart failure have to be looked for. Hence, when the practitioner is confronted with a case of acute circulatory collapse his first consideration must be as to whether he is dealing with a fundamental defect in the central cardiac pump (acute heart failure) or with a fault confined to the peripheral vascular apparatus (peripheral circulatory failure). His decision will hinge on the presence or absence of upstream manifestations. If there are no symptoms or signs of left- or right-sided congestive heart failure there can be no sort of heart failure. Hence acute heart failure will display evidence of left-heart failure, such as dyspnoea, orthopnoea, and pulmonary congestive

signs and signs of right-heart failure, such as engorged cervical veins and liver engorgement. Collapsed cervical veins, on the other hand, speak a very low venous pressure significant of peripheral circulatory failure. Fishberg's implication that cases of coronary thrombosis are divisible into those with shock and those with heart failure does not constantly accord with our experience. We are of opinion that signs of heart failure appear coincidentally with shock in coronary thrombosis about as frequently as they fail to appear in coronary thrombosis without shock. The diagnosis of coronary thrombosis is further advanced by the discovery in the heart itself of signs suggestive of cardiac damage, such as heart sound failure, gallop rhythm, and cardiac arrhythmias. Tic-tac rhythm is more characteristic of peripheral circulatory failure than it is of organic heart disease: even when it does occur in organic heart disease the circulatory state is usually that of acute heart failure. Cardiac enlargement and murmurs usually have antedated infarction. The final proof of myocardial damage, *i.e.*, of infarction, is as a rule to be found in the coronary thrombotic pattern of the electrocardiogram.

Diagram illustrating cardiac collapse in coronary thrombosis.

The clinical picture of coronary thrombosis may be summarized as follows:—

- (1) Pain due to coronary insufficiency setting in acutely and producing a relative localized myocardial ischaemia and anoxaemia which not only outlasts 20 minutes but goes unrelieved by any existing collateral inter-coronary anastomotic circulation.
- (2) Peripheral circulatory failure (downstream manifestations).
- (3) Congestive failure (upstream manifestations).
- (4) Clinical evidence of myocardial necrosis such as fever, sweating, leucocytosis or increased sedimentation rate.
- (5) Persistent electrocardiographic changes.
- (6) The appearance of acute pericarditis as revealed by a friction rub.
- (7) The occurrence of embolism, especially in septal infarction.

Libman holds that hyposensitive individuals are more apt to exhibit coronary thrombosis in terms of shock rather than of pain. Their relative inability to feel pain may puzzle the diagnostician, not only in cases of coronary thrombosis but also in other conditions, such as

duodenal ulcer. Painless coronary thrombosis, however, is commoner in those displaying some degree of congestive failure. In these latter subjects pain equivalents or substitution symptoms, usually a seizure of dyspnoea, proclaims the onset of coronary thrombosis.

Rapidly developing injury to the myocardium, productive of cardiac collapse, is likewise responsible for the induction of acute heart failure in some cases of diphtheria. We have already referred to the acute heart failure induced by paroxysmal tachycardia: other tachycardial arrhythmias such as flutter and fibrillation may similarly precipitate acute heart failure. A third group of acute heart failures is due to sudden and pronounced mechanical hindrance to the heart in carrying out its work, *e.g.*, to cardiac tamponade (sudden accumulation of blood or fluid in the pericardium), massive pulmonary embolism, ball-valve thrombus obstructing the mitral orifice.

The Adams-Stokes' syndrome is the classical example of acute heart failure of syncopal type. Some cases are due to transient attacks of ventricular fibrillation and not to lesions of the conduction system; asystole results in either circumstance. The main disturbance is obviously an inadequate blood supply to the brain or rather a paroxysm of cerebral ischaemia, productive of a seizure of unconsciousness. Heart failure in cardiac syncope or the syncopal type of acute heart failure is almost instantaneous and consciousness is lost because the diminution of the cardiac output is sudden and severe. The clinical picture here resembles that of the neurogenic type of peripheral circulatory failure (primary shock), such as a pugilist may display on the receipt of a blow on the solar plexus. The characteristics of the Stokes-Adams' syndrome are bradycardia, syncope, and convulsions, even in recumbency. In the gravest attacks the patient lies unconscious and motionless. The facies, especially of the previously ruddy-faced individual, is most striking: he now presents an ashen-grey or livid corpse-like aspect with glassy dull eyes, widely dilated pupils and sometimes conjugate deviation. The cervical veins are enormously engorged. There is a gasping respiration every 30 seconds. Respiration may, however, be stertorous and suggestive of cerebral haemorrhage or Cheyne-Stokes' breathing may develop. No pulse is felt and no heart sound is heard for 2 to 3 minutes. The sphincters are relaxed and Babinski's sign may be elicited. Then the face flushes pink and the pulse returns and the heart sounds are heard. The breathing is resumed within 1 to 2 seconds and consciousness returns within a few seconds. The patient is dazed for 15 to 30 minutes. The attack is ended.

In the cardiac collapse (coronary thrombosis) type of acute heart failure, heart failure sets in less acutely than in this cardiac syncopal type of acute heart failure. Loss of consciousness too is unusual in the former type, although we

do see occasional cases of coronary thrombosis ushered in with loss of consciousness.

*Blood pressure recordings.*—The fall in blood pressure which attends the onset of coronary thrombosis has long been regarded as one of the most striking manifestations of the altered hæmodynamics of this condition. Nevertheless, in 1937 we found to our surprise that certain physicians delicately refrained from taking the blood pressure in suspected or actual coronary thrombosis. They had been unduly alarmed by the 'dangers of blood pressure examinations in coronary thrombosis' (Hyman and Parsonett, 1932). These dramatic writers alleged that the attending physician's blood pressure recordings 'undoubtedly played a sinister part' in the untimely death of an old lady of 70, who developed peripheral embolic blockage after coronary thrombosis. As I read this indictment of the unfortunate general practitioner in the case, I felt that he might well have derived a modicum of comfort from Pascal's observation: 'The doctor sometimes cures, sometimes kills, *but he always consoles*'. Whilst we deprecated frequent fussy baumanometric measurements, we nevertheless continued our rapid routine reading of the blood pressure in this emergency without any suggestion of a mishap. And so the local trepidation associated with the recording of blood pressure in coronary thrombosis quickly subsided.

Sometimes in the painful stage of coronary thrombosis, peripheral vaso-constriction associated with the attendant shock, causes an early rise to precede the fall in blood pressure which ordinarily documents coronary thrombosis. An attack of angina pectoris is often accompanied by a rise in the blood pressure but the time-test and other features generally prevent confusion. Peripheral vaso-constriction may likewise sustain or even further elevate the blood pressure in hypertensive heart failure. Indeed in 'high pressure stasis', the blood pressure may fall only when the heart, the powerhouse of the circulation, is repaired somewhat by rest, digitalis, and diuretics. In fact, if the blood pressure does not now decline, this indicates that the insufficient hypertensive heart is not responding satisfactorily to treatment. In 'low-pressure' failures, on the other hand, a rising blood pressure commonly signifies an improving heart muscle.

#### HEART SOUND CHANGES IN ACUTE AND IN ORDINARY HEART FAILURE

We shall again take coronary thrombosis as our example of acute heart failure. In *Diseases of the Coronary Arteries and Cardiac Pain*, by Levy, Paul White and others, it is briefly stated that in coronary thrombosis 'the heart sounds are weak and tic-tac or gallop rhythm may be heard'. In *Diseases of the Heart* by Lewis it is still more briefly stated that 'The heart sounds (in coronary thrombosis) are indistinct, gallop rhythm is frequent'. Some expansion of these

remarks concerning the heart sound changes in coronary thrombosis may enhance their diagnostic value for the general practitioner.

If the first heart sound is suddenly observed to have become faint and muffled and the second relatively loud in an individual previously known to possess a normal intensity of his first and second heart sounds, then these altered heart sound findings are highly significant of a sudden impairment of the contractility of the heart, i.e., of an acute heart failure, such as coronary thrombosis. Heart sound recordings in coronary thrombosis indicate that the muffling of the first sound is caused by a loss of high frequency vibrations due to either a loss of muscle tone or change in intraventricular pressure, the result of the injury to the heart muscle. However it may be, this faintness and muffling of the first heart sound in coronary thrombosis is best appreciated at the apex where the ventricle abuts on the chest wall. In one's appreciation of the coincident relative loudness of the second heart sound at or to the left of the apex, especially in elderly subjects with possible aortic sclerosis, it is well to recall that the second sound heard in the aforementioned area is mainly the transmitted aortic component of the second heart sound. In all affections of the myocardium the physician should note also the loudness of the first sound at the base, where normally the first heart sound is rather less loud than the second sound. In coronary thrombosis the heart sound alterations observable at the apex are likewise detectable at the base where however the first sound disappears long before it does at the apex. Systemic hypotension weakens the aortic second sound. In the acute heart failure of coronary thrombosis described here the heart sounds at the base are usually inaudible. The obesity of many men and women in Bengal is commonly so gross as to render satisfactory auscultation, even of the relatively normal heart, impossible except for those endowed with really good hearing. In these obese subjects the heart sounds are not infrequently best heard over the xiphisternum, where however one or both sounds may have a peculiar scratch or grunch which must not be confused with pericardial friction. Likewise in emphysema the heart sounds are often best heard over the epigastric angle, where however they may take on a ringing metallic quality from the flatulent stomach so common in these subjects. A special failure of the first sound at the apex as contrasted with that at the xiphoid cartilage together with coincident weakness of the aortic second sound has been reported in some cases of coronary thrombosis. Sometimes in coronary thrombosis the almost complete muffling of the heart sounds everywhere resembles the 'silent heart' one associates with a large pericardial effusion. Overacting heart sounds, on the other hand, occasionally attend coronary thrombosis: in severe cases they herald a further thrombosis or congestive failure: in less severe cases they

become progressively less demonstrative. Some cases of coronary thrombosis show no detectable heart-sound changes.

Whereas feeble heart sounds are almost the rule in acute heart failure, loud heart sounds may sometimes be heard in chronic or ordinary congestive failure. Most writers have stressed the fact that in the stage of failure, mitral stenosis retains its snappy first sound even when the characteristic murmur has altogether disappeared and that the sounds of the thyrotoxic heart tend to retain their loud and angry character. Few, however, have commented upon the fact that in some cases of congestive failure the sounds become louder with the development of failure and then become fainter when failure recedes or when final circulatory collapse supervenes. The practitioner is naturally nonplussed by these loud heart sound findings in congestive failure because tradition has led him to expect heart sound failure coincidently with heart failure. I have been interested for many years not only in loud heart sounds in certain congestive failures but also in loud gallop rhythm, the extra sound of which is sometimes far from being the soft thud that the tradition-bound might anticipate.

#### ANGINA PECTORIS

'In this secret and fell disease', remarked Clifford Allbutt, 'there is a fascination to which no physician is a stranger, a fascination in its dramatic events and in the riddle to read'.

'The only established mechanism of cardiac pain', concludes Fishberg, 'is ischaemia of the myocardium—others are purely hypothetical'. In our view, the theory that does not bear the test of practice should be revised or rejected. Thus, Allbutt's aortic theory is at once put out of court by its signal failure to explain the likelihood of sudden death in angina pectoris. This most unpleasant possibility follows angina pectoris like its shadow. In the opinion of Keefner and Resnik, the likelihood of sudden death is indissolubly linked with the underlying mechanism of angina pectoris. In consonance with our conception of the mechanism of angina pectoris the cause of sudden death in this condition is ventricular fibrillation due to sudden myocardial anoxaemia.

Angina pectoris is a chronic recurrent symptom-complex due to paroxysms of localized relative myocardial ischaemia, the result of coronary insufficiency of less than '20 minutes' in duration (usually less than 3 minutes by the clock). It may occur on exertion, on emotion, during rest, or during sleep. Repeated attacks induce replacement fibrosis in myocardial localities afflicted by coronary arteriosclerosis and constantly under-nourished in consequence thereof. Myocardial weakness and congestive failure are the logical sequelae of such a progressive replacement of myocardial fibres by connective tissue. Angina pectoris, however, inhibits activity. Hence, as a rule, congestive

failure does not supervene until after coronary thrombosis has complicated the course of angina pectoris. Indeed, angina pectoris may now altogether disappear as a result of local necrosis of the P-factor producing area. Perhaps more commonly congestive failure and auricular fibrillation limit activity and thus obviate attacks of angina pectoris. On the other hand, the higher oxygen requirements of the dilated heart and the lowered coronary income in failure lead to more frequent seizures of angina pectoris. In the last-mentioned circumstances, the physician should exhibit digitalis (tablets digitalis folia, gr. 1, *b.d.*, *p.c.*, or  $\mathcal{R}$  tincture digitalis, m. x, aquam chloroformi, ad.  $\mathfrak{z}$  1, *t.d.s.*, *p.c.*) and not nitrites, for the relief of anginal pain. Digitalis is probably harmful in angina pectoris associated with a small or normal-sized heart.

Certain remarks made years ago by Parkinson and Bedford are much in vogue to-day. Concerning angina pectoris they used to say that 'an individual either has angina pectoris or he has not'. They severely disapproved of 'anginoid pain' and of such misleading and apologetic terms as 'mild angina', 'secondary angina' and 'pseudo-angina' or 'false angina'. They heartily endorsed Potain's dictum that 'there are no false diseases: there are only false diagnoses'. Whenever possible a diagnosis of angina pectoris should include a statement of its aetiology, *e.g.*, coronary arteriosclerosis, hypertensive arteriosclerotic heart disease, aortic insufficiency, syphilitic aortitis with ostial stenosis, calcific aortic stenosis, paroxysmal tachycardia, coronary embolism, arterio-venous fistula, thrombo-angiitis obliterans, periarteritis nodosa and mycotic aneurysms of the coronary vessels, and so forth.

Coronary arteriosclerosis and cardiac hypertrophy usually combine in varying dominance to narrow the coronary reserve. Thus, angina pectoris in the middle-aged and elderly is commonly due to the summation of hypertension and coronary arteriosclerosis: the grade of the latter is usually insufficient in itself to yield angina. Indeed, angina pectoris may be the main complaint of a hypertensive arteriosclerotic heart disease subject until congestive failure or coronary thrombosis supervenes. In the renal hypertension of young persons and of eclamptics, on the other hand, angina pectoris is distinctly rare because coronary arteriosclerosis is absent herein. Hypertensives of both sexes and especially menopausal hypertensive, like rheumatic heart disease sufferers, are remarkably prone to develop cardiac neuroses. It should, however, be borne in mind that cardiac neurosis or neuro-circulatory asthenia may overlie and obscure the presence of angina pectoris in the hypertensive arteriosclerotic heart disease subject: evidence of vascular vulnerability elsewhere, *e.g.*, absence of pulsation of the dorsalis pedis arteries, intermittent claudication, retinal arteriosclerosis, peripheral arteriosclerosis, etc., would favour the presence of a complicating angina pectoris in

such case. A doctor of the last century observed with more cynicism than accuracy that 'the man with arteriosclerosis of his radial arteries has warmed both hands before the fire of life'. Coronary thrombosis is a much more likely accident in coronary arteriosclerosis without hypertension than in hypertensive arteriosclerotic heart disease. Hence the prognosis of the latter is correspondingly more cheerful. The incidence of angina pectoris and of coronary failure in Indians is engaging our attention at the present time. Coronary failure, by the way, is attended by pain and shock as in coronary thrombosis, but is found wanting in respect of permanent electrocardiographic changes and of the evidences of heart muscle necrosis. So far, we have been impressed by the great rarity of angina pectoris in Indians notwithstanding their relatively high incidence of hypertensive arteriosclerotic heart disease and of coronary thrombosis. Incidentally, some writers inaccurately employ the term chronic myocarditis to describe the clinical picture associated with coronary artery disease. Pathologically chronic myocarditis is a chronic but active inflammatory lesion of the myocardium due to bacterial or non-bacterial excitants. As the damage associated with disease of the coronary vessels is due to nutritional changes, the term arteriosclerotic heart disease states what we know and not what we imagine. Angina pectoris is associated with narrowing of one or more of the larger coronary vessels. The senile heart is characterized by extensive or diffuse arteriosclerosis of the finer coronary branches.

'Angina pectoris', states White, 'is a symptom of individuals in the upper walks of life'. We do not subscribe to this notion that angina pectoris is largely a matter of tone, social atmosphere, or something a plain medical writer cannot convey. Just as a history of lightning pains justifies the diagnosis of tabes dorsalis on the history alone, so does a history of effort angina justify the diagnosis of angina pectoris solely in its symptomatology. In general, the pain of angina consists of combinations in varying preponderance of two pain components: it consists of pain transmitted directly and indirectly from the heart. It is notoriously susceptible of misinterpretation by the patient. Its character and distribution may be quite atypical. If, for example, the discomfort begins in the epigastrium after meals, is associated with belching, and is apparently relieved by alkalis, the patient will naturally insist that it is 'indigestion'. In fact, angina pectoris quite frequently does masquerade under the guise of indigestion. If angina pectoris is coincident with some non-cardiac disease, the anginal distress may become hopelessly commingled with and entangled in the symptomatology of the concomitant non-cardiac disorder. Thus, not infrequently the definition and differential diagnosis of angina pectoris may occasion even an experienced physician quite considerable

difficulty. In our experience less intelligent patients are often hopelessly incapable of detailing the more complex forms of anginal pain: when called upon to do so they usually grin in an apologetic and speechless manner, utter a few fragmentary human noises and depart with a McLean's powder for their 'indigestion'. Their educational level and discriminating and descriptive powers are totally inadequate for the crucial portrayal of the pain, upon which the diagnosis of angina pectoris is fundamentally based. Little wonder that statistics show that the highest incidence of angina pectoris is amongst the medical profession and the lowest amongst the day-labourer and the farmer. The other factors responsible for this divergent class incidence shall be discussed later.

Libman, Fishberg, White and others have fittingly stressed atypical forms of angina pectoris and the practitioner would do well to bear these forms in mind, especially when dealing with middle-aged patients, labelled 'arthritis of the left shoulder' or 'neuritis of the arms'.

Atypical angina may be encountered in the form of a persistent dull aching pain, in the left more often than in the right shoulder region. The pain is unaffected by exercise or nitrites: it is irresponsive to physical therapy, the form of treatment generally sought by the patient: it is often worse at night and morphine may be required to secure sleep. This shoulder pain is not the usual radiation of the sub-sternal pain to the left shoulder and left arm. It is a continuous and intractable pain that, in our experience as in that of others, may precede or follow angina pectoris or cardiac infarction. We have not found any local radiological changes in these shoulder pain cases. A sub-deltoid bursitis was found in one case by my surgical colleague. But the precise mechanism of this shoulder pain remains obscure.

Spillane and White have recently reviewed a group of patients with eccentrically placed anginal pain, the mechanism of which is likewise obscure. 'A long-recognized example of these larval or fractional forms of angina pectoris', they stated, 'is that in which pain on effort appears only in the arms, the crucial sub-sternal pain being absent'. This eccentric pain of angina pectoris has been described by Herbeden, Osler, Allbutt, and Mackenzie. Retrograde angina or Potain's *angina reuversee* is another eccentric and interesting form of angina pectoris. 'The flow of pain is reversed: it starts in the wrist, elbows or jaw and only settles behind the sternum when fully developed, so that on exertion a patient may complain of pain in the wrist or teeth'—Evan Bedford. In our view, Vaquez's retrograde angina arising in the rectum is a visceral hysteria and in support of this opinion certain remarks of Clifford Allbutt are worth quoting in their entirety: 'What, I repeat, should we think of a lecturer who threw together into the same class and under the same name the functional hemiplegias of

hysteria and the hemiplegias due to cerebral disease. Surely it is levity to confuse the sequels of unstable "neurotics", mostly women, with the assault of one of the fiercest and most searching afflictions which can fall upon steadfast and resolute men. But the most egregious example of this eccentricity which I have noted is the description, by a well-known modern physician, of a case of "angina pectoris originating in the clitoris"!

Conversely in gall-bladder disease, pain arising in the gall-bladder may radiate down cardiac pathways sensitized by coronary artery disease.

The up-to-date practitioner readily recognizes the distinctive features of neurocirculatory asthenia, including left mammary pain. In consequence there has been a notable and gratifying decline in the erstwhile popularity of 'angina pectoris'. When, as Harrison has pointed out, angina pectoris, præcordial aching due to the heart consciousness of cardiac neurosis and reflex soreness of the pectoral muscles are present in the same patient there is considerable danger, unless a careful history is taken, that the significant pain may be masked by the two unimportant sensations. Such a case is very briefly presented at the end of this note.

There is an interesting group of cardiac neurotics, exclusively women, of considerable therapeutic importance in that they respond poorly and react badly to the barbituric acid group of hypnotics and sometimes to morphine as well. Alvarez, who first identified these peculiar women in his abdominal practice, well describes them as hypertensive, overactive, markedly fatigued and somewhat psychopathic. Our own impression is that these women 'fight' the barbiturates. In spite of, say, ten grains of medinal at bedtime, patients with this idiosyncrasy truthfully report next morning that they 'hadn't a wink of sleep', or that they had 'snatches of sleep with terrible nightmares'. Chloral is about the only drug that induces satisfactory sleep in these nervy women:  $\mathcal{R}$  Syrupi chloral and tincturæ valerianæ ammoniatæ, of each 3ss, ammonii bromide, grs. x, aquam chloroformi ad. 5i. Sig. 5i secundis horis, ad. doses IV. S.O.S. Passiflorine is their best general sedative: one teaspoonful in glucose water after the midday and evening meal for 20 days.

A classical example of this temperament and idiosyncrasy was lately under our care.

Anglo-Indian lady with 'a long history of nervous heart attacks'. Six weeks prior to admission she had a very bad 'attack' with vomiting which even morphine failed to control: in fact she felt worse after morphine. Medinal and luminal had, she said, 'given her insomnia and left her a bundle of nerves'. Our diagnosis was coronary thrombosis type III six weeks ago; angina pectoris supervened; cardiac neurosis localized to præcordium (to the organ inferiority of Adler and somatic compliance of Freud); reflex soreness of the left pectoral muscles; idiosyncrasy to barbiturates; no discoverable septic foci (septic teeth, tonsils, etc., may underlie cardiac neurosis).

#### ELECTROCARDIOGRAPHIC INTERPRETATIONS

Thomas Lewis stands at the origin of electrocardiographic interpretation. He stated in the most lucid and conclusive fashion the fundamental principles of clinical electrocardiography. He thought out and made of one piece, solid and permanent the whole system of electrocardiography. As this man of genius has remarked (1937), 'electrocardiography has taken us far, having filled great gaps in our knowledge of these maladies (heart disease), for it is a means of directly examining the all-essential heart muscle'. Unfortunately, however, states Master (1939) 'there has been neglect of the fact that identical changes in the electrocardiogram may result from alterations in the size, shape, and position of the heart, in the absence of any myocardial disease whatever'.

Changes in the electrocardiogram may be due to—

- (1) Cardiac arrhythmias,
- (2) Muscle damage, acute or chronic,
- (3) Alterations in the size, shape, and position of the heart,
- (4) The action of certain drugs, notably digitalis, quinidine, and morphine.

An impression lying down at the bottom of my mind for a long time is that many physicians do not appreciate the dependence of the cardiogram upon (3) which include such factors as age, body position, habitus, obesity, pregnancy, hypertension, valvular disease, congenital heart disease, pulmonary disease, and chest deformities, which alter the contour of the heart. Thus, certain electrocardiographic changes are being constantly mis-interpreted as evidence of myocardial damage, as in fact 'toxic myocarditis', 'rheumatic infection' or 'coronary sclerosis', when in reality myocardial disease is altogether absent and the electrocardiographic changes in question merely reflect some alteration in the size, shape, or position of the heart.

An up-country primipara, aged 22 years, in the last trimester of pregnancy was recently referred to me for opinion as to her heart. Her previous history was excellent. Lately, she had become aware of exertional palpitation. Her local doctor discovered 'extra-systoles' and hastily, albeit most carefully, transferred her to an electrocardiographer in Calcutta. Her cardiogram showed left axis deviation, a large  $Q_3$ , and an inverted  $T_3$ , which, being interpreted, spelled 'coronary sclerosis and toxic myocarditis'. The general condition of the patient was excellent. Radiography confirmed a raised diaphragm with a transverse lie of the heart which was not appreciably enlarged. Her investigation was otherwise negative. Her tracing was regarded as a pregnancy effect, due to the transverse position of her heart. A diagnosis of gestatory heart disease (functional heart disease of pregnancy) was made and no special restrictions were imposed. The lady's pregnancy and puerperium were quite uneventful.

Gestatory heart disease is a physiological syndrome produced by one or more of the following factors: increased cardiac work as the result of the increased demands of pregnancy, changes in the position of the heart, the arterio-venous fistula-like action of the placenta. Circulatory function commences to return to normal even before delivery. The circulatory peculiarities of the acute phase of beri-beri also bear a striking resemblance to those of arterio-venous aneurysm. Classical examples of 'reversible heart' are encountered in myxœdema, beri-beri, arterio-venous aneurysm, and congenital cavernous hæmangioma.

In neurocirculatory asthenia, rotation of the perfectly healthy though long, narrow, vertical or hanging-drop type heart, produces right axis deviation, large P-waves, low QRS<sub>1</sub>, high QRS<sub>2</sub>, and QRS<sub>3</sub> and even inversion of T<sub>2</sub> and T<sub>3</sub>. Hence the subject of neurocirculatory asthenia who escapes an electrocardiographic misdiagnosis of either 'rheumatic infection' or 'toxic myocarditis' is indeed twice blessed.

We freely acknowledge the fact that acute tonsillar infection and other inflammatory diseases can produce transient electrocardiographic changes such as changes of the conduction time, increase of the duration of the electrical systole, flattening of the T-wave, pictures resembling infarction with negative coronary type T-wave. But we emphatically insist that our electrocardiographic interpretations will become much less lugubrious and infinitely more correct if we correlate certain electrocardiographic changes with radiologically observable changes in the size and shape and position of the heart. 'An appreciation of the dependence of the electrocardiogram on the size, shape, and position of the heart is absolutely fundamental', states Master (1939), 'in the interpretation of the electrocardiogram'. Alterations in the size, shape, and position of the heart, in the absence of any myocardial disease whatsoever, may produce changes in the cardiogram in every respect identical with those found in cases of myocardial damage. Our interpretation of the electrocardiographic changes in aortic stenosis may be recalled. At all events, we shall, perhaps, now understand why some patients that we sent to England with dismal diagnoses, substantiated by 'abnormal' cardiograms, were, to our surprise and possibly embarrassment, reported by the London cardiologist to have exceptionally sound and healthy hearts.

At the National Heart Hospital, Parkinson and Bedford (1928), whose experience in the correlation of electrocardiographic and radiological findings is quite unique, never failed to emphasize the fact that certain electrocardiographic changes may depend entirely on some alteration of the heart size, shape, or position and not at all on the myocardial state which may in fact be remarkably healthy. If these authors

## DIAMIDINO-STILBENE IN THE TREATMENT OF KALA-AZAR

By L. EVERARD NAPIER, F.R.C.P. (Lond.)

and

G. N. SEN, M.B. (Cal.), D.T.M.

School of Tropical Medicine, Calcutta

By a process of incomplete experimentation and false deduction, it was concluded that certain guanidine derivatives, by virtue of their hypoglycæmia-producing properties, were capable of destroying the trypanosomes in experimentally infected mice. In attempting to confirm these observations, Lourie and Yorke (1937) found that insulin had no trypanocidal properties *in vitro* or *in vivo*, that *in vivo* one of these hypoglycæmia-producing compounds, namely

(Continued from previous column)

cannot afford to neglect such vital correlations, assuredly we cannot presume to do so.

In man there is no correlation between the heart rate and the shape and position of the heart nor between the heart rate and the electrocardiogram. In general, the heart rate is very rapid in small animals (600 p.m. in the mouse, 300 p.m. in the guinea-pig, 250 p.m. in the cat and 125 p.m. in the dog) and slow in large animals (55 p.m. in the horse and 46 p.m. in the elephant).

I am grateful to Lieut.-Colonel J. C. De, I.M.S., Principal of the Medical College and Superintendent of the Medical College Hospitals, Calcutta, for permission to publish this paper.

synthalin, did not in fact produce hypoglycæmia except when given in doses sufficient to damage the liver, but that *in vitro* it had powerful trypanocidal properties.

This led to an investigation being undertaken under the auspices of the National Institute of Medical Research and the Liverpool School of Tropical Medicine (King, Lourie and Yorke, 1938) demonstrating the trypanocidal properties of a number of allied preparations, and later to another investigation by Dr. A. J. Ewins of Messrs. May and Baker on a series of aromatic compounds of the amidine group; amongst the latter 4:4'-diamidino-diphenyl ethylene was prepared.

Yorke (1940) used this preparation in the treatment of one case of kala-azar with apparently good results. The same writer also reported that other workers, including Dr. R. Kirk working in the Sudan, had had good results, but full details were not given.

One of the writers recently had an opportunity to discuss this subject with Dr. Warrington Yorke and at his request undertook to give a more extended trial to this drug in India. Meanwhile, Messrs. May and Baker had sent a generous consignment of 4:4'-diamidino-diphenyl ethylene (diamidino-stilbene, M.&B. 744) to the Director, Calcutta School of Tropical Medicine, for trial; this consignment he very kindly handed over to us.

This paper is a preliminary report on the results of this trial.

*The patients.*—Seven out of the eight patients who had a full course were Indian male patients in the hospital attached to the Calcutta School of Tropical Medicine. In each case the diagnosis of kala-azar had been made by the finding of leishmania in bone- or spleen-puncture material. The disease was of moderate duration, except in case 7 in which it was apparently of about 6 weeks' duration when treatment was started, and in case 4, in which it was of 18 months or more. Two other patients were attending the kala-azar out-patient clinic; one had a full course of eight injections and one ceased to attend after five injections, given on alternate days.

*The dosage.*—In our choice of dosage, we were guided by the clinical experience with this drug quoted by Dr. Warrington Yorke and by our own general experience that it is better to give as near as possible to the maximum tolerated dose at first, in order to ensure the maximum effect of the drug and establish its specificity (or the reverse, in which case it can be discarded immediately), and subsequently, if possible, to reduce the dosage, in order to find out the minimum effective dose, rather than to start too cautiously and in the event of failure to be uncertain if it is the drug or the dosage that is at fault. We therefore gave initial intravenous doses equivalent to 0.001 gramme per kilo body-weight. Though this dose was usually

tolerated without adverse symptoms, the patients became flushed, had a burning sensation all over the chest and abdomen, and slight dyspnoea, but these sensations passed off fairly rapidly. In a few instances the ill-effects were more disturbing (*vide infra*). We then increased this dosage slowly, usually by 0.01 g. (actual), up to 0.002 g. per kilo body-weight, but, as weights in our hospital are recorded in pounds, we subsequently first settled the maximum dose to be aimed at in each case, on the basis of 0.001 g. per pound weight, and then gave an initial dose of 0.050 g. (actual), if this was not more than two-thirds of the maximum dose, and increased the dose by 0.010 g. (actual) up to the maximum dose. We gave 8, 10, or 12 daily injections.

*Ill-effects.*—It is of interest that most of the ill-effects occurred in the first few cases treated and early in the treatment. Equivalent initial doses did not affect the subsequent patients, nor after tolerance had been established did subsequent larger doses in the same patient cause a repetition of the ill-effects.

The ill-effects amount to a marked exaggeration of the flushing and burning sensation mentioned above. One old woman with an oriental sore who was given a relatively very small dose (about 0.00025 g. per pound) became pulseless for some minutes, a second with kala-azar had severe burning and vomited, and future treatment was abandoned in both cases. A number of patients had rigors—these are noted on the charts. The symptoms were relieved almost immediately by adrenalin and in one patient, who had vomited on each occasion, a prophylactic dose of 0.125 c.cm. of adrenalin before the injection seemed to prevent the vomiting.

It was probably a coincidence that two patients developed pneumonia, one definite lobar pneumonia and the other, a child, bronchopneumonia, during, in one case, and, in the other, immediately after, the course of treatment. In both cases, M.&B. 693 was given and the condition cleared up in the usual way. Both of these patients had unusually high leucocyte counts, and the former had lung symptoms from admission.

One patient developed acute congestion of the conjunctivæ in both eyes with marked photophobia after the eighth and ninth injections; another injection was given, but the condition was not exaggerated. The eyes were normal again within a few days. No cause could be attributed, by the ophthalmologist, except an error of refraction; the fundus was normal.

In no instance did the treatment produce any psychological changes, nor did our patients exhibit the deplorable degree of moral turpitude reported by Dr. Kirk (Yorke, *loc. cit.*).

*Progress.*—It was unfortunate that many of the cases were in an afebrile phase when treatment was started. In cases 2 and 6, the temperature came down about the middle of the course of treatment. On the other hand, in other cases (*vide chart, case 7*) there was a distinct

reactionary rise and the temperature was maintained at a high level until the course was finished.

In all but the diabetes case the weight improved, in some considerably. Except in case 4 the spleen was markedly reduced and disappeared under the ribs so that at the time of discharge it could not be felt or could only be felt on deep inspiration. In case 4, there was little or no reduction after the first course, but after the second, it was more mobile and only about 3½ inches (originally 7 inches) below the costal margin.

The blood picture improved quite remarkably in every case; the red cell count and hæmoglobin showed a sharp rise despite the fact that no tonic or hæmatinic drug was given, and the leucocyte count was 8,000 or more in every case but two at the time of discharge.

**Proof of cure.**—This has always been a difficult problem. We have found (Napier, 1937) that immediately after the completion of an efficient course of neostibosan viable parasites could still be demonstrated in the spleen, but that in the course of a week or so they disappeared spontaneously, i.e., without further specific treatment; on the other hand, even when cultural methods have failed to show their presence, the patient has sometimes relapsed. Time alone is the test. However, some indication can be obtained from sternum puncture after a short interval and we did this in five of the eight patients; in one case parasites were still present 11 days after the last injection, and there is some reason to believe that this patient was not cured. In the other four cases, no parasites were found and it is believed that they were cured.

Data of the eight cases of kala-azar that had a full course are given in the table and temperature charts. A few further notes on each case are given below:—

**Case 1.**—Afebrile; abdomen distended and liver enlarged and tender. Spleen puncture was difficult on account of the distension and little material was obtained. Tibia puncture was done with a Salah needle and a good result obtained.

**Reaction.**—Flushing of the face only.

A few days after the last injection of M.&B. 744 was given the child developed pneumonia; this responded well to M.&B. 693 and the temperature was normal in 5 days; resolution followed, but the child's weight fell to 23 pounds. Subsequently he improved steadily.

**Case 2.**—A diabetic, incidentally the only case in our 20 years' experience at the School in which the two diseases have been seen in the same individual. His fever was of a high continuous type suggesting enteric.

**Reactions.**—Flushing of the face, burning sensation all over the trunk, dyspnoea, and slow and almost imperceptible pulse. Rigors after 0.050 and 0.060, but later tolerated 0.080 g.

Insulin was not given during the treatment by M.&B. 744 and his blood sugar rose considerably.

Temperature fell after the second injection, but rose occasionally to 99.5°F., and was finally normal after the course was finished. He was a difficult patient and left hospital a week later.

**Case 3.**—Admitted with high fever, lung symptoms but without definite signs, and a slight leucocytosis.

**Reactions.**—Rigor after 0.065 g.

Temperature fell on the third day, but rose again and definite signs and symptoms of lobar pneumonia were noted on the 12th day. M.&B. 693, six tablets a day for 5 days brought the temperature down to

Case 3.

normal again (see chart). He improved rapidly but insisted on leaving the hospital.

**Case 4.**—A 'chronic' type of case; long duration, large hard spleen, and moderate intermittent fever.

**Reactions.**—Flushing, burning sensation, and rigors for the first few injections, later none.

Temperature fell to normal during the first course, but the spleen remained large and firm. Spleen puncture 11 days after the last injection showed leishmania still present but scanty. No fever during or after the second course; spleen still large, but softer and movable. His Wassermann reaction was positive at the time of admission.

Case 6.

**Case 5.**—Almost afebrile with respiratory symptoms but no physical signs.

**Reactions.**—Slight febrile reaction (100°F.) after first injection (0.05 g.), with flushing, burning sensation over abdomen, etc. No reaction after fifth injection (0.09 g.).

Temperature settled again to normal and remained so throughout.

**Case 6.**—A febrile case, moderately high remittent.

**Reactions.**—Rigors after 0.060 but later tolerated 0.080, also flushing and burning sensation.

Temperature came down during the course, but was not finally normal until the injections were discontinued (see chart).

**Case 7.**—Admitted on the 14th day of fever of a high continuous type with clinical diagnosis of typhoid. The Widal was negative and the extremely low leucocyte count suggested kala-azar, but no parasites were found in the sternum-puncture material. Meanwhile, the temperature fell to normal, but the spleen showed signs of enlargement and after a month became puncturable, i.e., came down well below the costal margin. Leishmania were found.

**Reactions.**—Moderately severe when the higher doses were reached. His face became flushed, burning of the

body, severe headache, injection of the conjunctiva and photophobia which lasted for a few days. He had a sharp febrile reaction after each injection (*see* chart).

Case 7.

Case 8.—Treated as an out-patient; injections given three times a week.

Reactions.—Fairly severe reaction after the first dose of 0.014 g., subsequently no more reactions until the last dose of 0.020 g.

He was brought to the hospital for a week or so after the last injection and was considered to be cured by his guardians; his spleen was not palpable.

Other cases.—Three other out-door patients were treated—two cases of kala-azar and one a case of oriental sore. One boy received only seven injections and did not appear again. The other two were women and both had alarming symptoms after the first dose (*v. s.*) and on this account we decided not to undertake treatment amongst out-door patients, until we had had more experience with the drug. One patient, a boy aged 10 years, weight 61 pounds, with post kala-azar dermal leishmaniasis is still under treatment: up to the present he has received 20 daily injections totalling 0.950 g., maximum individual dose 0.060 g. (not well-tolerated). There is evidence of distinct improvement in the local lesions; under similar conditions treatment with an antimony preparation would not have produced any dramatic result.

Discussion.—We must emphasize the essentially preliminary nature of this report and in view of its incompleteness it is perhaps necessary to justify its publication.

Since antimony preparations were first used in the treatment of leishmaniasis in 1913, a very large number—the figure probably running into thousands—of antimony compounds have been prepared, some hundreds have been tested, and of these some dozens have been found to be efficacious; other drugs, which contained no antimony molecule, especially those which have proved useful in trypanosomiasis, *e.g.*, Bayer 205, and tryparsamide, and the all-conquering sulphonamides, have been tested in kala-azar, but up to the beginning of this year no drug that did not contain antimony has been proved to have any specific action in this disease, though from time to time hopes have been raised by apparent cures in one or two cases, or from the reports of inexperienced workers. The finding,

therefore, of a non-antimonial preparation that is effective in kala-azar is a matter, firstly, of considerable academic importance, and, secondly, one that may have far-reaching practical repercussions, for many obvious reasons of which not the least is that at the present moment the best antimony preparations are not available in the quantities in which they are required; therefore any claim to such a finding certainly demands confirmation.

Some of the difficulties of the clinical testing of anti-kala-azar drugs have been referred to above and have been discussed elsewhere by the senior writer (Napier, *loc. cit.*). The proper assessment of the relative efficacy of any drug necessitates a very extended trial—this writer's first report on neostibosan included 61 cases and his subsequent report 254. Though such an extended trial as this may not be warranted in this instance, it will in any case probably be a year or so before sufficient data have been collected to answer the many questions that arise, and therefore the expression of an interim impression seems to be called for.

The senior writer has, during the last 20 years, tested clinically in the treatment of kala-azar, under controlled conditions, in some thousands of cases, a very large number of preparations; of these many have been discarded and others have been selected and have taken their places in the pharmacopœias. He therefore feels that he is qualified, not only to carry out such an investigation on the comparative therapeutic value of this drug, but to express a tentative opinion on the drug before the stage where its full value, as compared with that of other drugs, has been accurately and scientifically assessed.

#### *Some of the questions that must be answered*

Very many questions remain to be answered, of which we mention a few.

The clinical progress in seven out of the eight cases who underwent a full course was extremely satisfactory and, from previous experience, we should expect most of them to be cured; the negative sternum-puncture findings add support to this expectation, but do not prove that cure has been effected. Time alone will show.

The dosage that we have been giving sometimes produces alarming symptoms, so that one could not advocate it, except under hospital conditions, and even under these one might encounter a hypersensitive patient in whom even more serious symptoms occurred. On the one hand, it is possible that we can find some means of obviating these symptoms, or, on the other, it may be necessary to adopt a lower standard of dosage. The former possibility is indicated by the fact that reactions have not been so severe or frequent recently as they were at first, and that in one or two cases a dose of adrenalin preceding the drug seemed to control the reactions.

Clinical experience with the drug has been so limited up to the present that its potentialities

Some of the bigger polyps contained a small amount of clear watery fluid which when expressed made these look quite flat. Histological examination showed the following:—

The papillomatous processes were obviously arising as proliferations of the Lieberkühn's glands which composed these polypoid masses (plate XXI, figure 2). Plate XX, figure 3, is a camera-lucida drawing of the section through a number of polyps with the whole of the thickness of the intestinal wall, and plate XX, figure 4, a single polyp of the bigger variety. These were seen to extend directly from the muscular coat. The submucosa was very scanty throughout the intestine and at places where the papillary projections appeared the submucosa was entirely absent (plate XXI, figure 2, and plate XX, figures 3 and 4). It seems probable that while the glandular proliferation extended into the lumen they also encroached on the deeper layers, thus causing the obliteration of the submucosa. The adenomatous character of these polypi are well seen in figure 2. No familial history could be traced.

**Case 2.**—Aged 30, was admitted into the hospital on 7th July, 1925, with the following:—

Constipation for eight days; no flatus was passed for five days; faecal vomiting for one day. On examina-

Fig. 5. Case 2.—Photograph of a piece of small intestine showing the two polypi. Note the irregular appearance of the growths.

Fig. 9. Case 3.—Photograph of a piece of large intestine showing one polypoid growth with the slender stalk. A number of elevated areas in the mucous membrane are also seen.

tion, the abdomen was found to be soft but tympanitic; temperature 98.6°F. P/R = 100/36. Tongue was dry and he looked extremely toxæmic. High tube enema produced no result, nor did the compound enema yield anything. Stomach wash was given which showed the content to be faecal in nature. A laparotomy was performed and an intussusception was found in the small intestine about a foot from the ileo-colic valve. It was felt that a foreign body caused the obstruction which on examination was shown to be a polypoid tumour mass which was responsible for the intussusception. About two feet of the gut were resected with the polypoid growth. The patient expired six hours after the operation. The resected gut on examination was found to contain two polypoid growths which were situated about a foot apart from each other (figure 5). The topmost one was larger and was 1½ inches by 1 inch in

size. The mass was separated into four divisions by means of three fissures within it. The growth was found to arise from the intestinal mucosa by a small elongated stalk. The lower growth was about half the size of the upper one and was nodular in appearance. Several blocks were made from different portions of both the tumour masses and the following were made out:—

The tumours were composed of different types of structural patterns at different places. At certain places the mass was composed of tissue which was simply adenomatous in nature (plate XXI, figure 6). There was glandular hyperplasia, showing no malignant change. This sort of picture was predominantly present at the area from where the stalk of the polypi originated. plate XXI, figure 7, shows another type of composition of the tissue which consisted of normal glandular structure with a few glands showing atypical proliferation. In the deeper portion of the growth the tumour showed marked atypical proliferation of the glands which were evidently taking a malignant turn (plate XXII, figure 8).

**Case 3.**—Aged 12, was admitted into the hospital on 16th March, 1939, with a history of continuous fever for nine days. On examination the patient was found to be toxæmic and after four days' stay in the hospital he died of toxæmia and circulatory failure. The body was sent for post-mortem examination with a diagnosis of enteric fever. The autopsy examination showed a much enlarged spleen, weighing 920 grammes, and a number of ulcerated areas in the jejunum and ileum. The character of these ulcers was like that of enteric ones. The large intestine, at the sigmoid part, showed a number of polyps. Besides these there were areas in the large intestine which showed slight nodular elevation in the mucous membrane (figure 9). Some of these areas looked just as prominences from the mucous surface, others presented distinct elevations. Histological sections from different portions of the elevated areas and the polypoid growths showed the following:—

The elevated areas showed slight adenomatous change in the simple tubular glands of the mucous membrane (plate XXII, figure 10). The definite polypoid growths on section showed very marked hyperplasia (plate XXII, figure 11) and sections from the deeper portions of the tumours showed frankly precancerous condition (plate XXII, figure 12).

### Comments and discussion

Multiple adenomata and malignant adenomata of the large intestine are two different pathological entities. Lockhart-Mummery (1935) has pointed out the difficulty of accepting such clear-cut divisions to differentiate between the two types and he has suggested the name adenomatosis, where numerous small polypoid growths occupied practically the whole of the large gut. This extremely rare disease has also been described as multiple adenomata and colitis polyposa. The condition has distinct familial predisposition. Our case 1 is an instance of such a condition; although the family history was not available the picture (figure 1) is a typical one. The patient had the first symptoms about six months before his death. It can be assumed that the lesion might have started earlier, yet the extensive nature of the involvement and the uncountable number of polyps clearly show the extreme rapidity with which the disease progressed. The histological picture of the individual growths did not suggest any malignant change (plate XXI, figure 2). We studied histological characters of the polyps of all the

Fig. 3. Case 1.—Camera-lucida drawing of a section of a piece of tissue showing a number of polypi with the intestinal wall. Note the finger-like projections of the adenomatous condition; some of these are overlapping each other leaving no healthy area.

Fig. 4. Case 1.—Magnified camera-lucida drawing from a section of the intestine showing a single polyp entirely. Note the absence of the submucosa. The adenomatous structure is sharply limited by the muscular layer which shows no change.

Fig. 2. Case 1.—Photomicrograph of the section of a piece of tissue from the intestinal wall; at one corner of the picture a small strip of the muscular coat can be seen; the rest of the picture is composed of the adenomatous structure. The submucous coat is practically obliterated.  $\times 150$ .

Fig. 7. Case 2.—Higher power photomicrograph showing the transition from the stage of simple adenoma to malignant change. Note the group of glands at the centre. These are different in nature from the normal ones and represent the initial stage of the malignant forms.  $\times 340$ .

Fig. 8. Case 2.—Photomicrograph of a piece of tissue from the deeper portion of the tumour showing mostly adenocarcinomatous processes; besides there are hyperplastic normal glands and a few transitional ones.  $\times 210$ .

Fig. 10. Case 3.—Lower power photomicrograph of a piece of large intestine from the elevated area. Note the normal glandular appearance and the simple adenomatous change in the same field.  $\times 150$ .

Fig. 11. Case 3.—Higher power photomicrograph to show the simple glandular hyperplasia taking malignant change. Note the gradual change from the benign to the malignant form.  $\times 210$ .

Fig. 12. Case 3.—High power photomicrograph of the tissue from the deeper parts of the polyp. The malignant nature of the growth is evident.  $\times 240$ .

sizes, but the nature of the growth was essentially the same everywhere, viz, simple adenoma. In the bigger polyps the growth varied only in quantity. It could be seen that the polypoid growth was sharply limited by the muscular layer (plate XX, figures 3 and 4), the submucosa being almost completely encroached by the growth. Although the individual growths were benign in nature histologically, the sum total effect of all these produced results which were far more injurious than that can be caused by simple irritation. The collection of mucus and cellular exudate and the faecal matter in between the different polyps gave the intestine a rigid structure and the finding at the rectal examination thus could be easily explained. Cases 2 and 3 are of course quite different in nature from case 1. Case 2 showed adenomatous polypi in the small intestine and case 3 in the large intestine. By studying a number of blocks from different parts of the tumours in both these cases, the transition from simple glandular hyperplasia to atypical proliferation could be made out. Plate XXI, figure 6, and plate XXII, figure 10, show a simple adenomatous condition. From this simple adenomatous condition a number of glands lying side by side with normal ones are clearly seen to assume an atypical nature (plate XXI, figure 7, and plate XXII, figure 11). This clearly shows the malignant tendency of these glandular structures. At other areas the normal appearance of the gland have almost disappeared (plate XXII, figure 8, and plate XXII, figure 12) assuming an appearance of malignancy. The question naturally arises whether these cells which are taking a malignant turn are simply transitions from normal structures or whether these particular cellular elements were endowed with a genetic capacity for malignant proliferation which was dormant but suddenly let loose later? This naturally takes us to the various theories as to the mode of production of new growths.

#### Summary

Three cases of intestinal polypoid condition are described, of which two cases occurred in the large bowel and one in the small intestine. One case was found to be a condition of multiple adenomatosis, a very rare condition, and two cases showed the pictures of simple adenoma of the mucous membrane showing malignant change.

In conclusion, our thanks are due to the Superintendent, Medical College Hospitals, Calcutta, for the case records and to the members of the staff of this department for the help rendered.

## ECTOPIC PREGNANCY

### (A CLINICAL NOTE)

By H. E. MURRAY, B.A., M.D., M.Ch., F.R.C.O.G.  
 LIEUTENANT-COLONEL, I.M.S.

Professor of Midwifery and Gynaecology, Medical College, Calcutta

SINCE Albucasis in the eleventh century first described extra-uterine pregnancy, a great deal of literature has accumulated on this subject. Nature has so arranged matters that the embryo of the human race is from an early date accommodated in and fed from the uterus. It would therefore seem reasonable to suppose that its conception should also take place there. However, this appears not to be the case; probably on account of the difficulty of transport for the delicate ovum. It is now established, practically beyond all doubt, that the human ovum is normally impregnated within the lumen of one of the fallopian tubes most usually at the fimbriated end.

Ovulation takes place about the 14th day of the menstrual cycle, counting the 1st day of the period as the 1st day of the cycle. The ovum, still surrounded by its zona pellucida, is extruded through the rupture of the graafian follicle and lies free near the surface of the ovary. The latter is in close apposition to the fimbriated end of the fallopian tube which attracts the ovum towards its open ostium. (The exact method of the entrance of the ovum into the tube is still unknown.) When the ovum enters the abdominal ostium of the tube, it is probable that the latter closes and is sealed by the enfolding action of the fimbriae. The ovum is now ready for impregnation, but, if this does not occur in 2 days, it dies, the corpus luteum undergoes necrosis, and the phenomenon of menstruation results.

If however the ovum is destined for impregnation, the procedure is as follows:—

The seminal fluid on ejaculation is deposited in the neighbourhood of the external os of the cervix uteri, and in the posterior vaginal fornix. At once the sperms begin to make their way through the cervical canal, and the uterine cavity, into the tube, and finally one fuses with the ovum usually in this fimbriated end. From all accumulated evidence it appears that only those sperms deposited in or around the external os are available for impregnation, and that the 'vaginal pool' (Adair, 1940) in the posterior vaginal fornix is merely excess. Sperms which are deposited in this pool are very short-lived owing to the acidity of the vaginal secretions which is inimical to them. Indeed sperms acted upon by the normal acid vaginal secretion may lose their motility in less than half an hour. Very rarely the ovum is impregnated in the ovary in the graafian follicle, giving rise to an ovarian gestation, only some 40 genuine cases of which have been reported up to 1927 (Eden and Lockyer, 1935).

Impregnation in the abdominal cavity has never been authentically reported though it has

been suggested. It is estimated that the sperms travel at such a pace that fertilization takes place within a few hours of coitus. Therefore coitus during the 10th to 15th day of the menstrual cycle is the most likely period in which to effect impregnation, *i.e.*, the 'dangerous period'. This is a much truer dictum than that of the opposite end of the cycle, *i.e.*, the so-called 'safe period'.

Normally, on fusion with the sperm, the impregnated ovum makes its way through the tube into the uterus and becomes embedded in the engorged endometrium which has been got ready for it. Therefore, it stands to reason that any factor which causes delay in this migration will favour the continuance of the pregnancy at the spot where the delay occurs, for the sperm being much smaller than the ovum can pass through a narrower lumen, and consequently any inflammation, kinks or adhesions which cause a partial stenosis of the tube may prevent the passage of the ovum. Some authorities state that, as long as the zona pellucida remains intact, the embedding of the ovum in the tube cannot take place. Therefore, anything which gives rise to premature shedding of this membrane favours a tubal pregnancy. The tube, being composed of tissue very different to that of the uterus, cannot dilate to accommodate a pregnancy of more than a few weeks, so that the onset of symptoms occur which, if neglected, may lead to rupture of the tube from over-dilatation. Rupture may also be caused by the eroding action of the trophoblast which is much more serious in the tube than in the uterus.

The fimbriated end of the tube is more dilatable than the uterine end, so that symptoms, or rupture, are more likely to occur early if the pregnancy is situated at the isthmus. Rupture of the tube in tubal gestation of the ampulla usually does not occur until towards the end of the second month, whereas it may take place in the first 2 or 3 weeks if the gestation is in the isthmal portion. This is an important point and is one which calls for accurate diagnosis of the situation of the pregnancy, on account of the urgency in undertaking operative interference at an early date.

The following case history is an example:—

Age 24, married 13 years: one child, seven years old. The patient was admitted at 12 noon on 19th July,

1939, as an acute emergency. The following history was available. Severe pain in the lower abdomen, and  
(Continued at foot of next column)

## PROLAPSE OF THE RECTUM IN CHILDREN AND THE ROLE PLAYED BY GALLOWS SPLINT IN THE CURE OF THIS CONDITION

By M. G. KINI, M.C., M.B., M.Ch. (Orth.),  
F.R.C.S. (Edin.)

Surgeon, King George Hospital, Vizagapatam (S. India)

PROLAPSE of the rectum is common both among adults and children. Among adults it is common after the 4th decade and in children between the ages of 2 and 4. Males were more commonly affected than females, and among children the ratio of male to female children was 9:1 in a total of ten cases treated so far. In none of the cases of prolapse of rectum among old people, could they give a history of prolapse in early life, as is stated in the textbooks. It is possible that the class of people who were suffering from this disease could hardly remember their past history and the question is still an open one. In children, however, it is common owing to bad hygiene, dietetic errors, and gastrointestinal infections. The prolapse in children may be complete or partial. In cases of partial prolapse, polypus is often the cause of this condition and these cases are brought to the hospital with a history of bleeding before,

(Continued from previous column)

some slight vaginal bleeding for last five days. Periods had been quite normal and regular, the last one about a month ago. The patient stated she was expecting her next period at any moment. Early that morning the patient suddenly got worse, so she was brought to hospital.

*On examination.*—She was pulseless, blanched, and collapsed. The abdomen was tense and swollen. The case was obviously one of intra-abdominal bleeding, probably from a ruptured ectopic. The patient was brought to the operating theatre at once and the abdomen opened. On incising the peritoneum free blood was seen in such quantity and under such tension that it spouted up into the air. As much as possible of this, about 16 ounces, was caught in a sterile bowl in which was a solution of sodium citrate, and this was given to the patient as an intravenous auto-transfusion during the operation. At first it was not clear where the bleeding was coming from, as no tumour could be felt, and the fimbriated ends of both fallopian tubes were seen. A rapid inspection of the spleen and other organs did not reveal any injury, so the blood was then swabbed out of the cavity with great rapidity when the small rupture at the isthmal end of the right tube was apparent (*vide illustration*). The bleeding was coming from a spouting vessel at the medial aspect of the rupture. The tube was removed in the ordinary way and the patient made an uneventful recovery.

My thanks are due to Dr. B. P. Tribedi, the Professor of Pathology in the Medical College, for the drawing of the specimen.

during, or after the motion. Sometimes the bleeding is of an alarming character, and frequent hæmorrhages cause anæmia and debility. In these cases removal of polypus cures the prolapse and improves the general condition of the patient. In cases of complete prolapse the mothers of the children generally seek admission with a history of dysentery or diarrhœa. On admission, the children are found to be emaciated with a complete prolapse, this in some cases being irreducible with marked œdema (figure 1). The problem of treating these

Fig. 1.—Complete prolapse in a child with œdema causing irreducibility.

children as out-patients is difficult, because the home condition of the majority of the people who seek advice is very poor. It is therefore necessary to hospitalize these cases.

The whole principle of treatment of this prolapse is :—

- (1) to reduce the prolapse and maintain it reduced,
- (2) to attend to the dietetic errors, and
- (3) to treat the infective condition of the intestinal tract which preceded the prolapse.

The reduction of prolapse in the majority of the cases is easy, but maintenance is difficult. The mode of evacuation either by sitting on a commode or in the usual way the Indian children defæcate is inimical to the cure of this condition. The following scheme has given satisfactory results :—

- (1) Both legs are slung up in a gallows splint, as in treating a fracture of the femur, so that the buttocks are slightly raised from the bed and the glutei strapped (figure 2).
- (2) The motion is examined for amœbæ and other infections, and, if present, treatment is given for this infection.
- (3) Diet is regulated and deficiency of vitamins supplied.

It is important that the child should have the motion lying in bed. This is the essential part of the treatment and this object is gained by using the gallows splint. The use of this splint perforce prevents the child from getting up and provides the rest that is so necessary for the children who are debilitated. To facilitate an

easy soft motion, the child is given liquid paraffin at night and a paraffin enema of 2 to 3 ounces through a rubber catheter high up in the rectum in the morning. With this simple treatment the prolapse becomes easily reducible and when reduced remains inside without recurrence. This method of postural evacuation prevents the straining and the lubrication of the bowel produces a soft motion in bed, preventing its recurrence. The child is kept in this splint for a minimum period of a fortnight during which time it picks up weight and general health, and thus cure is obtained. Ten

Fig. 2.—The child in the gallows splint with extension of limbs and reduction of prolapse, ten days after the institution of treatment. Note the general well-being of the patient

children with complete prolapse were treated in this way and all the children had a cure at the time of discharge and on follow up four have reported no recurrence, two have died due to other diseases and four have not replied due to improper address and other causes.

### Conclusion

The essential part of the treatment is reduction of prolapse and to maintain it reduced until the general condition is improved and the cause dealt with. The use of gallows splint has contributed to the rapid cure of this condition and has proved useful for the following reasons :—

- (1) It necessarily confines the child to bed.
- (2) It gives complete rest which is so necessary in debilitated children.
- (3) Raising of buttocks helps in the reduction of congestion associated with prolapse and thus helps in its reduction and prevents recurrence.
- (4) It facilitates nursing and especially the use of bed-pan for an easy evacuation without disturbing the child.

## SMALLPOX AND SULPHONAMIDE

By T. B. PATEL, B.Sc., M.B., B.S., B.H.Y., D.P.H.  
andB. P. B. NAIDU, M.D. (Edin.), M.H., D.P.H.,  
D.T.M. (L'pool)

(From the City Fever Hospital, Arthur Road, Bombay)

*Introduction*

SMALLPOX is primarily a disease of children, but the introduction of protective vaccination in early childhood has resulted in the greater prevalence of the disease among the adult population.

In Bombay, we have a large floating population who migrate periodically from rural areas in search of employment and these constitute the bulk of our labouring class.

TABLE I

Compiled from hospital records for the years 1923 to 1939\*

Age period	VACCINATED		UNVACCINATED	
	Cases	Deaths	Cases	Deaths
0-5 ..	181	6 ( 3.3%)	1,085	457 (42.1%)
5-10 ..	232	8 ( 3.4%)	474	84 (17.6%)
10-20 ..	2,527	93 ( 3.7%)	1,529	429 (28.0%)
20-30 ..	2,839	203 ( 7.1%)	1,867	859 (46.0%)
30-40 ..	599	44 ( 7.3%)	491	225 (45.8%)
40-50 ..	115	19 (16.5%)	97	58 (60.0%)
50 and upwards	62	13 (21.0%)	51	29 (57.0%)

\* Data taken from the Annual Reports of the City Fever Hospital, Arthur Road, Bombay, from 1923 to 1939.

This table is instructive in that it points to some important deductions, namely, (i) among the vaccinated the immunity wears off by the 10th year; (ii) the unvaccinated have a heavy mortality should they contract the disease;

(iii) mortality among the vaccinated is considerably less, as compared with the unvaccinated.

In Bombay, we have smallpox with us every year; during some years the disease assumes epidemic proportions.

*Hospital cases*

Cases that are admitted into this hospital are from the poor labouring class and usually from the adult population. A good proportion of these cases seek hospital treatment only when the disease is in advanced stage.

*Classification of smallpox cases*

Cases which are admitted for treatment are grouped clinically under four types, namely, the discrete, the semi-confluent, the confluent, and the hæmorrhagic.

This table shows that under hospital treatment the mortality among the discrete cases is negligible; the confluent type has a mortality of about 47 per cent and this is due to the fact that these cases develop a septic stage from which many succumb. The hæmorrhagic type has the highest mortality, 88 per cent.

In the discrete type, the deaths that occur are due to pneumonia. In the semi-confluent type, deaths occur only in those cases which develop sepsis, and the mortality varies from 4 to 20 per cent. In the confluent type the deaths are mainly due to sepsis. The stage of suppuration is usually on the 7th or the 8th day of the disease, and the patient succumbs to septicæmia or toxæmia. The infecting organism in the majority of the cases is the staphylococcus, but in some cases streptococci are also found. Specific treatment with vaccines and sera has not been a success. This type may be further subdivided into two varieties; in one the rash is flat instead of being raised and prominently projected; in the other the rash presents the usual characteristics. The hæmorrhagic type is the most severe manifestation of the disease;

TABLE II

Compiled from hospital records for the years 1930 to 1939

Years	DISCRETE		SEMI-CONFLUENT		CONFLUENT		HÆMORRHAGIC	
	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths
1930 ..	559	6	308	18	224	83	204	169
1931 ..	14	0	4	0	5	2	6	4
1932 ..	136	0	80	1	37	15	49	44
1933 ..	1,130	4	436	33	294	138	257	236
1934 ..	57	0	50	1	30	18	26	21
1935 ..	361	0	232	8	214	78	114	99
1936 ..	217	0	275	9	139	62	79	67
1937 ..	286	0	193	5	144	94	28	27
1938 ..	837	0	305	3	398	199	131	121
1939 ..	106	0	56	3	32	21	16	15
10 years ..	3,703	(0.2%)	1,939	(4.1%)	1,517	(46.8%)	910	(88.2%)

in this also, we have noted two forms; in one the hæmorrhage occurs from the onset of the disease, and the rash is of the purpuric variety while there are hæmorrhages from the mucous membranes of the conjunctiva, mouth, etc. It is also attended with hæmaturia, melæna, hæmoptysis and hæmatemesis. The patient usually succumbs within 7 to 10 days of the onset. In the other variety hæmorrhage is not seen until after the rash has fully developed; it is then found in the pox. This type has been described as hæmorrhagica pustulosa. These cases have been treated in the past with serum from convalescent cases; the results have not been encouraging, as the mortality among the treated was nearly the same as in the control cases.

*Researches into the treatment of confluent and hæmorrhagic cases*

In 1924, 25 cases of the hæmorrhagic type were treated with convalescent serum and the results were not encouraging; the late Dr. Patel considered that 'the antitoxins in 20 c.cm. of the convalescent serum are probably not enough to neutralize all the toxins in the body'.

In 1933, some selected cases of the confluent and hæmorrhagic types were treated with sera obtained from calves used for the preparation of vaccine lymph at Belgaum, serum obtained from locally immunized sheep, and serum from convalescent patients.

TABLE III

Treatment	Cases	Deaths	Controls	Deaths
Calf serum ..	20	15	20	14
Sheep serum ..	2	2	2	2
Convalescent serum	25	20	25	18

During the same year, confluent and hæmorrhagic cases were exposed to the rays of Vitalux lamp for varying periods from 5 to 30 minutes according as the patient could bear the heat. These rays had definite result in drying up the pox earlier than usual in the septic stage.

During the year 1938-1939, some selected cases of the septic confluent type were treated with sulphonamide and uleron administered orally.

TABLE IV

Treatment	Cases	Mortality, per cent
Sulphonamide .. ..	125	25.0
Uleron .. ..	19	32.0
M & B. 693 .. ..	16	37.5

Uleron seemed to be definitely toxic in the doses administered; some of the cases were treated with M.&B. 693 in the early eruptive stage, before the development of pustules. It

neither aborted the eruptive stage, nor did it prevent the development of the pustular stage. Sulphonamide seemed to be effective in the treatment of the late septic manifestations such as septicæmia, arthritis, furunculosis and in lung complications.

*Sulphonamide and confluent smallpox*

Results obtained with sulphonamide in the selected cases treated during 1938-1939 justified a further trial with the drug during this year with adequate controls.

From January to May 1940, we have treated 91 cases of the semi-confluent type with 64 controls and 60 cases of the confluent type with 63 controls. In June there has been a great drop in admissions for smallpox. As one of us (T. B. P.) has taken up a new post it seemed desirable that the results we have obtained be summarized in order that others engaged in the treatment of smallpox may give further trial to this drug, so that in course of time a successful way of dealing with the confluent type of smallpox may be evolved.

The sulphonamide group of drugs have established their therapeutic value in the treatment of diseases such as cerebrospinal fever, pneumonia, gonorrhœa and puerperal fever. It is claimed that the drug is specific against organisms of sepsis, staphylococci and streptococci. Our results in the treatment of confluent cases of smallpox justify the use of this drug.

TABLE V

*Summary of cases treated with sulphonamide during January to May 1940*

	Treated	Mortality, per cent	Controls	Mortality, per cent
Semi-confluent cases:				
Vaccinated	59	18.6	32	28.1
Unvaccinated	32	18.7	32	34.4
Confluent cases:				
Vaccinated	32	50.0	30	93.3
Unvaccinated	28	64.3	31	93.5

These figures are admittedly small, but that sulphonamide does exert a beneficial action is clear.

We have employed sulphonamide tablets sold by Parke, Davis & Co. and by Glaxo Laboratories. Two tablets were administered orally at four-hourly intervals for the first 7 days; thereafter one tablet was given four-hourly for the next 7 days. The maximum amount administered varied from 44 to 47.5 grammes. In a very large number of cases the amount of the drug administered was small, as the drug was withheld as soon as the temperature reached normal.

During the administration of sulphonamide we have observed very few untoward symptoms:

(Continued at foot of next page)

TABLE II

	Day of fever	H-agglutination	Vi-agglutination	REMARKS
Case 8	8th day	— 25	+ 25	Clinically enteric.
	15th "	+200	+100

	22nd "	Not done	+400	

Statistical note by Mr. Sastri, statistician of the University of Madras

	Positive reactions	Negative reactions	Total
Vi-agglutination	202	53	255
H-agglutination	160	95	255

Proportion of positive reactions in Vi .. 0.7922  
Proportion of positive reactions in H .. 0.6274  
Difference .. 0.1648

Standard error of the difference :  
 $\sqrt{\frac{0.7922 \times 0.2078 + 0.6274 \times 0.3726}{255}} = 0.0395$

Therefore,  $\frac{\text{Difference}}{\text{Standard error of difference}} = \frac{0.1648}{0.0395} = 4.172$

Hence, the difference is highly significant and in detection Vi-agglutination is superior to H-agglutination.

Positive reaction

	Vi-agglutination	H-agglutination
Enteric fever cases	202	160
Non-enteric fever cases.	12	5
	214	165

Out of the 214 cases giving positive reaction by Vi method, 94.4 per cent had enteric fever.  
Out of 165 cases giving positive reaction by H-agglutination method, 97.0 per cent had fever.  
We have to find out whether the difference between the two proportions is significant or not, to test whether

one of the methods is more efficient in making correct diagnosis than the other.

Standard error of difference:

$$\sqrt{\frac{0.944 \times 0.56}{214} + \frac{0.970 \times 0.030}{165}} = 0.021$$

Therefore,  $\frac{\text{Difference}}{\text{Standard error}} = \frac{0.026}{0.021} = 1.238$

Hence, the difference is not significant. From this we cannot say that the specificity of H-agglutination is superior to Vi-agglutination. But it must be noted that the number of non-enteric cases is too small compared with enteric cases.

Acknowledgments

We are indebted to Dr. C. G. Pandit, Acting Director, King Institute, and to Lieut.-Colonel H. E. Shortt, I.M.S., Director, King Institute, Guindy, for their encouragement, to the latter also for helpful suggestions and criticism in the preparation of this paper. Our thanks are also due to the superintendents of the Government Royapuram, Government Royapettah, Government Victoria Caste and Gosha and Government Women and Children Hospitals for their permission to make use of the clinical material. We are also thankful to Dr. S. Venkatasamy of the King Institute, Guindy, for his assistance in this investigation.

## EXISTENCE OF LEPTOSPIROSIS IN RANGOON

By B. M. DAS GUPTA

(From the Protozoology Department, Calcutta School of Tropical Medicine)

TAYLOR and GOYLE (1931) found in Rangoon that out of 100 *Nesokia bengalensis* examined 42 were infected with leptospira, while among the house rats, *Rattus rattus* and *R. concolor*, 23 showed the infection. They also noted that a rat strain isolated in Rangoon corresponded with a Sumatra rat strain, but not with human strains isolated by these workers in the Andamans.

There is little doubt that human leptospirosis also exists in Burma, although there is, as far as I am aware, no published record of the occurrence of the disease\*.

In July 1939, Lieut.-Colonel G. C. Maitra, I.M.S., the then Director of the Pasteur Institute, Rangoon, sent to me a specimen of serum from a case of jaundice with a request to perform an agglutination test for evidence of leptospiral infection. The serum was put up against the different strains of leptospira then available in my laboratory.

TABLE I

Strains	SERUM DILUTIONS			
	1-20	1-40	1-80	1-160
Strain Chopra, Calcutta (classical <i>L. icterohæmorrhagiæ</i> ).	+	+	+	+
Strain Wijnberg (classical <i>L. icterohæmorrhagiæ</i> ).	+	+	+	+
Strain Andamans CH31	—	—	—	—
Strain Andamans CH11	—	—	—	—
Strain Mg. Tin Tin*	+	±	—	—

\* This strain was isolated by me from an Andaman case; homologous with a Java bat strain, 90C.

In order to obtain the limit of agglutination, further dilutions were made as follows:—

TABLE II

	1-1,000	1-10,000	1-100,000	1-1,000,000
Strain Chopra	+	+	+	±
Strain Wijnberg	±	—	—	—

It is evident from the results presented in the above tables that the serum was obtained from  
(Continued at foot of next column)

\* Since this paper was sent to the press, I have come across a reference to the occurrence of leptospiral jaundice in Rangoon in the 'Annual Report of the Burma Pasteur Institute and Bacteriological Laboratory for the year ending 31st December, 1929, and the 31st March, 1930, respectively'. The serological nature of the causal organism was not, however, determined.

## RABIES IN LOWLIER ANIMALS

By S. D. S. GREVAL

LIEUTENANT-COLONEL, I.M.S.

The School of Tropical Medicine, Calcutta  
and

M. J. NICHOLAS, I.M.D.

The Pasteur Institute, Calcutta

### Advice in a case of tortoise bite

A RESIDENT of 'A' in the United Provinces was bitten by a tortoise while bathing in the river. Advice regarding anti-rabies treatment was required at Calcutta by a relative on 17th October, 1940.

Tortoises do not usually bite bathers in rivers. Two questions arose—Was there anything wrong with this particular tortoise? Had anybody at 'A' ever heard of a case of rabies in man or animals after a tortoise bite? These questions could not be answered satisfactorily by the relative. The advice given was that the treatment should be taken if the biting animal had behaved in an obviously unusual manner and if cases of rabies in man or animals were known to have occurred from bites of tortoises.

### Rabies in the tortoise

There is no mention in the available literature on the subject, in English or French, of naturally-occurring rabies in tortoises. Street virus, however, has been injected into brains of turtles and proved by passage into rabbit brain to have persisted for months. In the brains of *Testudo mauritanica* and *Clemmys leprosa* (a fresh-water species) it persisted for 302 and 150 days, respectively (Remlinger and Bailly, 1931, 1932). The turtles did not show any sign of rabies.

The difference between turtles and tortoises is not sharp. That a tortoise can acquire infection in nature, remain healthy and impart infection by bite are possibilities. Identical occurrences have been observed in bats.

Incidentally, 'unusual' behaviour may and actually does fall short of signs of rabies and yet is a very useful guide in rabies. When during a hunt jackals turn on the hounds they behave unusually. Rabies in the pack usually follows.

(Continued from previous column)

a case of leptospirosis and the infecting organism was homologous with the classical *L. icterohæmorrhagiæ*.

My thanks are due to Lieut.-Colonel G. C. Maitra, I.M.S., Director, Pasteur Institute, Rangoon, for sending me the material on which this note is based.

### REFERENCE

Taylor, J., and Goyle, A. N. (1931). *Indian Med. Res. Mem.*, No. 20. Thacker, Spink and Co., Calcutta.

Local information regarding incidence of rabies, specially from small localities, is very valuable. The impression produced by the actual suffering of this rare catastrophe and by the hopelessness of the situation is retained by the inhabitants for a long time.

#### *Rabies in other lowlier animals*

Other lowlier animals which have been experimented upon are the hedgehog (*Eurinaeus europaeus*) and the spermophile (*Spermophilus citellus*). The spermophiles were resistant during hibernation. The hedgehogs, on the other hand, transformed the fixed virus into the street virus (Jonnesco, 1932). The latter experiment would show that the hedgehog was particularly suitable to be a host of rabies virus. It may be one of the natural reservoirs.

Zoologically hedgehogs and spermophiles being mammals are above tortoises which are reptiles. In popular language, however, all of them are lowlier animals amongst the lower animals.

Attention has been recently drawn to bats, some of which have definitely been proved to carry rabies and others are, therefore, under suspicion (Greval and Nicholas, 1940). The bats are also lowlier animals.

Attention was also drawn to rabies in the mongoose (Greval, 1932, 1933). The mongoose, however, is a carnivore and ranks with the dog which is not a lowlier animal.

#### *Natural reservoir of rabies*

One of us (Greval, *loc. cit.*) has suggested that like the fire in ancient India, before the introduction of matches, rabies smoulders in forests and flares in human habitations. The smouldering probably occurs in the wild carnivores which do not always die of it. It is now suggested that it may occur even in the lowlier animals which may not be much inconvenienced by it. It is not in the best biological interest of a parasite always to cause lethal infection, *e.g.*, rabies in lower animals and man. Such an infection would exhaust the supply of hosts in time and thus terminate the existence of the parasite.

#### *Danger of anti-rabies treatment*

In taking the treatment there is a risk of developing the post-treatment paralysis. The paralysis, however, is a rare event and the risk must be preferred to certain death, should rabies develop as a result of the bite. Besides, the majority of cases of paralysis, definitely attributable to treatment, which have come to the knowledge of the writers during the last 19 years, have completely recovered. During the last six years, out of 35 cases reported from the various anti-rabies institutes of India and Burma only 7 proved fatal.

### ON USING WATER INSTEAD OF DUST FOR DILUTING PARIS GREEN IN MALARIA CONTROL\*

By PAUL F. RUSSELL

FRED. W. KNIPE

and

T. RAMACHANDRA RAO

In another report (Russell and Jacob, 1939), one of us referred in passing to the use, at our field station, of a dustless method of diluting Paris green based, with modifications, on that recommended by Barber *et al.* (1936). After two years' successful experience with this modified procedure in Pattukkottai taluk, we believe a report may be useful, for the measure appears to us to have great value in India.

#### *Technique*

First, the following stock suspension was prepared:—

#### *Stock suspension*

Kerosene oil (Elephant brand—		
Socony)	..	400 c.c.
Paris green	..	200 c.c.
Egg albumin, dry, powdered, commercial	..	1 gramme†

The above ingredients were added, in the order mentioned, in a Winchester bottle holding 3 litres and thoroughly shaken. (The total volume will be found to be 480 c.c.m.) For convenience, separate tins of definite volume were used for measuring out kerosene oil and Paris green. The latter can be measured easily in a tin and, if quite dry, can be poured. The stock suspension must be thoroughly shaken every time some has to be poured out. (No water for mixing with egg albumin is being used, as after repeated tests it was found that it tended to make the stock suspension coagulate so that it was then impossible to keep the Paris green floating.)

In the laboratory, a number of glass vials—shell vials, 4 inches  $\times$  1 inch, with rims and

\* This note is based on some routine studies of malaria investigations, a project under the auspices and with the support of the International Health Division of the Rockefeller Foundation co-operating with the Health Department of Madras Presidency and the Pasteur Institute of Southern India, in Coonoor, Nilgiris.

† Egg albumin is not mentioned in the original article but was suggested to us verbally by Dr. Rice as having been found useful. We agree that it is.

supplied with corks—were each filled with 25 c.cm. of the stock suspension, the bottle being vigorously shaken at each pouring. These filled vials were then ready for use in the field, to which the spraying coolie took the following equipment (*see figure*) :

Fig. 1.—Coolie equipped to spray Paris green by dustless method. Carrying Hudson sprayer, tin dipper and funnel, 'cartridge' belt of vials containing stock suspension. Photograph also shows type of canal edge successfully treated by this method.

#### Field equipment

20 to 25 filled vials.

One khaki belt 4 to 6 inches wide (cartridge belt type). This was made with khaki drill by a tailor, and had individual pouches to hold vials.

One tin can measuring out exactly 1,000 c.cm. When not in use this was hung on a hook or a flap of the belt on the left side.

One tin funnel fitted with a wire gauze sieve.

One Hudson Sterling no. 115 sprayer.

The spraying coolie, with the above field equipment, proceeded to the breeding places and carried on as follows :—

#### Field procedure

1. Removed the pump from the sprayer.

2. Took 2 litres of water from the breeding place and poured it into the sprayer tank, filtering it through the funnel to remove any floating matter.

3. Removed one vial from his belt, vigorously shaking it and then pouring the contents into the sprayer tank. Taking a small quantity of

water into the empty vial, it was again shaken and poured into the tank to remove the last of the Paris green.

4. Poured three more litres of water from the breeding place into the sprayer tank as before. (This brought the total water used to 5 litres for every 25 c.cm. of stock suspension.)

5. Replaced the pump plunger and pumped to desired pressure.

6. Then slung the sprayer on his back and proceeded to spray, ordinarily keeping the nozzle 1 to 1½ feet above the water surface.

The sprayer tank was kept agitated now and then with a few swings of the hip. Ordinarily 700 to 900 square feet were sprayed with 25 c.cm. of stock suspension and an average South Indian workman used between 20 to 25 vials a day.

#### Use in Senjayakollai

This method was used in Senjayakollai as one phase of a control programme by minor engineering methods in that village. First season's spraying began on 15th July and ended on 5th December, 1938. The interval between treatment was 4 to 5 days from July to 5th November and thereafter 7 days. The unusually short interval allowed at first was due to the observation that *Anopheles culicifacies* larvae were developing at the rapid rate of one stage per day. The following breeding places were treated :

	Length (yards)	Area sprayed (square yards)
Branch irrigation canals ..	2,350	1,330
Irrigation channels ..	5,195	1,730
Tank edges ..	..	660
Borrow pits ..	..	2,500
Wells (120 sprayed) ..	..	94
Total area sprayed per time	..	6,814 (approx)

There were 33 spraying rounds during the period and our record of the number of vials used was 1,818 for 31 rounds, or an average of 58.6 vials per round. This means that approximately 107.7 square yards or 969.3 square feet were covered per vial. (We estimate that the width of sprayed area along a canal bank was 1 foot.)

During 1939, spraying by this method was carried out from 7th August to 25th December at intervals varying, as in 1938, from 4 to 7 days. In 1939 only field channels and ditches were sprayed. (In neither year were the extensive rice fields around this town treated.) The total length sprayed per round in 1939 was 5,305 yards and area sprayed was estimated at 1,768 square yards. There were 32 rounds of spraying in which a total of 629 vials was used. The approximate average area sprayed per vial in 1939 was 76.8 square yards or 691.2 square feet, somewhat less than in 1938.

### Discussion

As to quantity of stock suspension required, this will of course vary with types of place being sprayed. From some special field trials, we believe it is probably safe to say that an average of 500 square feet can be covered per vial in general use. This is about 60 square feet per cubic centimetre of Paris green. Our figures were higher, but we were usually dealing with canal edges. We frequently check our results, since all our work is on an experimental basis, and we are certain that this measure was effectively controlling breeding in the places sprayed, frequently even in the presence of considerable vegetation.

Several tests of the method were made, with careful larva counting before and after. In every case the test showed excellent results. One such test may be mentioned as an example. On 7th April, 1940, in a newly-made roadside drain, 85 feet  $\times$  3 $\frac{1}{2}$  feet, there were 12.7 anopheline larvæ, all stages, per standard dip. One pupa was found in the course of the dipping. Vegetation was scanty. This ditch was sprayed by the above technique in the usual way. Twenty-four hours later the ditch was again sampled by standard dipping but not a single larva was taken. One pupa was found and some freshly-laid ova. In an adjoining ditch, where no spraying was done, numbers of larvæ per standard dip were the same before and after the experiment. These results agree with other tests at other seasons and in other types of breeding places.

### Costs

Average expenses may be figured as follows for one day's spraying by our coolie of approximately 12,000 square feet, using 24 vials of stock suspension.

#### Recurring expenses

	Rupees*
Kerosene 500 c.c. at Re. 0-11-6 per gallon ..	0-1-3
Paris green 250 c.c. at Rs. 70 per 100 lb. ..	0-8-10
Egg albumin 1 gramme at Rs. 42 per 10 lb. ..	0-1-3
Cost of 750 c.c. stock suspension ..	0-11-4
Coolie, 1 day at Rs. 9 per month ..	0-4-9
Cost of 1 day's spraying ..	1-0-1

#### Initial expenses

	Rupees*
Hudson Sterling sprayer (115) ..	30-0-0
Spare parts .. ..	2-0-0
Vials .. .. (approx.)	8-0-0
Belt .. ..	2-0-0
Funnel, tins, etc. .. ..	3-0-0
Total cost for equipment ..	45-0-0

\* A rupee at present rate of exchange may be taken as equivalent to £0-1-6 or U. S. \$0.32. One rupee contains 16 annas and each anna 12 pies. Prices have risen due to war conditions. These are pre-war actual figures.

Footnote.—Some useful figures:—

- 100 c.c. Paris green weigh 142 grams or 0.313 lb.
- 100 c.c. Egg albumin (powdered) weigh 53 grams.
- 1 Imp. gallon kerosene oil = 4,564 c.c. equivalent to 1,2009 U. S. gals.
- 1 pound (avoirdupois) equals 454 grams.

Equipment should be good for at least two years, and the sprayer for considerably longer period if properly used. One might reasonably add As. 2 per day for depreciation and say that (at pre-war prices) one can treat effectively 12,000 square feet by this method per day using one coolie at a total cost of Re. 1-2-1 per time.

### Summary

Using a modification of the dustless method of diluting and spreading Paris green recommended by Barber *et al.* (*loc. cit.*), we have had excellent results, especially in treating irrigation canal and channel banks, during two seasons in south-eastern India. It is our belief that the method is effective, cheap, and simple.

## A Mirror of Hospital Practice

### BANTI'S DISEASE?

By PRAN NATH CHHUTTANI, M.B., B.S. (Punjab),  
D.T.M. (Cal.)

*The 'Shalimar', Gangtok (Sikkim)*

In view of the case report of Banti's disease by Captain J. W. D. Goodall, I.M.S., in *I.M.G.*, July 1940, it may be of interest to record the following case:—

A Pathan farmer, aged 35, coming from Ghazni (Afghanistan), sought admission to the Mayo Hospital, Lahore, on 22nd December, 1938, to have his enlarged spleen removed.

*History.*—Twelve years before admission patient had noticed a mass under the left costal margin which he soon came to learn was his spleen. It had been steadily increasing in size all these years. Though for the first three or four years after this incidental discovery he was quite fit and without any other symptoms yet after this period he insidiously started feeling below the mark and would get attacks of epistaxis occasionally, to start with in the hot summer months only. The severity of these attacks was variable, the amount of blood lost being from a teaspoonful to about a cupful. At the same time he began to have attacks of intermittent fever which lasted for about a fortnight at a time and recurred every four or five months. Epistaxis and fever as above had been with him for about eight years before admission. He never had hæmatemesis or any other hæmorrhages. As the indigenous treatment did not benefit him and as he now also got breathless at work he left his country to have his enlarged spleen removed.

Family history revealed nothing relevant.

*Physical examination.*—General examination revealed anæmia; tongue and nails pale; no icterus; nothing abnormal in the circulatory and respiratory systems; spleen enlarged below the umbilicus. Consistency hard. In the middle of the palpable portion of the anterior border of the spleen there was a vague swelling about the size of an orange. Liver not palpable. No signs of ascites. No œdema.

*Laboratory investigation.*—Normocytic hypochromic anemia. There was eosinophilia of 12 per cent but no cause could be discovered. Stools showed no helminthic or protozoal infection. Wassermann reaction was negative. Preliminary and subsequent blood reports

*Acknowledgment.*—I wish to thank Lieut.-Colonel A. Chand, I.M.S., visiting physician and Professor of Medicine, Mayo Hospital and Medical College, Lahore, for so kindly permitting

TABLE

	DATE			
	14th January, 1939	2nd March, 1939	15th March, 1939	15th April, 1939
Hæmoglobin (Tallqvist method)	65 per cent	..	70 per cent	80 per cent
White blood cells per c.mm.	8,125	16,000	11,375	8,750
Red blood cells per c.mm.	3,560,000	..	2,850,000	3,960,000
Polymorphonuclears	54 per cent	73 per cent	70 per cent	34 per cent
Lymphocytes	32 " "	6 " "	14 " "	42 " "
Large mononuclears	2 " "	3 " "	0	0
Eosinophils	12 " "	18 " "	16 per cent	24 per cent
Size (Eve's halometer)	7.3 $\mu$	..	8.2 $\mu$	7.8 $\mu$
Bleeding time	2 minutes	..	1 minute 30 seconds	..
Coagulation time	4 minutes 45 seconds	..	4 minutes 15 seconds	..
van den Bergh reaction	Negative in all phases	..	Indirect only ++	..
Platelet count	Did not contra-indicate splenectomy, exact count misplaced.	..	160,000 per c.mm.	..
Reticulocyte count	..	..	3 per cent	2 per cent

have been tabulated. Urine was normal except for presence of urobilin.

Patient was sent back to the surgical ward with the visiting physician's opinion that though there was no indication for splenectomy yet there was no contra-indication for the operation. The patient was put on iron and ammonium citrate—90 grains a day—on 15th January, 1939, and ultimately, on 21st February, successful splenectomy was performed. There were no adhesions around the spleen and removal was easy. There was about a pint of effusion in the peritoneal cavity. Liver was markedly shrunken. It was the agreed opinion of everybody that its size was not more than one-eighth of normal. It had the characteristic hobnailed appearance. Recovery after the operation was interrupted by the development of broncho-pneumonia. Operation wound healed normally. He was referred back to the medical ward on 14th March when his respiratory complication had considerably improved. His blood report on 15th March showed macrocytic hyperchromic anemia (see table). van den Bergh—indirect was ++. Conjunctivæ bore obvious icterus. Patient was put on intensive campolon therapy and subsequently his blood picture and general condition much improved and he was discharged on 17th April, 1939.

*Point of interest.*—Advanced hepatic cirrhosis as seen on the operating table was surprising in view of absence of any definite clinical indication.

*Discussion.*—1. Can such a case be labelled Banti's disease? There was no leucopenia. There was history of repeated intermittent fever but it started after obvious enlargement of spleen had been there for four years. There was no definite evidence of malaria either—no malarial parasites could be found. (Patient did not have any fever during his stay in the hospital except that due to the post-operative complication of broncho-pneumonia.) Personally I feel a diagnosis of Banti's disease is justified.

2. Was splenectomy justifiable? In view of the advanced cirrhosis this seems questionable.

me to report this case of his which I had the chance to study when working as a house physician of his medical unit.

### SEVERE HÆMATURIA RESULTING FROM THE USE OF M.&B. 693

By KRISHNA GOPAL KARMAKAR, L.M.F.  
Resident Medical Officer, Carron Tea Estate, Carron P. O., Jalpaiguri

A FEMALE child, aged 6 years, was attacked with slight fever on the 2nd July, 1940. Her temperature came down to normal next day. But it rose to 102.5°F. at night and came down to 99°F. on the following day (4th July). Malignant tertian malaria parasites were found in the blood and 6 grains of quinine bishydrochloride were injected intramuscularly. Another injection of quinine was given in the same strength on the 5th July. But in spite of these injections the temperature was oscillating between 100°F. and 102.5°F. On the 7th and 8th July two more injections of quinine, 6 grains each, were administered. The fever did not yield. Bowels were constipated and moved by calomel and salts in the early stage. Later on, the child had occasional loose foul-smelling motions. Urine was very scanty during 24 hours. Pulse rate varied between 108 and 120 per minute. No abnormality was found in the lungs.

*Urine.*—Reaction—acid. Chemical examination—phosphates present. Microscopical examination—pus cells, epithelial cells, organisms—Gram-negative bacilli (*B. coli*?), diphtheroids, Gram-positive cocci in pairs and chains.

*Stool.*—No evidence of dysentery or helminth infection.

*Progress.*—The fever was irregular (99° to 102°F. axillary temperature). Hexamine was tried for three consecutive days from 11th to 13th July, to disinfect the urine, but it did no good. Four tablets of M.&B. 693 were given daily from the 17th to the 19th July. After three days of sulphapyridine treatment the child passed about 4 ounces of dark blood during micturition at 5 a.m. on 20th July. The specimen was sent to the laboratory and the report showed this to be hæmaturia and not hæmoglobinuria. The hæmaturia was thought to be due to the

toxic action of M.&B. 693 which was stopped immediately. Plenty of fluids and big doses of alkaline mixture were given. The child had intense pain in her lower abdomen and 5 hours later she again passed about 6 ounces of red-coloured urine. Tincture hyoscyamus was administered with alkaline mixture to relieve the spasmodic pain. Next time, she passed clear urine during defæcation. The hæmaturia took place on the 18th day of illness when the child was very devitalized owing to prolonged illness.

Another specimen of urine was sent to the laboratory for examination on the 21st July. Reaction—slightly acid, albumin—nil. Microscopical examination—red cells numerous, pus cells, epithelial cells—present, organisms—scanty, *B. coli*—present, few.

Lastly, the patient was given *B. coli* vaccine (P. D. & Co.) with steady improvement, the temperature gradually coming down to normal on the 6th August, 1940.

The case is of interest on account of hæmaturia apparently caused by the toxic action of M.&B. 693.

My thanks are due to Dr. Baird, the group medical officer, for his kind and valuable help in the treatment and to Dr. S. K. Sen, in charge of the Nagrakata Central Laboratory, for the pathological reports.

## A CASE OF AIR EMBOLISM AS A RESULT OF ARTIFICIAL PNEUMOTHORAX TREATMENT

By AMIR CHAND, F.R.C.P. (Edin.)

LIEUTENANT-COLONEL, I.M.S.

*Professor of Medicine, King Edward Medical College, Lahore, and Visiting Physician, Mayo Hospital, Lahore and*

K. L. WIG, M.B., B.S. (Pb.), M.R.C.P. (Lond.),  
M.R.C.S. (Eng.)

*Medical Officer In-charge, Rai Bahadur Amar Nath Tuberculosis Institute, Mayo Hospital, Lahore*

Air embolism is a very rare but a very serious complication of artificial pneumothorax treatment. It occurs most frequently during the induction of pneumothorax, though cases have been recorded in which it occurred during a refill by the needle entering and tearing an adhesion. There are four possible methods by which air may enter the blood stream and cause embolism :—

(1) Air may be injected into a pulmonary vein owing to faulty technique.

(2) Air may be sucked into a pulmonary vein from the tubes and the manometer, there being negative pressure in these venous channels.

(3) The production of an air pocket under pressure may tear a recent adhesion and open up a venous channel in it, which may absorb the injected air. In such a case embolism may occur some time after the induction.

(4) If the needle should penetrate an adherent lung, the movement of the lung, with respiration, across the needle point might cause the needle to open a venous channel to the air of an alveolus or a bronchiole, from which, if it keeps open long enough, it may absorb large quantities of air.

Air embolism, though the most dangerous complication of artificial pneumothorax treatment (AP), is so rare, that we suggest the advisability of different workers recording the details of all cases of air embolism so that it may be possible ultimately to establish which of the above is the commonest cause. Only a proper comprehension of the causes will lead to the devising of proper methods to check this serious complication. The following case, which clearly illustrates what the cause was in this particular patient, is being published with this intention. This is the first case that we have had during the last four years during which period some thousands of AP fills, including some hundreds of primary fills, were given :—

A female, about 40 years of age, was admitted into the tuberculosis wards as a case of pulmonary tuberculosis. Artificial pneumothorax had been started on her left side at some other centre. An x-ray skiagram of the chest however revealed that the disease was bilateral, involving the whole of the upper lobe on the left side, and showing many foci of infiltration in the right upper and middle lobes.

It was decided to keep a selective collapse on the left side but also start a collapse by AP on the right side, and then maintain a bilateral selective collapse. However, before this could be done, she developed a small quantity of pleural effusion on the right side, and a high temperature as a result. After the acute stage passed off, it was decided to withdraw the effusion and replace it by air. Only a few ounces of clear fluid could be removed, but a needle passed a few interspaces above, showed the pleural cavity to be adherent there and no air was given. Next morning an attempt at AP was made again. After properly anesthetizing the tissues by 1 per cent novocaine, the pneumothorax needle was passed. The manometer failed to show any movement, and we were going to take out the needle, when the patient began to shout and cry aloud that something serious had happened. The needle was at once taken out. No air had been given because there had been no movement of the manometer. The patient continued crying aloud, and complaining of tingling and numbness all over the body, but more on the right side. She expectorated about one ounce of bright red frothy blood immediately after the needle was taken out.

As the patient was known to be very hysterical, it was at first thought that she had developed a hysterical fit. She however soon became semi-conscious, could not recognize anybody, and tossed about continuously in her bed. An examination of the nervous system revealed an exaggeration of deep reflexes all over the body, a positive extensor plantar response on the left side, and loss of abdominal jerks on the left side. It became clear by now that air embolism had occurred involving probably the cortical area on the right side. Examination of the heart revealed no abnormality in the sounds.

She gradually became completely comatose and began to show signs of complete hemiplegia on the left side. The face was drawn to the right side, both the pupils were dilated; the left was wider and completely inactive to light reflex and while she showed occasional automatic movements of the right side, the left side was completely immobile and flaccid.

This state of affairs lasted for many hours. The next morning she was found to be slightly better. The pupils were less dilated and both were reacting to light. She was partially conscious. The left side was still paralysed, but no longer flaccid. The knee and the ankle jerks on this side were exaggerated and the plantar response was extensor. She however soon became restless and violent, tossed about in her bed, was delirious and talked incoherently all the time. The physical signs remained unchanged. This state lasted

for three days. During this period there was complete insomnia and the ordinary hypnotics failed to give any relief. On the third night, the house physician on night duty gave her a dose of chloral hydrate at about 9 p.m. and 3ii of paraldehyde per rectum at midnight. As both these failed, he gave 1/6th gr. of morphin at 4 a.m. She went to sleep at about 12 noon, continued sleeping till about 4 a.m. next morning and woke up quite calm, and in her senses. The paralysis began to pass off gradually and had almost completely disappeared in another four or five days.

The case is obviously one of air embolism—probably involving the cortical area on the right side, though exact localization was not possible, as so long as the delirious state lasted complete examination of the nervous system could not be done. This case, however, presents certain peculiar features. No air was given and hæmoptysis occurred at the start of the symptoms. It may be argued that there might have been some sucking of the air from the tubes and the manometer by some pulmonary vein. In that case there should have been some movement of the manometer, but there was none. Hæmoptysis however gives the clue. It seems that the needle passed into the lung substance, ruptured some pulmonary vein, and the open vein, owing to the negative pressure in it, absorbed large amounts of air from the ruptured lung alveoli or bronchioles. Many workers have put forward the view that this is the predominant if not the sole cause of air embolism in artificial pneumothorax cases. This case proves that this is certainly one of the causes. This fact is, in our opinion, of practical significance in one important aspect. If this view of air embolism be accepted, we should use even for primary fills thin needles rather than the usual thick blunt needles, so that the tear in the vein when it does occur may not keep open. Moreover, there would be no use employing special gases like oxygen or carbon dioxide for the primary fills as is the practice in some centres.

#### A CASE OF ABDOMINAL PREGNANCY

By (Mrs.) S. MOZUMDAR, M.B. (Cal.), F.R.C.S. (Eng.)  
Superintendent, Zenana Hospital, Jammu,  
Kashmir State

A PATIENT was admitted into the hospital on 6th April, 1940, for an abdominal tumour. The history was that about 13 months ago she thought she became pregnant and had all the signs and symptoms of pregnancy to the end of full nine months. She seemed absolutely certain on the point of foetal movements, but not much faith was put on her statements, as so often the observations of these village women are inaccurate and therefore misleading. At the end of nine months, when nothing happened, she went to a hakim who gave her some 'strong' medicine and her abdomen started shrinking. From the size of a full-term pregnancy, the tumour had reduced to that of

about seven months. But finding that it did not reduce any further, she sought the aid of the hospital.

**Examination.**—The patient was of an average build, middle-aged, had six children, was slightly anæmic, and debilitated. There was a hard, painless, lobulated tumour in the abdomen, rising well above the umbilicus; a much larger lobe on the right side, separated by a groove from a smaller lump on the left. The mobility was fair but not too free. There was no thrill and no sign of inflammatory trouble. The tumour was taken to be a uterine fibroid, with a possible left parovarian cyst added on (the left lump was in fact a parovarian mass, as it turned out on operation). The patient having agreed to a laparotomy, I opened the abdomen under spinal anaesthesia on 18th April. Directly on opening the peritoneal cavity, I found some dark reddish-green fluid in the abdomen, and a fully-formed full-term foetus lying free in the abdomen. The larger right lobe of the tumour was the curled up and twisted foetus, and the left lump was the rolled up, smoothed-out placenta, implanted on the original site of ruptured left fallopian tube. The fimbriated end of this tube was clearly seen while examining the specimen after the operation, so that it was not a case of tubal abortion—but one of tubal rupture, as the placental mass was implanted about midway down the length of the left tube. The ovary also was intact on this side; the whole foetus, with cord and, this implanted placenta, was removed *en bloc* by resection of the left tube near the uterine end. Fortunately, in this case, the placental implantation was on a small compact smooth surface—and was not adherent to any other organ in the abdomen, which is so often the case, leading to severe hæmorrhage on trying to remove the placenta.

The patient made an uneventful recovery.

The interesting part of the case is the very correct and accurate history given by the patient, which was not taken seriously by us as so often their histories are misleading, specially with regard to pregnancy and foetal movements.

During convalescence, the patient was questioned again regarding the pain, etc., during the time of the tubal rupture—but it was all negative. Evidently, here was a case of very gradual stretching of the tube and escape of the foetus into the abdomen in a 'genteel' manner, without any of the violent symptoms of an acute abdomen.

The patient left the hospital on the 26th day.

#### A CASE OF SELF-OPERATION FOR VENTRAL HERNIA

By M. M. D. CHUGHITAI, M.B., B.S., M.R.C.S., L.R.C.P.,  
L.M., D.T.M. & H., D.P.H., D.O.M.S.

Divisional Medical Officer, North-Western Railway,  
Quetta

A PATIENT, Anglo-Indian male, apparently intelligent, aged about 48 years, a railway shed man, was brought to hospital for admission on 6th June, 1940.

**History.**—The patient had had a ventral hernia about the size of a big orange for the past six years. On 2nd June, 1940, he cut the protruding part with a sharp pair of scissors, sutured the skin with an ordinary needle and thread, and carried on his usual routine of life. He stated that he sterilized the instruments by boiling and washing his hands. On the morning of 6th June, presuming that the wound had healed, he took out the stitches. Soon after, he had a fit of coughing and the wound gave way. A part of the intestines gushed out but he kept them back with the pressure of his hands.

**Condition on examination.**—There was a transverse wound about 4 inches in length through all the layers including the parietal peritoneum at the level of the umbilicus and nearly half of the small intestines was protruding out of the abdomen. General condition of the patient, however, was fairly satisfactory. The gut remained exposed for about 15 minutes.

*Treatment.*—The patient was immediately anesthetized and the gut pushed back into the abdomen with great difficulty. The peritoneal cavity was closed. The two recti were approximated and sutured, and the abdominal wall closed. Drainage was maintained through a small tube which was removed after 48 hours. The patient developed slight temperature which was suspected to be due to sepsis and was accordingly treated with Baeteramide injections.

The patient was discharged after three weeks and is doing his usual duties with a protective bandage.

I am indebted to Dr. S. C. Chatterjee, Chief Medical and Health Officer, North-Western Railway, Lahore, for giving me valuable suggestions and permission to publish these notes.

## DEVELOPMENT OF SOME FEMALE SECONDARY SEX CHARACTERS IN AN ADULT MALE

By P. N. GHOSE, M.B.

Medical Officer, Kanknarrah Jute Mills, Kankinara

Mr. X, Hindu, male, aged 24 years, married at 18 years and had got a male child of 2½ years age. He says at 21 years of age, i.e., about three years ago, his breasts started to develop, and at present they are fairly big in size. The lumps inside get periodically swollen and become painful, but there is no secretion up till now. He says since his breasts started developing his voice is becoming sharper, and his penis and testicles are getting smaller. His sexual desire is intact all along.

On examination Mr. X looks a thin-built young man, with a narrow chest and a rather broad pubis,

with scanty development of hair on his face. His voice is rather sharp and more like a female than an adult male. His breasts are fairly big in size. The left one is bigger than the right. There are dark pigmented areola with thick pigmented nipples. On palpation there are definite glands with ducts and they are tender on pressure.

The external genitals are those of an adult male type. The two testicles with cords are there. The penis and the testicles are rather smaller than the average size. There is no

abnormal opening anywhere around the perineum.

The case is under observation for further development.

## AN UNUSUAL CASE OF ANAPHYLAXIS

By R. M. LLOYD STILL

MAJOR, I.M.S.

Civil Surgeon, Myitkyina, Rangoon

and

B. BHATTACHARJEE, M.B., B.S. (Rangoon)

Civil Assistant Surgeon, Myitkyina, Rangoon, Burma

On 25th November, 1939, one Dr. A received an injection of anti-tetanic serum 500 units, for a

shoe-nail bite on his heel. Almost at once he developed the following symptoms and signs:—

(1) *Symptoms.*—Severe constricting pain across the chest, inability to breathe properly and giddiness.

(2) *Signs.*—Cyanosis of the face, urticarial eruptions all over the body and weak pulse leading to a complete collapse.

Realizing that he was having an attack of severe serum sickness, adrenalin 1/1,000 1 c.cm. was given subcutaneously and artificial respiration was carried out for a short time. He recovered from the acute symptoms within half an hour but felt very weak and giddy. This feeling of constriction across the chest continued throughout the day but with diminished severity. He was given calcium lactate gr. x, three times a day. He passed a restless night.

On 26th November he complained of distension of his upper abdomen with feeling of nausea and belching. He gave himself a double dose of Seidlitz powder to relieve his distension. During the course of the day he did not pass a motion or any flatus and there was no relief of his abdominal distension. A turpentine enema was given with no result. By the evening the distension was accompanied with severe colicky pain in the upper abdomen. Pituitrin 0.5 c.cm. gave him no relief and morphia ¼ gr. with atropine was given to relieve him and induce sleep.

On 27th November he was transferred to the civil hospital, Myitkyina.

He was a well-nourished man of 28 years.

*Past history.*—(a) Two years ago when he had received an injection of anti-tetanic serum, he had an attack of urticaria which had yielded to treatment with adrenalin.

(b) History of amoebic dysentery when he was a student. During that time had had a full course of emetine.

A complete physical examination was done on admission and the findings were as follows:—

Pulse—104 per minute, temperature—100°F., respiration—26 per minute. No anæmia, no jaundice, no enlargement of glands. Tongue—coated, furred but moist. Gum and teeth—normal. Abdomen: Inspection—moderate distension of upper abdomen. Moves freely with respiration. Palpation—no definite rigidity was present anywhere but tenderness and guarding of the muscles on deep pressure were discovered in both the hypochondriac areas. There was no localization of tenderness.

Liver and spleen were not palpable.

Percussion—tympanitic resonance found all over abdomen. Auscultation—intestinal gurgling noises could be heard in all the four areas of the abdomen. Heart and lungs—nothing abnormal detected. Jerks and superficial reflexes were normal. Rectal examination showed no tenderness in the appendicular area.

The following treatments were given:—

(1) Pituitrin 0.5 c.cm. was injected and half an hour after a flatus tube was passed. There was no result. A turpentine enema was given with return of clear fluid and no result.

(2) He was placed in Fowler's position and turpentine stupes were given four hourly.

The pulse rate, temperature and the rate of respiration were recorded hourly.

The following examinations were done that day:—

(1) Blood for malaria parasites, with negative result.  
(2) Blood for total and differential counts with the result: Polymorphonuclears—87 per cent, lymphocytes—8 per cent, large mononuclears—4 per cent, eosinophils—1 per cent, basophils—nil.

Total white blood corpuscles—12,000 per c.mm.

In the afternoon the distension was causing him intense discomfort and pain and he became very restless. The pulse went up to 118 per minute, respiration 28 and temperature 101°F. A stomach wash with sodi bicarbonate a drachm to a pint was given with immediate relief. It may be mentioned here that from the 25th the patient had taken nothing by mouth and therefore rectal saline with glucose was given every four hours since admission.

The relief after the stomach wash was only temporary because by 8 p.m. in the evening he again complained of distension. The distension again became most distressing and in the early hours of the 28th he begged to be given a stomach wash to relieve him.

Our diagnosis was one of either acute cholecystitis or acute pancreatitis, and surgical interference was considered but did not appear justified. We decided to call a surgeon in consultation. He agreed that a laparotomy was not justifiable.

On the 28th the stools were examined and found to contain Charcot-Leyden crystals. A course of emetine was commenced. Urine was examined and nothing abnormal was detected except a trace of albumin.

The temperature on the 28th morning was 99.4°F., pulse 102, respiration 24. During the course of the day, temperature and pulse remained steady. The day passed in a similar manner, i.e., severe distension of the upper abdomen, relieved temporarily by stomach wash and this was done three times during the day.

A carminative mixture was given three times a day and pituitrin 0.5 c.cm. twice daily. Calcium gluconate 10 per cent was injected intramuscularly once only. He took a little ovaltine and a few sips of beef tea. Paraldehyde was given at night to induce sleep but with no effect.

On the 29th his condition was similar except that tenderness of the abdomen was localized to the gall-bladder area, but Murphy's sign was not positive. He still complained of a colicky pain starting from the right hypochondriac region and passing across the upper abdomen ending somewhere near the splenic area. The temperature went up to 102°F., pulse to 120 per minute and he showed signs of exhaustion. Urotropine grs. 10 was added to the mixture. Bismuth salicylate was given in  $\frac{1}{2}$  drachm dose three times a day and ephedrine sulph. was given in  $\frac{1}{2}$  gr. dose. Nothing gave him any real relief except the stomach wash. This too was for only a few hours giving way to severe distension, agonizing pain and restlessness.

On the 30th certain signs appeared which supported our diagnosis of acute cholecystitis, e.g., icteric tinge of conjunctiva, presence of bile in the urine and definite tenderness in the gall-bladder area, where a lump was felt. Morning temperature came down to 99°F. and maximum during the day rose to 102°F. Pulse was between 104 and 120 per minute. We then gave fractional doses of calomel and olive oil an ounce at night.

But till the early morning of 1st December stomach wash had to be carried on as frequently as before and he craved for it.

On the 1st December his condition showed signs of definite improvement. The colic had disappeared and no stomach wash was required. Although the distension was still present it was no longer causing him much discomfort. The icteric tinge of the eye became more pronounced. He was put on the following diet:—

Coffee, barley-sugar, glucose water, Bovril, chicken broth and a small quantity of Benger's food. The maximum temperature was 101.4°F. He passed a lot of flatus and also had a few motions without enema.

From the 2nd December the condition progressed rapidly towards recovery and he was treated mainly as acute cholecystitis.

### Comments

The case has been described in detail as this is the first of its kind encountered by the writers and no mention could be found in any textbook.

In the *Indian Medical Gazette* of November 1939, mention has been made of serum sensitivity in families, but no such family history is forthcoming in this case.

The patient is now well and at work but states that he is unable to take any fatty food.

The final diagnosis of acute cholecystitis was of course not difficult. The problem concerns

the aetiology and pathology. Our suggestion is that there was an allergic condition causing swelling and hyperæmia of the whole intestinal tract which eventually settled in the gall bladder giving rise to the signs and symptoms mentioned.

### A CASE OF DUODENAL OBSTRUCTION

By RICHARD E. STRAIN, M.C.P.&S., M.C.C., M.D.

*Miraj Medical Centre, Miraj, India*

A WOMAN, 35 years old, was admitted to the Miraj Medical Centre complaining of sudden onset of severe pain in the right lumbar region eleven days previously; onset was noted at 4 p.m., after a big meal and while the patient was urinating. Pain was localized and so severe that the patient was carried home immediately and remained in bed until admission into the hospital. At 10 p.m. vomiting was first noted; vomitus was bile-coloured and contained only food particles. Vomiting had persisted until admission—no hæmatemesis noted. Vomiting was promptly initiated by taking food or fluids by mouth and was associated with cramping pain in the epigastrium preceded by visible, palpable, and audible peristalsis. Several bowel movements without mæna occurred after onset, the patient having had a bowel movement the day of admission described as small and hard. Dysuria without hæmaturia and associated with nocturia (two to three times) had been present several months. No chills, fever, injury, or history of digestive distress was obtainable.

Physical examination disclosed a woman with dry skin and tongue. Temperature—97.6; pulse—116; respirations—20; blood pressure—116/70. Pyorrhœa was marked. Chest, heart and lungs were normal.

On inspection the abdomen disclosed a narrow sub-costal angle below which fleeting peristalsis was visible. After drinking two teaspoonfuls of water, this was immediately markedly exaggerated; the movement being from the left costal margin to the right. When the wave reached the right costal margin, gurgling was heard without the use of the stethoscope. No distension was noted. Palpation disclosed extreme rigidity of the right lumbar region extending anteriorly almost to the mid-line of the abdomen. Some spasm and rebound tenderness was noted in the right lower quadrant. A flat note to percussion was noted over the lateral portion of the right upper quadrant and down the lateral side of the right lower quadrant. No definite masses were palpable.

It was thought that the patient was suffering from a perforated ulcer (localized) with some spread down the para-colic gutter and associated with partial obstruction of the duodenum or a peri-renal collection causing obstruction—the exact nature of this being uncertain.

Laboratory examination disclosed: hæmoglobin—58 per cent (14.5 gm. as 100 per cent); red cells—4,710,000; leucocytes—26,400; differential count: polymorphonuclears—90 per cent of which 20 per cent were young non-segmented or 'stab' cells; 10 per cent lymphocytes. Catheterized urine—reaction alkaline; specific gravity—1.005; albumin—one plus (basis of one to four); sugar—negative; leucocytes—four plus; red cells—one plus.

Glucose intravenously and by proctodysis was given; duodenal intubation was started; a transfusion of 400 c.cm. of citrated blood was given. Mouth hygiene consisting of saline mouth washes alternating with Dobell's solution were started at once as a foul mouth was noted. A 'flat plate' x-ray of the abdomen disclosed only increased density in the right upper quadrant.

The following morning the right lower quadrant was quite rigid; a doughy irregular mass was palpable, thought to be matted intestines, over the pubic bone and into the right lower quadrant extending to the umbilicus. Blood urea was reported at 152 mg. per 100 c.cm.; Kahn test was negative. It was thought the process was spreading, possibly owing to increased tension and gangrene, so operation was decided upon. Because of the marked lumbar rigidity and to keep from contamination of the general peritoneal cavity, the incision was placed far laterally in the right upper quadrant.

Under local anaesthesia the peritoneal cavity was opened and normal small bowel displaced. The colon was not seen. No free fluid was present. On displacing the small bowel at the mid-line and apparently just below the greater curvature of the stomach there was a black, gangrenous mass about five inches in diameter with numerous soft spots felt. A hand could be inserted posteriorly part of the way round the mass but it seemed continuous with the vertebral column. As it seemed cystic, aspiration was attempted and 2 c.cm. of dark blood was obtained. The mass was incised and two handfuls of old blood removed. Nothing could be felt in the cavity except an irregular lining wall. A drain was inserted in the area it being thought the patient had had a pancreatic hæmorrhage or a ruptured posterior ulcer, although the pylorus felt normal as far as one could judge.

Post-operatively the patient responded well; the temperature reached a peak of 99.2°F. the first 24 hours and remained normal the second 24 hours. Blood urea was reported at 160 despite a fluid intake of over 3,500 c.cm. of glucose and saline daily with a urinary output of 1,200 c.cm. The third post-operative day the afternoon temperature rose to 102; slight swelling and pain was noted over the left parotid which increased rapidly and markedly. Lugol's solution was started, 20 minims every two hours, after the technique of Leithauser and Cantor (1940) who report 23 consecutive cases so treated without a death. Despite aspiration and Lugol's solution, the patient died five days after operation and three days after the onset of parotitis.

Permission was secured for abdominal post-mortem examination. The drain inserted in the mass was well walled off by omentum and small bowel. The remainder of the abdomen was clear. The cæcum was found in the left lower quadrant—the ascending colon going to the splenic flexure; turning back upon itself without obstruction to form the descending colon. The descending duodenum was greatly dilated measuring five inches in diameter. Just medial to the right kidney was a black mass which was retro-peritoneal and by pressure upon the duodenum (which was quite securely held retro-peritoneally rather far to the right of the mid-line) had produced obstruction. All the peri-renal tissue was quite hæmorrhagic; no pus was encountered; the capsule stripped easily from the kidney; there was no gross evidence of injury or damage to the kidney itself. The renal vessels were completely bound up in a mass of partially organized blood clot a little over four inches in diameter. It was impossible to trace the original course of the renal vessels but it appeared that the original hæmorrhage must have come from one of the renal vessels, as the mass so securely enclosed them and hæmorrhage faded as this area was moved away from. The aorta appeared normal.

The pancreas, liver, and spleen were normal in appearance. The duodenum, when incised, was normal except for the marked dilatation.

This presents an interesting case of duodenal obstruction associated with a congenital anomaly of the colon; the obstruction was caused by a retro-peritoneal hematoma whose origin seems to have been a spontaneous hæmorrhage from one of the renal vessels without gross evidence of injury to the kidney. Death probably was caused by the severe parotitis, as the patient's

abdomen was quite soft without distension and food in small quantities was being taken without discomfort before death.

### PER-RECTUM M.&B. 693 IN A CASE OF PNEUMONIA

By S. R. LOKRE, L.M.P.

*Private Practitioner, Residency Indore, Indore (C. I.)*

A boy aged seven years was suffering from high fever, rapid pulse, hurried respiration, cough with rusty sputum, and pain in the chest. Bacteriological examination of the sputum was not practicable but clinically the signs confirmed it to be a case of pneumonia in which the whole right lung was involved.

A mixture containing liquor ammonium acetatis, sodium citrate, sodium bicarbonate, aromatic spirits of ammonia, tincture digitalis, brandy, syrup tolu, and water was given four times a day. Along with this one tablet of M.&B. 693 suspended in a little water was ordered an hour after the dose but it was not retained. I tried it in milk, but the patient vomited it again. Next I tried M.&B. 693 with a nicotinic acid tablet and gave them as a paste in honey but the combination did not agree with the patient and he vomited.

Next day the patient became semiconscious and showed signs of meningism which induced me to give M.&B. 693 per rectum. I dissolved two tablets of M.&B. 693 in one ounce of milk and gave it per rectum morning and evening. They were retained. For three consecutive days I continued the process as he tolerated the drug well when given per rectum. Combined injections of transpulmin 1 c.cm., redoxon 1 c.cm. and cardiazol-ephedrin m. 5 orally were also given last thing at night.

On the fifth day with this line of treatment his temperature, respiration, and pulse settled and congestion of the lung cleared. Thereafter the patient made an uneventful recovery.

The case is reported so that others may be induced to use the rectal route when the patient is unconscious and oral administration causes vomiting.

### SUB-LINGUAL GLAND CALCULI

By KAMAL NAIN, L.T.M., I.M.D.

*Shahpur City*

A MOHAMMEDAN female aged about 45 years, thin, came to me with a sub-lingual swelling and pain. Its duration was 15 to 20 days. She had a feeling of discomfort and pain on touch and pressure.

*Examination.*—There was a swelling about half an inch from the lower surface of mouth on the inner side of the cheek towards the anterior part. It was semi-soft and had a feel like an abscess. I gave her some gargle and advised her to come the next day. She felt discomfort and pain and had the swelling opened at a hospital and felt better after the tension was relieved. After three days she again came to me and wanted me to examine her as she was still getting pain. I saw a white spot in the wound and seized it with forceps and a hard nodular stone about an inch long came out. I made a thorough search and found another of similar size. After that the wound quickly healed up.

# WHY AGAROL FOR CONSTIPATION ?

Among the therapeutic measures advocated for overcoming constipation, none has proved more consistently successful than AGAROL—the original emulsion of mineral oil and agar-agar with phenolphthalein.

Agarol renders the fæcal mass plastic and pliable with unabsorbable moisture. It lubricates the intestinal

tract and gently stimulates peristalsis, ensuring an easy and complete evacuation.

Used over a reasonable period, Agarol gradually restores muscular tone and functional activity of the bowel, with the gratifying assurance that natural evacuation will follow without the need for further medication.

# MANDECAL

(Compound Calcium Mandelate B.D.H.)

## IN URINARY INFECTIONS

Mandecal is of the utmost value in the treatment of urinary infections particularly when sulphanilamide is

- (a) ineffective—as in streptococcus faecalis infection,
- (b) contra-indicated—as in anæmia and marked debility,
- (c) unacceptable—as in fastidious or hypersensitive patients.

Collateral administration of acidifying agents is unnecessary when Mandecal is employed, and gastric disturbances are rarely produced.

## B.D.H. CHEMOTHERAPEUTIC PRODUCTS of established value

### S.U.P. 36

S.U.P. 36 is of marked value in the treatment of various infections characterised by pyrexia, particularly those affecting the respiratory system, such as the common cold, influenza and pneumonia. It effects an immediate reduction in temperature and reduces the period of incapacity to one half. S.U.P. 36 is issued in solution in ampoules for intramuscular injection.

### MANGANESE BUTYRATE B.D.H.

Manganese Butyrate B.D.H. is used primarily for the treatment of furunculosis, carbuncles, erysipelas, boils, whitlows and ulcers. It is of value also in acute complications of gonorrhœa caused by secondary micro-organisms.

### CONTRAMINE

Contramine is used in the chronic stages of disease such as rheumatic conditions, gonococcal infections and in chronic metallic intoxications. Contramine is normally administered as a solution by intramuscular injection, but it is available also in pessaries for the treatment of gonorrhœa and leucorrhœa in women; Contramine suppositories and bougies are also available.

### THIO-HISTAMINE

Thio-histamine, which consists of histamine in combination with sulphur, is similar to Contramine in pharmacological and therapeutic effects but it is used in the treatment of acute cases of gonococcal and other bacterial infections.

# Indian Medical Gazette

DECEMBER

## THREE QUARTERS OF A CENTURY OF UNINTERRUPTED PUBLICATION

THE present number completes our seventy-fifth volume.

The first number of the *Indian Medical Gazette*, dated January 1866, appeared in a very different world from the present one. In India, Her Majesty's Government had taken over the functions of the East India Company just eight years before, and the Suez canal was nearing completion, but was not officially opened until three years later, so that the early numbers of this journal had to be carried round the Cape before they could be read in England. It is tragic that the later numbers of our seventy-fifth volume should once more have to travel the same way—but for a very different reason.

### *Medical Science, 1866 to 1940*

The scientific world has undergone even greater changes since our first number saw the light of day. In 1866, Darwin's *Origin of Species* had been published only seven years, antiseptic surgery was still unknown, and Pasteur had just finished his famous *Études sur le vin*, was investigating the silkworm disease that was threatening the silk industry of France, and had not yet turned his attention to human disease. Cholera was raging in Europe, whither it had travelled overland via Egypt; the opening of the canal a few years later provided a more direct route for epidemics of this mysterious disease—mysterious in that its cause was not discovered until nearly 20 years later; subsequent epidemics took only a few months to reach Europe from their home in India, but international quarantine regulations, based on our knowledge of the cause of the disease, have changed this channel of infection into a veritable filter which protects Europe and western countries, not only from cholera but from many other epidemic diseases. The next year, 1867, Lister introduced antiseptic surgery and in this branch of medical science a new era began. An event which went largely unnoticed at the time, for its repercussions in tropical medicine could not be anticipated, occurred in 1874 when Ehrlich introduced the dried stained blood smear; six years later Laveran demonstrated the malarial parasite, but thirty-one volumes of the *Indian Medical Gazette* had been published before Ross discovered pigmented bodies (oöcysts) in two 'fawn coloured' mosquitoes (anopheles) in the small laboratory in the grounds of the Presidency General Hospital in Calcutta (September number, 1897). But meanwhile, other things had been happening; in 1873 Obermeier discovered

the spirillum of relapsing fever, in 1880, Eberth isolated the typhoid bacillus and Evans—an Anglo-Indian veterinarian—discovered the trypanosome of surra, in 1882, Koch, who six years earlier had cultivated anthrax in artificial medium, discovered the tubercle bacillus, and in the following year the cholera vibrio, and in the same year Klebs discovered the diphtheria bacillus. In 1887, Bruce discovered the causative organism of Malta fever, in 1894, Kitasato the plague bacillus, and in 1897 Shiga the bacillus of dysentery. During this period Manson was working out the cause and method of transmission of filariasis, and his inspiration and suggestions undoubtedly led up to Ross's great discovery. The next century opened with the discovery of the trypanosome as the cause of sleeping sickness, and leishmania as the cause of kala-azar and oriental sore, although an unmistakable Leishman-Donovan body had been depicted in an article in the *Indian Medical Gazette* of 1885 by Cunningham who described it as the probable causative agent of the latter disease, and in 1905 Schaudinn discovered the treponema of syphilis.

The first 40 years of the life of the *Indian Medical Gazette* constituted a great age of parasitological discovery; the subsequent period saw possibly even greater advances in a variety of directions. In 1910, chemotherapy was virtually born with Ehrlich's discovery of salvarsan as an anti-syphilitic remedy. Its early triumphs were mostly in tropical medicine; although Germany had lost her colonies, paradoxically her chemists enjoyed an almost complete monopoly and at the conclusion of the 1914-1918 war a flood of synthetic preparations was released from the big German chemical factories; amongst the most successful of these were Hans Schmidt's series of pentavalent antimonials used from 1918 onwards, with such dramatic results in the treatment of the hitherto fatal kala-azar, and Bayer 205 which though over-heralded has taken an important place in the treatment of human trypanosomiasis and a more important one in that of cattle. In 1926, plasmochin appeared and four years later atebirin, the first synthetic compound that could be used in the place of quinine in the treatment of malaria (the first published report of its clinical use appeared in the *Indian Medical Gazette*, April 1932); finally in 1935, the sulphanilamide group of preparations, which were led by Domagk's 'prontosil', brought this chemotherapeutic era to what one feels, must be its crescendo, though the crescendo is still being held. Even before the war, the British and American chemists seem at last to have begun to take the initiative, and during the last few years many of the most valuable preparations have been of British origin, so that we are not handicapped in 1940 as we were in 1914.

Two other branches of medical science, endocrinology and radiology, came into being, as

such, during the latter half of the journal's career, though foreshadowed in its earlier days, by the work of Claude Bernard (1813-1878) and Brown-Sequard (1817-1894) who formulated the theory of internal secretions, and in 1895 by Röntgen's discovery of x-rays. Both have made steady and at times dramatic advances throughout this period.

Finally, at the very beginning of the century, the vitamin theory was originated by Hopkins (1906) and given more definite form in 1912 by Funk. From the original three, A, B and C, the vitamins have multiplied like the traditional rabbit; vitamin D was identified in 1920, vitamin E in 1922, and since then the early vitamins have been divided and subdivided, and entirely independent ones have been added, so that they number far more than the 26 letters of the alphabet, even if the orderly labelling had been maintained. This discovery of the vitamins was not only in itself of the greatest importance, but it has had a most stimulating effect in our attitude towards that fundamental medical science, dietetics, which during the 'parasitological era' was tending to be neglected. Most of the early vitamins have been chemically identified and many have been synthesized, as also have many of the endocrines, so that if the first half of this journal's life was spent in a parasitological era, the second half must be called an era of chemistry.

#### *Early Contributors*

All these great advances and sweeping changes in medical science will be found reflected month by month in the *Indian Medical Gazette*, whilst in many instances the first announcement of an important discovery was made in its pages; in fact a very fair history of not only tropical, but modern medicine as a whole, could be written from a careful study of these seventy-five volumes. We have not made any such detailed study, but a perusal of the early volumes shows that most of India's famous medical scientists, and these have been not a few, have used the *Indian Medical Gazette* as their mouthpiece; these include such men as Vandyke Carter, Norman Chevers, Sir Joseph Fayrer and D. D. Cunningham, to mention some of the earlier ones, but the journal numbers amongst her contributors others besides those who had adopted India as their field; for example, in the number for February 1872 there is a letter from Charles Darwin commenting on a paper that had appeared a few months earlier. To Sir Ronald Ross's contributions we have already referred. Sir Leonard Rogers was an early and regular contributor. The original papers on all his important work on kala-azar, emetine in amœbic dysentery, and intravenous saline in cholera will be found here. The earliest contribution we have found was 'on the use of calcium chloride to lessen hæmorrhage during operation with an illustrative case' in the May number, 1896, and his last, on epidemic forecasts, in March 1933,

37 years later. Another famous medical scientist, also fortunately still living, who was a frequent contributor, is Sir Robert McCarri-son; his first paper appeared in April 1903.

#### *Medical Publications in India*

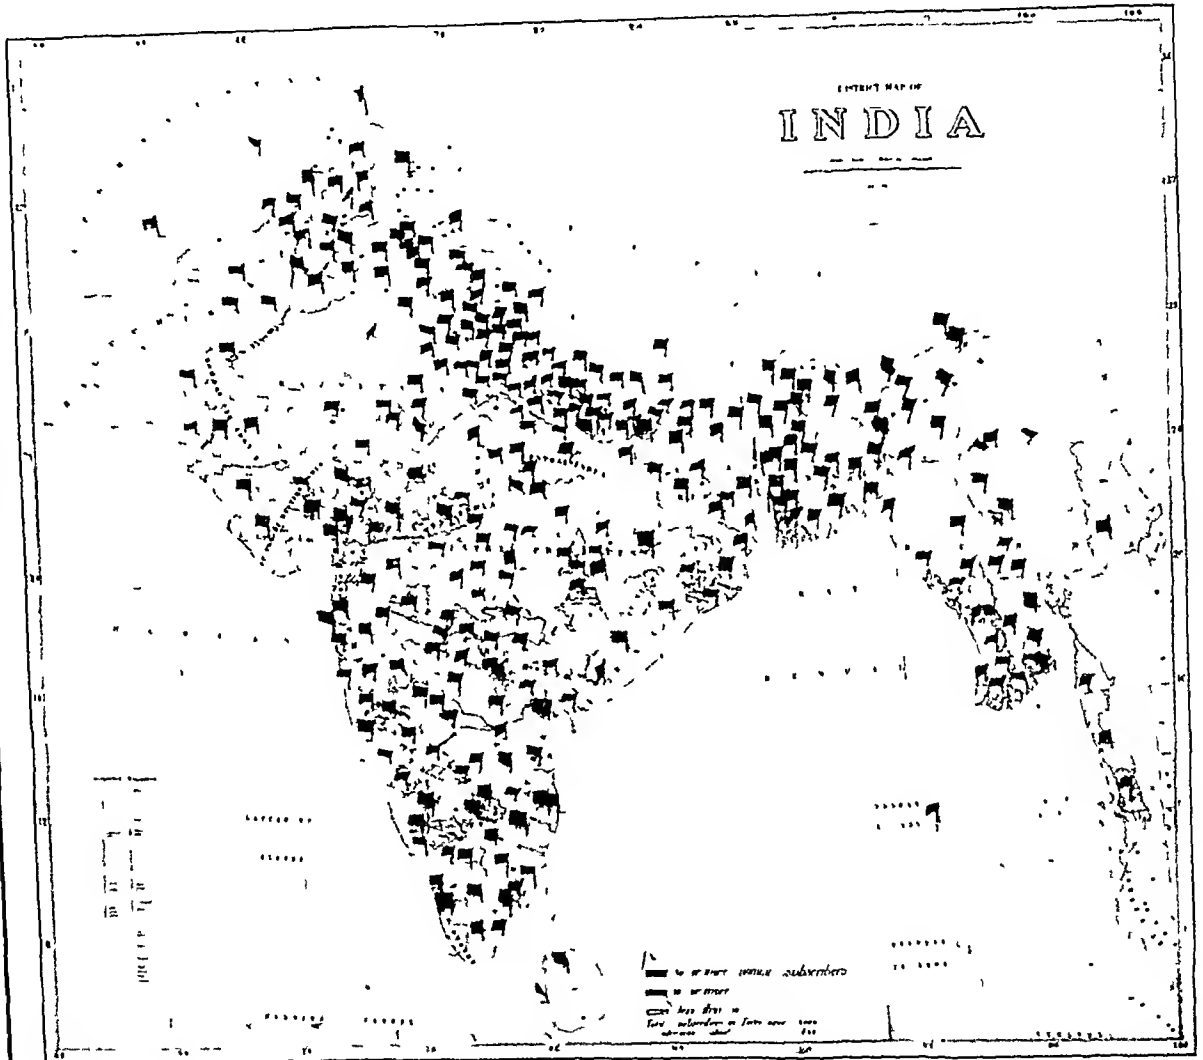

In 1866, medical publication in India was not in a very flourishing state, though it was by no means in its infancy, for in 1825 the *Transactions of the Medical and Physical Society of Calcutta* was published (by Messrs. Thacker & Co.) at first annually, then biennially, for a short time quarterly, and later irregularly, until 1845. The *Transactions* of a similarly-named Bombay society was first published in 1838 and maintained publication for at least 50 years; according to Crawford (*History of the Indian Medical Service*) it was still being published in 1914, but we can trace no volumes since 1889, and even up to that date it had obviously not appeared very regularly. Many other medical and scientific journals were published and enjoyed careers of various length, usually short; others were announced but did not appear. An exception appears to have been the *Indian Annals of Medical Science*, latterly published by Thacker, Spink & Co., which ran for 23 years from 1854 to 1877 and overlapped the *Indian Medical Gazette* by 11 years.

In its early days, the *Indian Medical Gazette* had no serious rivals and it can claim not only to be the oldest journal in India that has maintained monthly, or even regular, publications up to the present day, but to be the oldest such medical journal in the Eastern hemisphere. Crawford, in his book referred to above, said 'the *Gazette* has been the most successful and most important medical journal issued in India' and 'now after 47 years it shows every sign of a vigorous future career'. To-day, 28 years later, we believe that the same words could well be applied.

In more recent years many other medical journals have come into the field. In 1911, the *Indian Journal of Medical Research* was first published. This has never been in any sense a rival of the *Gazette*, but it did relieve the pressure on its space, by publishing many scientific papers which, though not entirely suitable for the general medical reader, naturally claimed the right to appear in India's leading journal.

The *Indian Medical Gazette* is an all-India publication and not in any sense local, not we sincerely believe in its outlook, in its contributors, nor in its circulation. Contributions come from all parts of India, as will be seen by a reference to recent numbers. An analysis of the 'original communications' during the current year, excluding the current number, shows that out of 153 contributions, only 65, or distinctly less than half, came from Bengal, 18 each from Bombay and Madras, 14 from the Punjab, 12 from Indian States, 8 from Assam, and 6 from the United Provinces; other British Indian provinces provided 8, Burma 2, Ceylon

# Distribution Map of INDIAN MEDICAL GAZETTE

Photograph of a map of India which shows the wide circulation of the Indian Medical Gazette. In the original map the flags are coloured, red indicating 50 subscribers and green 10, and numbered; this gives a more accurate idea of the relative number of subscribers in each district, but the figures are not visible in this photograph.

1, and Afghanistan 1. The circulation also is essentially all-India in character, as the accompanying map shows, though it has a quite considerable foreign circulation. Nevertheless, as Calcutta is thirteen hundred miles from Bombay and over a thousand from Madras, to mention two other important medical centres, it is not unnatural that medical men in these provinces should want to have their own journals. The *Antiseptic*, first published in 1904, in Madras, has had a successful career and is still appearing. In Bombay earlier ventures in the way of monthly journals have not been very successful, but seven years ago a fortnightly, the *Medical Bulletin*, appeared and is maintaining a high standard both from a literary and a scientific point of view. In Calcutta, the *Calcutta Medical Journal*, the journal of the Calcutta Medical Club, has had a successful career of 36 years, in its own sphere, as also has the *Journal of the Indian Medical Association*, first published in 1930 as the *Indian Medical World* and under its present name in 1931. An example of a specialist journal is the *Indian Journal of Pediatrics*, a carefully edited and well-printed journal, which has appeared quarterly since 1933, and as time goes on there will be room for many more specialist journals of this type, for the number of good-class contributions that are sent to us is far beyond the capacity of one journal and many have to be refused on grounds other than their scientific quality.

Many other journals of various and varying standards have appeared, and to-day the list of monthly medical journals in India must run into some dozens.

### *The Indian Medical Gazette*

Since it was first published the *Gazette* has probably had its ups and downs, but these are scarcely reflected at all in its pages. It has shown a slow but steady expansion from the beginning; the first half dozen volumes had 20 to 24 pages in each number; in 1873 there were about 28 pages; in 1885 the number rose to 32; from 1895 onwards each number usually had 40 pages and occasionally the number rose to 48, but from the beginning of the century it appeared to fall back slightly to a steady 40, until 1922 when another advance was made to 48 and then to 52 pages; in 1928 the number rose to 60 and in 1936 to 64 pages in each issue. There has never been any suggestion that at any time contributions were difficult to obtain, nor is there any sign of 'padding'. The Indian medical periodicals of the early part of the last century, though scholarly, and often abounding in Latin quotations, usually made dull reading and consisted of little more than a series of case notes, but the *Gazette* introduced a more lively atmosphere. Admittedly case notes were numerous, but they did not predominate, and the *Gazette* was much more of a journal, on the lines of the *British Medical Journal*, its senior by just 25 years, or the

older *Lancet*, than its predecessors in India had been. Changes in character have been slight and have been the direct outcome of a change of scientific environment.

The format of the first number was almost the same as the current one, and the price was Re. 1-8 for a single copy as it is to-day, but the monthly subscription was a little higher. This is not surprising, for as late as 1885 the number of annual subscribers was only 141. The first page was not unnaturally devoted to an introduction stating the aims of the paper. 'Original communications' followed, and in this first number these consisted only of seven case notes on various subjects, e.g., syphilitic cirrhosis, atelectasis pulmonum, and a hermaphrodite, and a statistical statement on the treatment of tetanus in the Medical College, Calcutta. The next communication is headed 'Cases from Practice', in which four cases are reported by one writer; the distinction between this, the previous section, and a later one is not clear. The next page, 6, corresponds to our 'editorial' page and in later numbers comes about the middle of the number, as ours usually does now. The 'editorials' were on 'Professional Co-operation', which was really a request for contributions 'to satisfy the ever-craving appetite of the reading public' (the editor to-day is more troubled by the ever-increasing output of the writing public), on the cholera Congress at Constantinople, in which a demand was made that India should 'send her wise men also', on Indian medical warrants and civil pay, and on Indian ethnology, which included what we should call to-day an *open* letter from Joseph Fayrer to the Council of the Asiatic Society, suggesting an ethnological exhibition. The next section was 'Reports on Hospital Practice' (the word 'Mirror' was introduced in 1872), twelve more case reports and another statistical statement. Under the heading 'Reviews' is a long discussion, which is continued in the next two numbers, on a report on leprosy issued by the Government of India, by C. Macnamara, a frequent contributor and later editor. In this number there were no 'reviews' in the sense in which we use the word now (perhaps wrongly), but in later numbers there is a heading 'Short Notices of Recent Books' which corresponds to the present 'Reviews' section.

The next section is a very interesting one from a contemporary point of view. It is headed 'Pharmacopœia of India'. The opening paragraphs are quoted *in extenso*.

'The profession is doubtless aware that Dr. Waring, of the Madras Medical Service, so well known for the interest which he has always taken in the development of indigenous drugs, and for his invaluable "Manual of Therapeutics", is now in England, engaged on the part of Government, in the preparation of a Pharmacopœia for India. The following lists of Indian medicinal plants have lately been received in this country, and circulated amongst those from whom it is probable that information may be derived. With a view to give [sic] the subject still wider publicity, and

to invite general co-operation, they are now published in these columns. The subject is one, financially and commercially, of the utmost importance. £20,000 are annually expended in the importation of European drugs to India, whilst the country contains effective substitutes, valuable even as simple native preparations, but which, properly prepared, might be obtained at little more than half the cost of the European importation and yield a considerable profit to speculators. To take a single instance, one of many—Gallic acid costs the state 12s. 1½d. a pound. About £80 sterling are expended annually in the supply of 130 pounds weight of the drug, which, if manufactured from mango seed, would cost about eight annas a pound; being Rs. 65, instead of Rs. 800 for the year's requirements.

We venture to indulge the hope that another septennial period will not pass away without our seeing the establishment of large chemical laboratories in each presidency—not mere repositories for the reception and distribution of imported drugs, or for the manufacture of a few tinctures, but pharmaceutical workshops on an extended scale, with highly qualified practical English chemists attached to them—men who would analyse and test the products of the country; and make preparations, of what was valuable, in the most efficient way.

Government might well initiate such a system, leaving it for completion, as they have done tea cultivation, to the enterprise of companies or of individuals. Information is solicited, meanwhile, on the subject of each indigenous product referred to in the two following lists.

Delete the word 'English', change the figures, and this might have been written to-day. Not 7 but 70 years have passed, and we are little nearer this goal.

The first list is headed 'Principal Medicinal Plants, etc., of India', and the second, 'The Medicinal Plants, etc., of India. The Properties of which Appear Deserving of Further Investigation'. There is then a list of indigenous plants prepared by Baboo Kanny Loll Dey, this includes *Plantago ispaghula*, whose medicinal properties are described as 'demulcent and emollient. Employed with best advantage in chronic diarrhoea and dysentery, and in all inflammatory affections of the mucous membrane of the alimentary canal' (*vide* p. 733 of the present number).

The number ends with 'Extracts from European Journals' ('Current Topics' from 1880), and 'Correspondence'. In the second number the journal is obviously finding its feet for in the original communications section the case reports are replaced by original articles—on linear extraction (by C. Macnamara), the pathology and treatment of cholera, the physiological effects of quinine, etc.

Two other paragraphs from the first volume are interesting. C. Macnamara, again, in a paper in which he reports the remarkable efficacy of ipecacuanha in dysentery but complains of its 'nauseous' taste, makes the following suggestion.

'It occurred to me, therefore, that the active principle of ipecacuanha, called emetina, might perhaps be substituted for the powdered root of the plant, in the same way that quinine is given instead of bark. Since last December I have administered emetina in several cases of dysentery, and it appears to exert exactly the same effect as ipecacuanha in controlling the disease; one grain corresponds to about 20 of ipecacuanha, and it

may be administered in the form of pills, or mixed with a little acidulated water.'

In the same number an editorial on cinchona alkaloids contains the following:—

'But the inquiry into medicinal efficacy of Cinchonidine, Quinidine, and Cinchonine, apart from its professional importance, is one of wide and general interest; for it bears very materially upon the extent of the success of Cinchona cultivation in India. If these principles proved to be, as supposed, even *nearly* [original italics] as efficacious as Quinine, the value of the high percentage of alkaloids in the Neilgherry Cinchonas will be considerably enhanced. If, on the other hand, their medicinal action is found to be much inferior, the commercial importance of these cinchonas will necessarily diminish in proportion. The medical officers engaged in this inquiry need hardly therefore be reminded how great a trust is reposed in their hands: upon their verdict will depend the settlement of an important medical and commercial question.'

It has been repeatedly shown that the other cinchona alkaloids are *nearly* as efficacious as quinine, yet the Neilgherry plantations were allowed to fail and the monopoly to go to Java, though the same line of argument has been used again and again in these pages and as recently as June 1938. Medical science has made remarkable advances in the last 75 years, but it has also shown a remarkable tendency to go round in circles; this is particularly the case where its natural progress has been impeded by failure of outside agencies to render it the support which it might legitimately expect.

#### *The Editors and Publishers*

The editors of the *Indian Medical Gazette* from the beginning until a few years ago were all members of the Indian Medical Service, with one exception, W. J. Simpson, Health Officer of Calcutta, who edited the journal alone for 4 years, from 1894 to 1897, though his name appears as editor in association with members of the service from 1889. The last service editor was Robert Knowles, who resigned at the end of 1932, on account of ill health. D. Boyes Smith was the first editor; he was afterwards professor of medicine at the Medical College, Calcutta, and later principal, and when he retired he became professor of military medicine at the Army Medical School, Netley.

Kenneth McLeod became editor in 1871 in association with C. Macnamara; both were apparently dynamic personalities; the former continued to edit the journal for 20 years, and even after his retirement was a regular contributor. Under his editorship the journal flourished and took up an established position in world medical literature from which it has never receded. He was followed by W. J. Simpson, referred to above, and then by W. H. Buchanan (later Sir Walter Buchanan) who except for periods of leave held the editorship for 19 years. After an intermission of 2 years during which David McCay was editor, J. W. D. Megaw (later Sir John Megaw), the director of the School of Tropical Medicine, Calcutta, took over the editorship and the journal entered on another flourishing stage of its career. The

increased demand on its space was met by a change in type and the addition of a number of pages, which necessitated the appointment of an assistant editor, and R. Knowles was appointed in 1923; he succeeded Sir John Megaw in 1928 and was editor until the end of 1932 (v. s.). Since that date, L. Everard Napier, who became assistant editor in 1928, has edited the journal, and P. A. Maplestone has been assistant editor. A list of editors is appended.

At one period the names of associate editors, usually one in Bombay and one in Madras, appeared on the title page of the volume. The object was of course to give the journal a less local character; this manœuvre which was in our opinion not necessary and in practice was never a success, the associate editorship being of necessity purely nominal, was finally dropped in 1922.

The editors have always been men actively engaged in some branch of medical science, but their fields of activity have varied considerably; the first editor, D. Boyes Smith, was a Fellow of the Royal College of Physicians, as is the present one; three others C. R. Francis, D. McCay, and W. J. Simpson have been members. Boyes Smith was a professor of medicine at the Calcutta Medical College, as also was D. McCay; J. W. D. Megaw, who later became Director-General, Indian Medical Service, was professor of tropical medicine at the School of Tropical Medicine, as is the present editor; R. Knowles was the professor of protozoology at this School. Kenneth McLeod, a Fellow of the Royal College of Surgeons of Edinburgh (apparently at the age of 20) and later an Honorary Fellow of the Royal College of Surgeons of England, was professor of surgical anatomy and clinical surgery, and later of surgery at the Medical College; C. Macnamara was professor of ophthalmic surgery and L. A. Waddell, professor of chemistry at the same college. W. J. Buchanan did not hold any academic appointments; he was in the jail department and became Inspector-General of Prisons, Bengal, in 1913 and was later knighted. W. J. Simpson was, as we have said, health officer of Calcutta.

The first sixteen volumes were published by Wyman & Co., the next three by Newman & Co., and in 1835 the *Gazette* was taken over by Messrs. Thacker, Spink & Co., who have published it since. Mr. C. F. Hooper, who was first associated with the *Indian Medical Gazette* in 1891, took over the management early in this century, and did much to improve the journal and expand its subscription list. 7

#### Policy

The *Indian Medical Gazette* has no 'platform', and its only policy is the furtherance of medical science. It does not even claim any special mission in furthering the interests of the practitioners of scientific medicine, though it has these at heart, for we believe that they will further their material interests best by ever advancing their science and perfecting them-

selves in the application of it to the relief of human suffering. Moreover, the interests of different sections of the medical community often appear to be divergent, and it has never been the policy of this journal to further the interest of one particular section of this community, though, from time to time when special injustices appeared to exist or to be imminent, it has felt compelled to protest, but, we believe, never selfishly, for, though most of the editors have been members of the Indian Medical Service, editorial support has usually been given on behalf of the lower grades of the medical services, such as the sub-assistant surgeons. If in the past the rule of avoiding partisanship, or even discussing controversial subjects of a political nature, has occasionally been broken, this has not occurred for many years, and never, we claim, under the present régime.

We have emphasized above that the *Gazette* is an all-India journal and that its contributions come from, and its readers live in, all parts of India; similarly, in the selection and priority of contributions we show no bias in favour of any race or creed, of any service, or of the holders of any particular qualification, for the contributors are Indian, British, and foreign, members of the I.M.S., I.M.D. and provincial services, railway, tea-garden and other industrial medical officers, and private practitioners, and articles by L.M.F.s and F.R.C.P.s, by M.D.s of London, of New York, and of Patna, and, we will add, even to-day, of Hamburg, all appear side by side. If in the past the journal has enjoyed some measure of success, we feel that it is due very largely to this liberal policy.

#### The Future

The last twenty years have seen considerable expansion and all-round improvement in this journal, but we are not content to leave it at that. The success of a journal depends to a great extent on its editors, publishers and printers, but to a greater extent on its contributors and its readers. This journal has a wide circulation, but, with an even wider one, it could afford to add more pages and institute other improvements. This is a matter in which we ask the co-operation of our present subscribers, for their own benefit.

The *Indian Medical Gazette* can look back on 75 years of very useful life, and, if civilization survives the ordeal through which it is now passing, as every omen is favourable, we are confident that the *Gazette* can look forward to a particularly bright future.

#### List of Editors and Assistant Editors of the *Indian Medical Gazette*

- D. B. Smith, 1866.
- J. A. P. Colles, 1867.
- C. R. Francis, 1868.
- J. T. Carter Ross, 1869 to 1870.
- N. C. Macnamara, 1871 to 1873.
- K. McLeod, 1871 to 1892.
- J. G. French, 1876 to 1877.

L. A. Waddell, 1884 to 1885 and 1897 to 1899.  
 W. J. Simpson, 1889 to 1897.  
 A. Crombie, 1892 to 1893.  
 D. M. Moir, 1897 and 1903 to 1904.  
 C. H. Bedford, 1897.  
 F. P. Maynard, 1898.

W. J. Buchanan, 1899 to 1918.  
 D. McCay, 1909 to 1910 and 1919 to 1920.  
 J. W. D. Megaw, 1921 to 1928.  
 R. Knowles, 1923 to 1932.  
 L. E. Napier, 1928 to date.  
 P. A. Maplestone, 1933 to date.

### HÆMATOLOGICAL TECHNIQUE

#### PART VI

By L. EVERARD NAPIER, F.R.C.P. (Lond.)

and

C. R. DAS GUPTA, M.B. (Cal.), D.T.M.

(From the Calcutta School of Tropical Medicine)

#### *The making and staining of blood films*

PROPERLY made and well-stained blood smears are essential for the white cell differential count, the enumeration of the nuclear lobes of neutrophil polymorphonuclears, as in the Arneth and Schilling counts, and also for the determination of the red-cell size by the Price-Jones' method.

For ordinary work blood films are made on 3-by-1-inch glass slides and for special studies on 2-cm.-square coverslip: only new slides and coverslips should be used if this is possible. The slide and the coverslip must be thin, completely transparent, scrupulously clean, and free from grease and dust.

#### *Cleaning glass slides and coverslips*

Place the slides and coverslips in sulphuric-acid-bichromate mixture\* and allow them to remain for twenty-four hours; this mixture should be kept in a large jar for the slides and in a small one for the coverslips. Decant off the cleaning mixture into another similar glass jar, which is then ready for use again. Transfer the slides or coverslips to a shallow enamelled tray or a big petri dish, and place this under a tap for 3 to 4 hours, stirring from time to time with a glass rod. Finally, wash with distilled water, dry with a piece of soft linen, and put them in a jar of absolute alcohol for twenty-four hours (methylated spirit may be used as a substitute). With a pair of forceps take out the slides or coverslips one by one, allow the excess of spirit to drain off, flame in a bunsen or spirit lamp, clean again with soft linen, and store in a dust-proof container—in a slide box for the slides and in a small petri dish for the coverslips. These are now ready for use for all ordinary work.

* Concentrated sulphuric acid	..	500 c.cm.
Potassium bichromate (powdered)	..	100 gm.
Water	..	.. to 1 litre

#### *Polishing the slides*

For special work, polish one side of a slide, cleaned as above, with jewellers' rouge for 2 to 3 minutes, clean with soft linen (selvyt cloth or silk is the best for this purpose), mark the polished side with a glass pencil, and store for future use in a dust-proof container.

#### *A. Spreading the film in the routine use of venous blood*

(i) *On slides.*—Put a few polished slides on a flat surface. With a syringe collect the blood from a vein (*vide* part I). Before putting the blood into the oxalated flask and while the needle is still attached to the syringe, put a small drop of blood on to the middle of the slide, a little away from the end. Apply the thin edge of another slide, with the corners cut off so that the spreading edge is narrower than the slide, or better still of a spreader (hæmocytometer coverslips make excellent spreaders on account of their smooth narrow edge), to the middle of the glass slide, slide it along until it makes contact with the drop of blood which will now spread along the edge of the spreader (slight lateral movement will accelerate this), then with the spreader at an angle of about 30° to 40° to the slide, push the spreader with the blood following it along the slide and raise the spreader abruptly just before the whole drop of blood has been used up. The film should be dried quickly by waving it in the air, or under an electric fan. An ideal film should occupy the middle third of the slide, should be of uniform thickness, should not have any tails, and when viewed under the microscope the red cells should just touch one another and there should not be any rouleau formation anywhere on the slide.

Fig. 1a shows a satisfactory film but with 'tails', and figure 1b a good film with a straight 'leucocytic edge'. They were drawn from above downwards. Figure 2 shows the low-power view of a satisfactory leucocytic edge; the leucocytes are actually discrete though the photograph scarcely gives that impression.

The important points are a perfectly clean slide, a good spreader, and a drop of blood of the right size; this last can only be gauged by trial and error, but, compared with the size of the drop required from a normal individual, a larger drop will be required from an anæmic patient

and a smaller drop from one with polycythemia or leukaemia.

a

Fig. 1.

b

Fig. 2.

(ii) *On coverslips.*—Place a few clean coverslips on a flat even surface. Proceeding as in (i) put a very small drop of blood on the centre of a coverslip; place another clean coverslip of the same size on the top of the drop of blood in such a way that the sides of the two coverslips are not opposed (see figure 3). If the two coverslips are clean, the blood will spread uniformly between them. Now draw apart the coverslips quickly but gently, and dry them quickly by waving them in the air or under an electric fan.

Fig. 3.

### B. From capillary blood from the finger or ear lobe

Prick the finger or ear lobe fairly deeply with a sharp surgical needle or with a blood gun, so that the blood flows freely from the wound. Apply the surface of a clean slide or coverslip to a small drop of blood and proceed as in A (i) or (ii).

#### Comparing the two methods

The method of choice is in our opinion the slide smear. The advocates of the coverslip method claim that it is the only way to obtain an even distribution of cells and that consequently reliable differential counts can only be made from coverslips. On the other hand, it is much easier to make a good film on a slide, and, if the whole drop of blood on the slide is utilized in making the smear and this drop is a small one, examination of such a smear will give as reliable information as examining a coverslip smear, the preparation of which demands considerable dexterity.

#### Staining blood films

All blood smears should be stained within twenty-four hours. If the smears cannot be stained immediately they must be fixed with methyl alcohol and stored in a dust-proof slide box for staining at a later date. The unstained slides must never be left uncovered on the working table as blood is readily eaten by the flies during the day and by cockroaches at night.

Romanowsky stains are used for all blood work. The most commonly used stains are those originated by Leishman, Wright, Jenner, and Giemsa. All these stains depend for their action on the compounds formed by the interaction of methylene blue and eosin, and the differences between the various stains are due to the proportion of the two stains. Excepting Giemsa's stain, the fluid stains are prepared by dissolving the dry powder in acetone-free pure methyl alcohol, so that a preliminary fixation with methyl alcohol is only required in the case of Giemsa's stain. Leishman's and Wright's stains are used in the strength of 0.15 per cent, and Jenner's stain in the strength of 0.5 per cent.

#### Preparing Leishman's, Wright's and Jenner's stains

Stains in powder or tablet forms and extra-pure acetone-free methyl alcohol for dissolving the stains should be obtained from some reliable firm. We have found the Gürr's\* stains to be very satisfactory.

All the glassware used in preparing the stains and in storing them should be scrupulously clean, and free from any trace of water; they should be rinsed first with absolute alcohol and finally with a little methyl alcohol.

Take the requisite amount of stain in powder or tablet form in a small glass mortar. Measure

\* George T. Gürr, 136, New Kings Road, London, S.W.6, England.

out the requisite amount of methyl alcohol in a graduated glass cylinder. Pour out about 2 c.cm. of methyl alcohol on the stain and grind well to make it into a thin paste. Add in small quantities at a time about half the total amount of methyl alcohol, grinding all the time. Carefully decant the supernatant dissolved stain into a clean glass stoppered bottle. Add more methyl alcohol to the undissolved stain, grinding as before. Again decant the supernatant stain into the bottle, continue the process until all the methyl alcohol is used up. If this is properly done all the stain will go into solution and no residue will be left at the end. Incubate the bottle with the stain at 37°C. for 24 hours when it will be ready for use.

#### A. Staining with Leishman's, Wright's or Jenner's stain

##### Reagents and apparatus required

1. Prepared stain, preferably in a drop bottle.
2. Distilled water (pH 7.0), or buffer solution with pH of 6.4 and made with acid monopotassium phosphate and disodium phosphate\*.
3. Fresh distilled water which is slightly acid in reaction.

4. Staining rack. This can be made with plasticine and a pair of glass rods of equal size and thickness, and may be placed at one end of a sink away from the water tap, or on a rectangular enamelled tray placed near a tap.

Glass beakers, cylinders, a pair of forceps, capillary pipettes, teats, etc.

**Technique.**—Put the slides on the staining rack taking care that the side with the blood film is upwards; also see that the two ends of the slides are in the same plane.

From a drop bottle, or with a pipette, pour on sufficient stain to cover the whole of the film; wait for one minute to allow for proper fixing; with a capillary pipette now add distilled water (pH 6.8 to 7.0) or the buffer solution—the same volume in the case of Leishman's and Wright's stains but double the volume in the case of Jenner's stains. With a capillary pipette or glass rod thoroughly mix the stain with the diluent to ensure a uniform mixture over the film.

When the mixture is allowed to settle, a scum will form on the top, if the proportion of the stain and diluent has been correct. According to the depth of staining required, allow the diluted stain to act for 5 to 10 minutes, in the case of Leishman's and Wright's stains, and 3 to 5 minutes, in the case of Jenner's stain.

The diluted or undiluted stains on the slides must not be allowed to dry up at any stage of the staining. Drying is prevented by covering the staining rack with a wide bell-jar, or other improvised device†.

* Monopotassium phosphate	.. 6.63 gm.
Anhydrous disodium phosphate	.. 2.56 gm.
Distilled water	.. up to 1 litre
Add 1 c.cm. of chloroform as preservative.	

† The precaution will seldom be necessary in humid climates, e.g., of Bengal and Assam, except in the hottest months, but will be imperative in drier provinces in India, and in other dry countries such as Iraq, Egypt, etc.

When the staining is complete, hold one end of the slide firmly with a pair of forceps, and place the stain-flooded slide under a running tap. This will wash off all the stain from the upper surface, while the bottom is cleaned by rubbing it well with the fingers of the left hand. The slide is now transferred to the beaker containing fresh distilled water and gently shaken to and fro till the colour of the smear becomes faintly pink. Now take it out of the beaker, wash again under the tap and allow it to dry. In order to dry it without allowing dust to adhere to the stained surface, the slide should be sloped against a vertical surface, e.g., a wall or the side of a box, with the film side inwards. (It is scarcely necessary to point out that heat should not be applied to a blood film at any stage in its preparation.)

When it is dry the slide is ready to be examined.

#### B. Staining with Giemsa's stain

It is more difficult to prepare this stain and it is better to purchase it in solution. Giemsa's stain as prepared by Gürr is quite satisfactory.

In staining with Giemsa's stain, preliminary fixing with methyl alcohol or some other fixing stain is absolutely necessary.

##### Preparing dilute solution

Take about 20 c.cm. of prepared distilled water (pH 7.0) or buffer solution in a clean transparent glass cylinder, add 20 drops of undiluted stain, or in other words as many drops of stain as there are cubic centimetres of water. Mix well by inverting the cylinder and see that the depth of colour of the mixture is such that, when held in front of the eyes, it allows a distant object to be seen through it.

(i) Place the slides to be stained on a staining rack, flood the slide with methyl alcohol and cover with a bell-jar, so that the methyl alcohol does not dry up on the slide. Allow the methyl alcohol to act for about two minutes, remove the jar and thoroughly wash with distilled water.

Now flood the slide with the diluted stain, cover with a bell-jar, and allow the stain to act overnight. Next morning wash and dry the slide as in A.

#### (ii) Combined staining with Leishman's, Wright's or Jenner's and Giemsa's

This is done exactly in the same way as in A but substituting the dilute Giemsa's stain as the diluent in place of distilled water or buffer solution.

#### (iii) Combined staining with May-Grünwald\* and Giemsa

Pour on undiluted May-Grünwald's stain just sufficient to cover the slide, place a bell-jar over the staining rack, allow the stain to act for 2 to 3 minutes, remove the bell-jar, and add an equal amount of neutral distilled water (pH 7). Allow

\* This can be purchased in solution and is available from G. T. Gürr (v.s.).

## MAKING PLASMA SAFE FOR TRANSFUSION

By S. D. S. GREVAL

LIEUTENANT-COLONEL, I.M.S.

Imperial Serologist, School of Tropical Medicine,  
Calcutta

THE intention is, (i) to state that it is not safe to give a transfusion of incompatible plasma, (ii) to suggest means of making the plasma safe, (iii) to indicate how stored plasma helps in transfusions, and (iv) to indulge in two speculations regarding the use of plasma in malignant growths.

### I. Incompatible plasma

A disaster in blood transfusion, occurring with dramatic suddenness, when an error in grouping blood has been made, is due to lysis and/or agglutination of the donor's corpuscles in the recipient's body. The donor's plasma, however, is not without effect. If it has not been made ineffective by dilution with the recipient's plasma it will lyse and/or agglutinate the recipient's corpuscles. This is known to occur when a dangerous 'universal donor' has served a recipient of a group other than O. His own corpuscles are inagglutinable; the effect produced is entirely due to the action on the recipient's corpuscles of the isohæmagglutinins in the donor's plasma.

If the danger from the plasma of a subject of group O is real then the danger from the plasma of subject A for subject B, from the plasma of subject B for subject A, and from the plasma of both subjects A and B for subject AB is also real. The writer holds that the danger from a dangerous 'universal donor' is real (Grevall and Chandra, 1939).

The risk from incompatible plasma would in fact be increased if the titre of sera a (from subjects B; III Jansky and Moss) and sera b (from subjects A; II Jansky and Moss) were of the same high order as that of sera ab (from subjects O; I Jansky and IV Moss). Such is

(Continued from previous page)

the diluted stain to act for 5 to 10 minutes according to the depth of staining desired, wash thoroughly with neutral distilled water and then flood the slide with dilute Giemsa's stain to act for 15 to 30 minutes according to the depth of the staining desired, and wash and dry as in A.

### Methods used in our laboratory

For all ordinary work Wright's staining method is used, and for special work, e.g., examining smears from the marrow, counting the nuclear lobes in Arnetz and Schilling counts, combined May-Grünwald and Giemsa's staining are preferred. For, with the combined May-Grünwald and Giemsa's staining, all the component parts of both mature and immature red and white cells are very well shown.

not the case. On the whole the isohæmagglutinins a and b in sera a and b are weaker than in sera ab. But sera a and b of high titre are found. The writer uses only these sera in grouping tests. A simple scheme for titrating the sera and excluding the risk has been given in the communication quoted in the last paragraph.

### II. Making plasma safe

Although the danger of injecting ungrouped plasma intravenously has not been plainly admitted, ideal plasma has been described and methods of making plasma (other than ideal) safe have been recommended and adopted. Plasma from subjects AB (Jansky IV and Moss I) having no isohæmagglutinins has been considered ideal (Editorial, *B. M. J.*, 1940). Bloods A and B have been taken in the same bottle to remove the isohæmagglutinins by absorption (Edwards, Kay and Davie, 1940). Plasma has been diluted with an equal volume of normal saline (Goldman, 1940; Smith, 1940). There are difficulties in obtaining the ideal plasma and in making the one other than ideal safe according to the devices mentioned. Subjects AB are scarce, absolutely, all over the world. Subjects B are scarce, relatively, in Europe and America; for every A a partner B cannot be found to fill the same bottle. Citrated plasma is likely to coagulate at times when diluted with an equal volume of normal saline and loses half its value always.

Davie (1940) who started by taking for storage, plasma from the blood of subjects of group 1 (Moss 1 or I, International AB) only now also takes it from the blood of subjects of group 2 (Moss 2 or II, International A). The latter plasma given after dilution with an equal volume of saline, without regard for the group of the recipient, is not likely to do much damage in England where the predominating groups are O and A. Besides, the isohæmagglutinin b it contains is likely to be, on an average, of a lower titre than the isohæmagglutinin a (from plasma of subjects B, Moss 3 or III) would be and may not affect an odd recipient of group B (Moss III) or AB (Moss I). Plasma from subjects of group 3 (Moss III, B) will not be so safe. In India, where O, A, and B are more evenly distributed, risk would be real. The nomenclature, outside the brackets, in this paragraph is of the original communication. The brackets give the writer's explanation and international nomenclature.

Incidentally, the risk will persist even when the plasma is given intraperitoneally or intramuscularly to an infant with a view to increasing the volume of blood in the circulatory system rapidly.

The writer recommends the following plan for selecting plasma which is safe, with respect to its isohæmagglutinin content, or making dangerous plasma safe:—

1. *Selection of safe plasmas.*—Plasma conforming to the standard of the safe universal

donor (Greval and Chandra, *loc. cit.*) with respect to the titre of isohæmagglutinin a and b is safe. Plasma ab (from subjects O) is thus selected. Plasma a (from subjects B) and plasma b (from subjects A) are selected similarly. Plasma o from subjects AB is of course ideal.

2. *Mixing of plasmas.*—Plasma a and plasma b may be a trifle over double the safe strength if they can be mixed in equal volumes. After mixing and keeping a day in the cold the titre will be found to be below the arithmetically calculated titre and safe. The arithmetically calculated titre of course will be half the previous titre of each isohæmagglutinin.

In India the discrepancy between groups A and B is not so marked as in England although group B predominates slightly. In a blood transfusion centre in a big town it is possible to get both the groups in about the same number. There will be as many bottles of stored A blood as of B blood. So far as the writer's experience of the titre of the sera goes, a great majority of the plasmas a and b can be made safe by mixing.

3. *Removal of isohæmagglutinin by absorption.*—Two time-expired (over 10 days old) bottles of bloods A and B, plasma from which is not safe to begin with and cannot be made so by mixing, are taken and termed first and second bottle. A third empty bottle is added. The supernat from the first bottle is transferred to the third bottle by a sterile system of two rubber tubes, a two-way adapter and a syringe. The supernat from the second bottle is then transferred to the first bottle by the same system and mixed gently with the deposit of red blood corpuscles. The supernat removed to the empty bottle is finally transferred to the second bottle and mixed with the deposit of corpuscles. Plasmas a and b are now in contact with the corpuscles A and B which will remove their isohæmagglutinins if kept at room temperature for 15 minutes and in the cold for half an hour. The agglutinated corpuscles fall to the bottom rapidly leaving a clear supernat which can be removed and bottled. A trace of colour can be disregarded.

For complete absorption of the isoagglutinins from a volume of plasma half a volume of corpuscles suffices unless the latter are A<sub>2</sub> or A<sub>3</sub> (slow A's). For a partial removal of the isoagglutinins even a smaller quantity will do.

The operation of removals and transfers must be performed with sterile precautions; or else the absorbed plasma will have to be filtered through a Seitz filter.

The agglutinated corpuscles are still either A or B although sensitized and available for making other preparations.

Dangerous excess of a or b from a serum ab can also be eliminated by suitable absorption. The entire contents can be removed by absorption with corpuscles AB from a subject AB.

4. *Dilution of plasma.*—If the devices described under 2 and 3 cannot be used the plasma

must be diluted to a safe strength *after its titre has been determined*. The diluting fluid should be 0.25 per cent sod. citrate in normal saline. The limit of safety of sod. citrate for an adult is 5 grammes.

Other dangers in plasma are those that also exist in stored whole blood. It might be thought that the danger from syphilis might be eliminated without the aid of a Wassermann test by filtering or drying plasma and thus removing or killing the spirochætes which may be present. The danger of a passive sensitization, however, brought about in a recipient by a syphilitic's blood remains: and sensitization accompanied by a subsequent assault is probably more important in the long story of syphilis than any immediate damage done by the spirochætes. The writer, therefore, does not recommend that the Wassermann test should be omitted.

Potassium ions are reported to increase in plasma when the whole blood is stored (Editorial, *J. A. M. A.*, 1939). Danger from them would be the same as the one arising from the use of the stored whole blood from which the plasma has been taken. This danger does not appear to exist. 'Data have been presented on the incidence and type of reaction occurring in a series of 1,458 transfusions of blood stored from one to thirty-eight days and 146 transfusions of fresh blood. No types of reactions were encountered that were distinctive of preserved blood' (DeGowin and Hardin, 1940). The blood had been taken in a sod. citrate solution for short storage and in a dextrose-citrate solution for long storage.

Incidentally, the plasma possesses all the advantages stored blood has over fresh blood. They are: (i) decrease in food and allergic reactions, (ii) extended observation on the state of health of the donor during an epidemic, and (iii) exclusion of blood of high coagulability in certain conditions (Greval, Chandra and Roy Chowdhury, 1940).

Plasma made safe by methods other than dilution can be dried for easy storage and transport. A method has been published (Davie, *loc. cit.*). On the whole, dried plasma has so far not been preferred to preserved liquid plasma. 'There was a place for dried plasma, but it could not replace plasma saline' (Davie, *loc. cit.*).

### III. Help given by stored plasma in transfusions

That stored plasma has a place in the treatment of sudden loss of blood has been discussed this year by different workers from different countries (Best and Solandt, 1940; Goldman, *loc. cit.*; Smith, *loc. cit.*; Davie, *loc. cit.*; Greval, Chandra and Roy Chowdhury, *loc. cit.*). That it prevents waste in a blood bank is also worthy of remark. One important consideration when blood is taken from voluntary, unpaid, public-spirited donors is that it should be made use of. Often, in a newly started blood bank,

blood taken for storage is limited to a bottle or two for each of groups O, A and B lest there should be no demand. Then the demand comes suddenly and there is no blood. All sudden demands can be satisfied wholly or partly by stored plasma for preparing which more bottles of blood can be taken for storage without fear of waste. Blood from group AB can also be taken, for the ideal plasma and for absorbing plasma of dangerous 'universal donors'. Ordinarily this blood is not taken.

#### IV. Two speculations regarding malignant growths

1. *Action of the isohæmagglutinins on malignant cells.*—An isohæmagglutinin is absorbed by all the cells of the body of a subject of the appropriate group. Will the rapidly-growing ill-formed malignant cells absorb it, become sensitized, and be adversely affected? Appropriate plasma or sera below a dangerous titre can be given intravenously. Even high-titre plasma or sera can be injected locally into the growth and applied as dressings.

2. *Possibility of replacing most of a patient's plasma.*—Normal humoral forces are probably capable of destroying malignant growths. Given a stock of compatible plasma, it should be possible to replace most of a patient's plasma in the course of a few days. The patient could be (i) transfused with compatible whole blood, (ii) bled and (iii) transfused with his own red blood cells and a healthy donor's compatible plasma. Steps (ii) and (iii) could be repeated. Will the replacement destroy the malignant growth?

#### Summary

1. Plasma may be incompatible like the plasma of a dangerous 'universal donor'.

2. Plasma stored for transfusion can be made safe by (i) selection, (ii) mixing, (iii) absorption and (iv) dilution. The Wassermann reaction should be done. Potassium ion concentration in the plasma is negligible if the red blood cells are removed in a few days. No distinctive reactions due to stored blood have

been recorded even after storage lasting 38 days.

3. The separation and storing of plasma will abolish waste in blood banks.

4. There are two speculations regarding the use of plasma in cases of malignant growths: (i) Will the appropriate isohæmagglutinin sensitize and destroy the malignant cells? (ii) Will the replacement of a patient's plasma by normal healthy plasma destroy the malignant cells?

#### Addendum (dated 13th November)

Since this communication was sent, a report on the preparation of serum from plasma of stored blood has become available (Clegg and Dible, 1940). The serum is preferred to the plasma because of the formation of particulate matter in the latter on standing. It has a high calcium content (six to eight times normal) and is recommended for use regardless of the group of the recipient.

The present writer makes three observations: (1) His opinion on the danger of incompatibility of groups remains unchanged. (2) The risk of producing favourable conditions for the anaerobic flora, responsible for tetanus and gas gangrene, by increasing appreciably the calcium content of the tissues (Topley, 1933), needs consideration, particularly in connection with street accidents and war wounds. (3) Removal of the particulate matter from the plasma by filtering should not be difficult.

## Medical News

### TUBERCULOSIS ASSOCIATION OF INDIA

#### TUBERCULOSIS NEWS

##### I. Tuberculosis Workers' Conference

THE second Tuberculosis Workers' Conference will be held in New Delhi from the 18th to 21st November, 1940. [The conference has now been successfully concluded.]

One whole day will be devoted to the discussion of the influence on the spread and development of tuberculosis of such environmental factors as poverty, over-crowding, under-nourishment and occupation of insanitary dwellings, and of the effects on the spread of tuberculosis of legislation including by-laws dealing with notification, erection of buildings, slum clearance, town planning and the regulation of lodging houses.

Other important subjects, such as tuberculosis surveys, uniformity of records of classification of patients and the results of treatment, will be discussed, as well as the interpretation of x-ray films and their recording. Further, a few clinical subjects dealing with the treatment of certain complications will also come up for debate.

The Conference will be opened and closed by Her Excellency the Marchioness of Linlithgow, President of the Tuberculosis Association of India.

##### II. Training Courses

The Tuberculosis Association of India, with the co-operation of the Bengal Tuberculosis Association, will organize a medical post-graduate course for training in

tuberculosis at the All-India Institute of Hygiene and Public Health, Calcutta, from the 15th January to 14th February, 1941.

2. The class will be limited to 30 registered medical practitioners—male or female—whether in Government service or otherwise. Ten seats will be reserved for practitioners in Bengal Province and 20 for candidates from other parts of India.

### III. Meetings

A central committee meeting of the Tuberculosis Association of India was held at the Viceroy's House, New Delhi, on the 28th October, under the presidency of H. E. the Marchioness of Linlithgow. Besides some routine matters, the following business was transacted. The committee approved the award of the Hassan Masud Suhrawardy Memorial Anti-Tuberculosis Challenge Shield for the all round good work on tuberculosis done during 1939 to the Madura Municipality which competed among 12 others. It was decided to request affiliated tuberculosis associations to send half-yearly (quarterly if possible) reports of their activities for incorporation in the tuberculosis news service of the central association. The committee also decided to proceed with the election of five members to the central committee from the affiliated associations. Finally, the committee resolved to offer to Dr. C. Frimodt-Møller, C.M.E. (Hon.), the present medical commissioner of the association, an extension of appointment by two years on the expiry of his present contract on the 30th April, 1941.

### IV. Tours

Lieutenant-General G. G. Jolly, chairman of the association, went on a tour of inspection to Bombay and Karachi during the second week of October and discussed with officers of the provincial tuberculosis associations the progress of anti-tuberculosis measures.

Dr. Frimodt-Møller, the medical commissioner of the association, paid a visit to Shillong on the 8th, 9th and 10th October to advise on the best tuberculosis scheme for Shillong and the province. He visited various proposed sites for a tuberculosis clinic and hospital at Shillong, and addressed a meeting of administrators and doctors held at Government House. While passing through Calcutta the medical commissioner discussed with the medical authorities of the B. N. and E. B. Railways how best they could co-operate in the anti-tuberculosis campaign.

### THE XVII ALL-INDIA MEDICAL CONFERENCE, VIZAGAPATAM, 1940

In connection with the scientific section of the forthcoming XVII All-India Medical Conference at Vizagapatam during the last week of December 1940, it is proposed to have symposiums in the following subjects in addition to the reading of papers:—

1. Surgery:—Surgical complications of filariasis.
2. Medicine:—High blood pressure, its ætiology, pathogenesis and treatment.
3. Obstetrics:—Maternal injuries of child birth.
4. Venereal Diseases:—Modern treatment of gonorrhoea.

The names of the openers of discussion on the above subjects will be announced in due course.

### LOCATION OF TUBERCULOSIS CLINICS

THAT if a tuberculosis clinic is to be of maximum benefit, it should be situated in, or as close as possible to, a thickly populated area, is the unanimous opinion of the committee of experts recently appointed by the Tuberculosis Association of India at the instance of the Government of India to consider what condition should govern the selection of sites for such clinics and whether any particular precautions were necessary in the case of clinics situated in populated areas.

The committee were also of the view that no particular conditions are necessary regarding the distance of a well-conducted clinic from the nearest house. They

recommended, however, that if a clinic is located in a part of a building used for other purposes, the clinic should have a separate entrance.

### FOR DISTINGUISHED SERVICE IN WAZIRISTAN

HIS IMPERIAL MAJESTY THE KING, EMPEROR OF INDIA, has been graciously pleased to give orders for the following appointment to the Most Excellent Order of the British Empire, for services rendered during the Operations in Waziristan, North-West Frontier Province:—

*To be an Officer of the Military Division of the said Most Excellent Order*

Lieut.-Colonel Robert Anceel Logan, I.M.S., Officer Commanding, No. 11 Field Ambulance, Waziristan.

### THE SULPHONAMIDE GROUP OF DRUGS IN THE TREATMENT OF PLAGUE

WE have received too late for publication in this issue, a paper from Lieut.-Colonel S. S. Sokhey, I.M.S., Director of the Haffkine Institute, Parel, Bombay, by himself, Dr. Wagle, and other members of the staff of this institution, on their results in the treatment of plague with anti-plague serum, sulphapyridine and sulphathiazole. The death rates in their three series were 28 per cent, 24 per cent, and 15 per cent, against 52 per cent, in the control series. The difference between any of the treated series and the control series is significant statistically.

The paper will appear in our next number.

### A SIMPLE METHOD OF OBTAINING ANÆROBIOSIS

WE have received an article by Major C. L. Pasricha, I.M.S., and Mr. S. K. Ghosh, of the School of Tropical Medicine, Calcutta, on this subject, for publication; it will appear in a later number. The main points are:—

A desiccator, or other suitable container which can be rendered air tight, is used; an ordinary tall glass tumbler covered with a petri-dish and made air tight with plasticine gives entirely satisfactory results, when only a small number of tubed cultures is to be incubated. Into the bottom of the desiccator are placed some moistened iron filings. There is a complete anærobiosis in about six hours. It is an advantage to evacuate the jar and then to admit hydrogen, but this is not absolutely necessary.

## Current Topics

### Hæmaturia from Sulphathiazole Therapy in Pneumonia

By JOHN H. ARNETT

(Abstracted from the *Journal of the American Medical Association*, Vol. CXV, 3rd August, 1940, p. 362)

THE tendency of sulphapyridine to form urinary crystals resulting in hæmaturia and even obstruction is by this time well known. Gross, Cooper and Scott have collected from the literature 36 cases of gross hæmaturia, with seven in which uroliths were specifically mentioned, complete bilateral ureteral block being disclosed at autopsy in one instance. Plummer and McLellan have reported two cases of unilateral calculus formation, one of which was fatal. Arnett, Shoup and Henry have reported a case of bilateral ureteral obstruction with recovery. The fact that similar complications can arise in the course of sulphathiazole therapy is now beginning to be recognized. Gross, Cooper and Scott have demonstrated concretions in the kidneys of rats receiving sulphathiazole,

# Prescribing a Laxative

WHEN, as frequently happens, the Physician is called upon to prescribe a laxative for prolonged personal use by the patient, Andrews Liver Salt merits special consideration. The main characteristics of this tonic laxative, listed below, suggest its wide range of suitability.

1. Andrews is pleasant tasting. All ages take it readily.
2. Andrews causes none of the griping or other discomforts which often create reluctance to continue the use of the more drastic purgatives. Its laxative action is due to the presence of magnesium sulphate and other salts, which increase the fluid content of the bowel by Osmotic action, and so lead to painless, easy evacuation.
3. Because of its natural and non-habit-forming action, Andrews—in suitable doses—may be taken with
4. every confidence by the physically weak and during pregnancy. This tonic laxative does not affect adversely the secretion of milk in nursing mothers. Indeed, the quantity of water taken with Andrews Liver Salt contributes to the extra liquids a nursing mother should take.
5. Andrews is particularly valuable in the case of patients liable to digestive trouble. The carbon dioxide which is liberated when Andrews is dissolved in water has a soothing effect on the stomach and a physical cleansing action on the stomach walls. Additionally, Andrews corrects excess acidity, stimulates the liver and promotes the flow of bile.
5. Andrews creates no dependence on artificial aid, but can be discontinued when the need for it ceases.

*Andrews Liver Salt increases the alkalinity of the body fluids and is, therefore, of great value in malaria and other feverish conditions for counteracting the excessive production of acid which takes place in such cases.*

## ANDREWS LIVER SALT

*A large size tin will be sent free on request, to any member of the Medical Profession.*

*SCOTT & TURNER LTD., Newcastle-upon-Tyne, England.*

# THE CALL OF PAIN

The call of pain is seldom stilled, and relief is of primary importance to the suffering patient. The paroxysmal pain of dysmenorrhœa, the persistent and intense throbbing of migraine, the shooting pains of neuralgia, the pain in affections of the bones and joints, the pain resulting from accidents — all these, and many other conditions, yield with impressive readiness to the sedative and analgesic efficacy of Veganin. With Veganin there is no systemic disturbance, no habituation. It may therefore be safely entrusted to the patient as a dependable means of relieving and preventing pain.

## VEGANIN TABLETS

Prepared by WILLIAM R. WARNER & CO. LTD., LONDON, ENGLAND.

### A Call for Help

*Veganin Tablets present acetylsalicylic acid, phenacetin and codeine in synergistic combination, whereby the individual action of each constituent is greatly enhanced.*

*Veganin Tablets are not advertised to the public.*

*Supplied in tubes of 10 and 20.*

*A trial supply to Physicians on request.*

MARTIN & HARRIS Ltd.,  
Mercantile Buildings, Lall Bazar,  
CALCUTTA.

Also at Bombay, Madras, Karachi  
and Rangoon.

and Pepper and Horack reported the death of a 77-year-old pneumonia patient who developed hematuria and oliguria while on sulphathiazole therapy. At autopsy the kidneys were found to be large and soft and their collecting tubules were dilated and contained crystalline material. In the case here reported severe hematuria and lumbar pain were present but the patient recovered.

It is the currently accepted belief that sulphathiazole, like sulphapyridine, may produce hematuria mechanically through the irritation caused by the crystals precipitated in the renal tubules and pelvis. No doubt the fact that in one present case, because of vomiting, it was impossible to maintain a sufficiently high fluid intake to prevent such precipitation was an important factor in causing the hematuria. The fact that such a complication may arise should not discourage the medical profession from using sulphathiazole, which is probably less toxic and more efficacious in cases of pneumonia than sulphapyridine. In 200 cases of pneumonia, half of which were treated by the former and half by the latter drug, Flippin, Schwartz and Rose report only one case of gross hematuria, and this occurred in the sulphapyridine group, while the mortality in the sulphathiazole group was lower by 3 per cent and vomiting was much less frequent. The point that should be emphasized is the importance of maintaining a sufficiently high fluid intake to prevent massive crystal formation. The fluid intake and urinary output should receive the watchful attention of the physician, and the urine should be examined at least daily for crystals and blood. If the intake can be kept in excess of 3,000 c.c. and the output at 1,500 c.c. or more a day, and if the drug is immediately discontinued and intravenous fluids are administered with the first appearance of lumbar pain or bloody urine, the dangers from renal complications will be reduced to a minimum.

### The Toxic Manifestations of Sulphanilamide and its Derivatives

By P. H. LONG,  
J. W. HAVILAND,  
L. B. EDWARDS,

and

E. A. BLISS

(From the *Journal of the American Medical Association*, Vol. CXV, 3rd August, 1940, p. 364)

It has become increasingly evident as time goes on that physicians often hesitate to use sulphanilamide or its derivatives because of a fear of the toxic manifestations of these drugs, while patients, because of their lack of appreciation of the possible toxic manifestations of this group of drugs, demand that the drugs be administered to them. These attitudes have at times brought about a somewhat peculiar situation.

It has seemed to us that physicians have been 'oversold' on the dangers connected with the use of sulphanilamide and its derivatives and that these drugs can be used with greater impunity than has hitherto been considered possible. It is for this reason that we have carefully analysed the incidence and types of toxic reactions occurring in hospitalized adults, 1,000 of whom were treated with sulphanilamide, 297 with sulphapyridine and 291 with sulphathiazole in the Johns Hopkins Hospital during the past few years. The results of this analysis are shown in the accompanying table.

It is obvious that certain deductions can be made from this group of patients in respect to the frequency and severity of the toxic manifestations of sulphanilamide or its derivatives, and we think that by a careful study of the clinical histories of these patients certain general conclusions can be drawn regarding the care of patients who are receiving these drugs.

In the first place it is to be noted that nausea and vomiting constitute a problem only as far as sulphapyridine therapy is concerned. We have noted that the more highly integrated the patient is, the greater the

chance that nausea and vomiting will occur in the course of therapy with sulphapyridine. In our Negro patients and in children, nausea and vomiting have caused little if any difficulty in the maintenance of therapy, but in the private wards this toxic manifestation has occasionally been a problem of grave importance. When severe nausea and vomiting occur, the fluid intake should be kept at a high level and sodium chloride administered either by mouth or parenterally in order to prevent dehydration and hypochloremia from developing.

Although adequate statistics are not available, it has seemed to us that dizziness is more common in the course of sulphanilamide therapy than when sulphapyridine or sulphathiazole is being used. The recognition that dizziness may occur is of great importance, especially with respect to patients who drive automobiles, perform heavy or light mechanical work, pilot airplanes or conduct other types of vehicles. All ambulatory patients who are receiving these drugs should be warned of the consequences that may arise from attacks of dizziness.

True toxic psychoses due to the drug are fortunately rare, but they may take almost any form; if a maniacal type of psychosis is present the patient should be carefully watched lest harm come to him. In general it is always best to stop the drug when such toxic manifestations arise. Neuritis, either peripheral or central, is fortunately very rare in the course of therapy with sulphanilamide, sulphapyridine or sulphathiazole, but if evidence of this toxic manifestation is noted the drug should be immediately stopped.

Cyanosis, either mild or severe, is very common in the course of treatment with sulphanilamide but is of little importance except possibly in older persons suffering from emphysema or any type of cardiac disease. In the course of treating lobar pneumonia with sulphapyridine we have never noticed that this drug contributed significantly to the cyanosis already present, and indeed we have repeatedly observed that successful chemotherapy was attended by a marked decrease in the degree of cyanosis present. Our experience with sulphathiazole leads us to believe that this drug produces minimal degrees of cyanosis.

Acidosis has not been reported in the course of sulphapyridine or sulphathiazole therapy, and in our experience it has practically been eliminated as a toxic reaction of sulphanilamide therapy by the concurrent use of sodium bicarbonate with each administration of sulphanilamide. We have never seen a clinical example of alkalosis produced by the administration of sodium bicarbonate in the course of sulphanilamide therapy.

Drug fever is an extremely common toxic manifestation in the course of sulphanilamide or sulphathiazole therapy. It may occur at any time from the first to the thirtieth day of treatment, but it is most commonly seen between the fifth and ninth day of treatment. Drug fever may be of three clinical types: a hectic remitting fever accompanied by chills of great severity, a steadily mounting fever and a low continuous fever. We are frequently asked to distinguish between the fever produced by the drug and the fever produced by infection. Since drug fever occurs most commonly from the fifth to the ninth day and since one expects the temperature of adequately treated patients to be normal by the third day, the appearance of fever, when all clinical signs are pointing toward a favourable termination of the disease, should immediately lead one to suspect that the rise in temperature is due to the drug and not to a recrudescence of the infection. Another factor of considerable importance is that when drug fever appears the patient begins to feel bad and almost always complains of headache and generalized malaise.

Simple drug fever in itself is probably not a dangerous toxic manifestation, but it has always seemed best to us to discontinue the drug if it makes its appearance. When the drug is stopped and fluids are vigorously forced, the temperature should return to normal within twelve to seventy-two hours, depending on the rapidity with which the drug is eliminated from the body. The slower the elimination of the drug, the more prolonged will be the fever.

Drug rashes are common in the course of sulphanilamide and sulphathiazole therapy but do not occur very often when sulphapyridine is being used. They may take any form, and we have seen crissipeloid, scarlatini-form, morbilliform, purpuric, erythema multiforme, papular, vesicular, pustular and nodular eruptions. In severe instances (especially if the drug is continued) the rash may progress to an exfoliating dermatitis. Rashes may occur at any time from the first to the thirtieth day of therapy. In a certain number of instances photo-sensitization of the skin seems to play a rôle in the production of the rash. For this reason patients who are receiving treatment with sulphanilamide or one of its derivatives should stay out of the sun until at least three days after cessation of therapy. A curious idea has recently become prevalent in this country, namely, that patients who have received sulphanilamide or one of its derivatives during the winter should keep out of the sun during the summer. There is absolutely no foundation in fact for this rumour.

Hepatitis characterized by jaundice without anaemia and a definite impairment of liver function has occurred in 0.6 per cent of patients who have been treated with sulphanilamide. This toxic reaction may occur early or late in the course of therapy. It has been noted that occasionally it accompanies dermatitis exfoliativa. In our experience the prognosis has been excellent if the drug is stopped immediately and fluids are forced, and as far as we know there has been no permanent impairment of liver function following recovery from this toxic reaction of sulphanilamide therapy. The

occurrence of hepatitis in the course of sulphapyridine therapy has been reported, but we have not seen it in our series of patients treated with this drug. As far as we know, hepatitis has not occurred in the course of sulphathiazole therapy, although it is to be expected.

Leukopænia with granulocytopenia may occur early or late in the course of therapy with sulphanilamide or its derivatives. In adults this toxic manifestation is relatively uncommon. We have noted a sharp drop in the leukocytes following a single dose of sulphanilamide in certain cases, and we have also noted that granulocytopenia may not occur until the sixtieth or seventieth day of treatment. Hence one must always be on the lookout for this type of toxic manifestation. It has been considered best to stop therapy with the drug if this toxic manifestation makes its appearance, but it must also be remembered that as far as we know there have not been any deaths reported from disturbances of the white cells during the first twelve days of therapy with any of these drugs.

Acute agranulocytosis is a rare complication of therapy with sulphanilamide and sulphapyridine and has not yet been reported in the course of therapy with sulphathiazole. This complication has in our experience occurred on the fourteenth or on a subsequent day of treatment with these drugs. The most common time for its appearance is between the seventeenth and the twenty-fifth day, although it may appear as late as the fortieth day of treatment. For this reason it is very important to check the white blood cell count at daily intervals on and after the

TABLE

*Manifestations of drug toxicity noted in hospitalized adults; 1,000 treated with sulphanilamide, 297 treated with sulphapyridine and 271 treated with sulphathiazole*

Reaction	Sulphanilamide	Sulphapyridine	Sulphathiazole
Nausea, vomiting ..	Fairly common	Frequent	Uncommon.
Dizziness ..	Common	Common	Uncommon.
Psychoses* ..	0.6%, occur early	0.3%, occur early	Not reported as yet.
Neuritis† ..	Very rare	Not reported	Not reported.
Cyanosis ..	Very common, early and late	Faint, common, early and late	Uncommon.
Acidosis* ..	1.9%, occurs at any time, rare if soda is used.	Not reported	Not reported.
Fever* ..	10%, generally 5th to 9th day, may occur 1st to 30th day.	4%, generally 5th to 9th day, may occur 1st to 30th day.	10%, generally 5th to 9th day.
Rash* ..	1.9%, may take any form, generally 5th to 9th day, may occur 1st to 30th day.	2%, may take any form, 5th to 9th day, may occur 1st to 30th day.	5%, nodular type common, may take any form, 5th to 9th day.
Hepatitis† ..	0.6%, early or late	Not seen, but reported	Not reported.
Leukopænia with granulocytopenia.† ..	0.3%, early or late	0.6%, early or late	1.6%, early or late.
Acute agranulocytosis† ..	0.1%, occurs 14th to 40th day, common 17th to 25th day.	0.3%, occurs 14th to 40th day, common 17th to 25th day.	Not reported.
Mild hæmolytic anaemia ..	3%, early and late	Rare	Not reported.
Acute hæmolytic anaemia† ..	1.8%, occurs 1st to 5th day	0.6%, occurs 1st to 5th day	Not reported.
Hæmaturia* ..	Not reported	8%, generally early	2.5%, generally early.
Anuria with azotæmia† ..	Not reported	0.3%, generally 1st 10 days	0.7%, generally 1st 10 days.
Hyperleukocytosis* ..	Generally in presence of acute hæmolytic anaemia.	Generally in presence of acute hæmolytic anaemia.	Not reported.
Injection of scleras and conjunctivas.*	Not reported	Not reported	4%, may occur with rash and fever, 5th to 9th day.
Purpura hæmorrhagica† ..	Not seen, but reported	Not seen, but reported	Not reported.
Ocular and auditory disturbances.*	Rare	Rare	Not reported.
Jaundice† ..	With acute hæmolytic anaemia or hepatitis.	With acute hæmolytic anaemia or hepatitis.	Not reported.
Painful joints* ..	Reported	Not reported	Reported with rash, etc.
Stomatitis* ..	Rare	Not reported	Not reported.
Gastro-intestinal tract disturbances.*	Bleeding rare, diarrhoea uncommon.	Rare	Not reported.

\* Best to stop drug and force fluids.

† Imperative to stop drug and force fluids.

# FOR THE TREATMENT OF URINARY INFECTIONS

## NEOKET

(Compound Mandelic Acid Granules)

Pleasantly flavoured, effervescent granules containing Mandelic Acid and Sodium Acid Phosphate. Neoket is free from the nauseating effects associated with ammonium chloride and as it contains no sugar it is equally suitable for diabetic and non-diabetic patients.

Supplied in 1½ oz. and 6 oz. bottles.

## AMMOKET

(Elixir of Ammonium Mandelate)

An elixir in which the unpleasant taste of ammonium mandelate is covered by means of suitable flavouring agents. Ammonium mandelate is metabolised in the body into urea and Mandelic Acid. The Mandelic Acid produced besides being bactericidal, renders the urine acid.

Supplied in 8 oz. and 16 oz. bottles.

# COW & GATE MILK FOOD

"THE FOOD OF ROYAL BABIES"

**Distributing Agents :** Carr & Co., Ltd., Wittet Road, Ballard Estate, Bombay,  
also at Calcutta, Karachi and Madras.

twelfth day of treatment with sulphanilamide or its derivatives. If the white blood cell count drops and the polymorphonuclear leukocytes are decreased, it probably means the beginning of acute agranulocytosis. The drug should be stopped and fluids vigorously forced in order that the drug may be eliminated from the body as quickly as possible. Outside of this measure, it is probably unwise to attempt other therapeutic procedures designed to combat the agranulocytosis, except that we believe that it is a good plan to use transfusions when the haemoglobin content falls below 70 per cent. In our experience the prognosis of agranulocytosis occurring in the course of therapy with sulphanilamide and its derivatives is good if the toxic reaction is recognized in its inception.

Mild, slowly developing haemolytic anaemia, in which the haemoglobin content drops 20 per cent or more during the first ten days of treatment, has occurred in 3 per cent of the adult patients treated with sulphanilamide. This toxic manifestation is rare in the course of sulphapyridine treatment and has not been reported as yet in patients who are receiving sulphathiazole. In contradistinction to acute haemolytic anaemia, it seems to occur as frequently in white as it does in Negro patients. These mild anaemias should not be considered as alarming toxic manifestations, as they generally disappear when the drug is stopped and may be combated by the administration of 0.6 gm. of ferrous sulphate daily. In patients suffering from chronic osteomyelitis or other diseases in which it may be desirable to prescribe sulphanilamide over long periods of time, occasional transfusions will help to control these mild haemolytic anaemias.

Acute haemolytic anaemias occurred in 1.8 per cent of our adult patients who were treated with sulphanilamide and in 0.6 per cent of those who received sulphapyridine. It has not yet been reported in the course of sulphathiazole therapy. In practically all instances it makes its appearance in the first five days of treatment with these drugs and can almost always be recognized clinically by the sudden development of pallor of the mucous membranes of the mouth and conjunctivas. Mild jaundice almost invariably accompanies this toxic manifestation of drug therapy and is especially noticeable in the scleras. In very acute fulminating cases, haemoglobinemia and haemoglobinuria may be present. Urobilin is consistently found in the urine. We have seen patients whose haemoglobin content has dropped as much as 70 per cent within twenty-four hours when this toxic manifestation has made its appearance.

If possible, it is always best to stop the drug when an acute haemolytic anaemia is present. However, in certain cases of severe involvement in which the continuance of therapy has been a life-saving procedure, multiple transfusions have been used in order to maintain the red blood cell count until the critical period of the illness has passed and it is possible to stop the drug. In most instances it has been necessary to administer one or more transfusions to combat this toxic manifestation.

Haematuria has not been reported in the course of therapy with sulphanilamide but is quite frequent when sulphapyridine or sulphathiazole is being used. Haematuria may be either microscopic or gross and may be a precursor of severe renal insufficiency. We have generally considered it best to stop the drug if haematuria makes its appearance, but in several instances we have observed patients in whom haematuria developed and in whom the continuance of therapy did not result in any grave kidney lesion.

Anuria with concurrent azotemia has not been reported in the course of sulphanilamide therapy but has been noted in the course of treatment with sulphapyridine or sulphathiazole. The anuria may be due to a true toxic injury of the tubules of the kidney, probably similar to that seen in mercury bichloride poisoning, or it may be due to the deposition of acetylsulphapyridine or acetylsulphathiazole crystals in the kidney tubules, and on occasion to the blocking of the renal pelvis and ureters by calculi composed of acetylsulphapyridine or acetylsulphathiazole.

If anuria makes its appearance, fluids should be forced by mouth and by the parenteral route. If vomiting is present, sodium chloride should be given by mouth or in the form of physiologic solution of sodium chloride by the parenteral route, because it is important to prevent hypochloremia from developing. If the anuria persists for more than twenty-four hours, the ureters should be carefully catheterized, and if obstruction is found an attempt should be made to wash out the ureters and renal pelvis gently with warm physiologic solution of sodium chloride in order to remove the renal calculi. If obstruction is not present, fluids should be forced, and in our experience all such patients have eventually recovered from this toxic manifestation of the drug.

Hyperleukocytosis has been seen in this series of cases only when acute haemolytic anaemia has been present. We have noticed total white blood cell counts ranging as high as 90,000 cells in the presence of acute haemolytic anaemia. These very high white blood cell counts probably represent an abnormal response of the bone marrow to a hurried call made on it by the rapidly developing anaemia. In this connection one should always remember that many nucleated red blood cells are being thrown into the circulation and that an allowance should be made for this fact in calculating the total white blood cell count.

Purpura haemorrhagica has not been seen in any of our cases but it has been reported as occurring in the course of therapy with sulphanilamide and sulphapyridine. If this toxic manifestation is noted, the drug should be stopped and fluids forced.

An injection of the scleras and conjunctivas, which may be so severe as to resemble 'pink eye', has been noted quite frequently in the course of sulphathiazole therapy. It generally occurs between the fifth and the ninth day of treatment with this drug, and its appearance is often heralded by burning and smarting of the eyes.

Other ocular and auditory disturbances, such as visual and auditory hallucinations and changes in visual and auditory acuity, have been noted in the course of sulphanilamide therapy, but they are rare.

Painful joints have been reported in the course of sulphanilamide therapy, and we have noted that several patients who have received sulphathiazole have had exquisitely tender, swollen joints. This toxic manifestation may be puzzling when the patient is suffering from gonorrhoea because of its resemblance to acute gonorrhoeal arthritis.

Stomatitis has been encountered rarely in the course of sulphanilamide therapy, while unexplained bleeding from the gastro-intestinal tract has been seen by us on one or two occasions in cases in which sulphanilamide or sulphapyridine was being administered. One patient who was receiving sulphapyridine had such severe bleeding as to bring about death. Occasionally cases are encountered in which the administration of sulphanilamide produces severe attacks of diarrhoea.

#### COMMENT

It is obvious from this description of the toxic manifestations of sulphanilamide and its derivatives that certain deductions can be made. We believe that, whenever possible, it is wise to utilize every available means of laboratory control in following patients who are receiving sulphanilamide or one of its derivatives. White blood cell counts, haemoglobin and urine examinations should always be done when circumstances permit this type of control. However, we are convinced that, with the exception of acute leucopenia, all the toxic manifestations of sulphanilamide or its derivatives which may occur in the first two weeks of therapy can be recognized by careful clinical observation, and we feel that no physician should hesitate to administer these drugs in therapeutically adequate amounts, provided he can see his patient at least once a day.

At the time the physician visits the patient who is receiving one of these drugs he should inquire as to his symptoms, especially in respect to headache, body aching or malaise, because these symptoms are often

the precursors of many of the toxic reactions of sulphanilamide or its derivatives. In addition to an inquiry about symptoms, the scleras should be examined for the presence of jaundice, the mucous membranes for pallor and the skin for evidences of rash. The temperature should always be taken in order to detect whether drug fever is present, and if the patient says that he has been having chills and at the time that it is taken the temperature is normal, arrangements should be made to have the temperature taken frequently during the next twenty-four hours in order to determine whether or not fever is present.

No special precautions have to be observed in respect to the urine of patients who are receiving sulphanilamide, but it is highly important that the urine of patients who are receiving sulphapyridine or sulphathiazole be measured daily. This does not mean that the attendants or family of the patient have to record the urine volume in cubic centimetres or ounces, but any standard measure, whether it is only cups, will suffice. As a matter of fact, in the case of infants it would probably be satisfactory to record the number of voidings daily. In this way it is possible to detect an oliguria which may herald an approaching anuria. The daily examination of the urine under these circumstances should consist of a careful examination of a fresh specimen for gross blood, and at the same time instructions should be given to the patient's attendants to stop the drug and administer fluids in large quantities if the urine looks bloody.

Finally, one should always remember that if a patient has once had drug fever, rash, hepatitis, leukopænia, acute hæmolytic anæmia, injection of the scleras and conjunctivas, diarrhœa or purpura hæmorrhagica in the course of therapy with sulphanilamide or its derivatives he is very likely to have a second, earlier and more severe toxic reaction if the drug is administered a second time. Therefore it is highly important to determine whether or not a patient has previously had a toxic reaction in the course of therapy with one or the other of these drugs. If he gives a history of a toxic reaction in the group which we have just enumerated, it is best to give a small test dose of the drug (0.3 gm.) and observe the patient carefully over a period of twelve hours before cautiously beginning the course of therapy. Patients who have had a toxic reaction caused by one of these drugs may have a similar reaction when another member of the sulphonamide group is prescribed.

### Photograph of a Sneeze

(From *Public Health Reports*, Vol. LV, 19th July, 1940, p. 1315)

SANITARIANS have long known that certain diseases are spread by the discharges from the mouth and nose, and that droplet infection plays a rôle in the dissemination of pathogenic micro-organisms. They have also known that such micro-organisms may be discharged into the air in greater numbers and to greater distances by the uncovered cough and sneeze than in ordinary breathing. But since such droplets are not visible under ordinary conditions, the risks of infection by this means have not been fully appreciated by the public, and the precautionary warnings of health officers to 'cover your cough and your sneeze' are not generally heeded.

If any one has failed to appraise fully the potential danger of spreading infection to others by an uncovered sneeze, he has only to study the accompanying photograph, taken by Prof. M. W. Jennison, of the Department of Biology and Public Health, Massachusetts Institute of Technology, which shows the expulsion of droplets in a violent, unstified act of sneezing.

According to Dr. C. E. Turner, who furnished the photograph, the picture was taken by the technique of ultra high-speed photography, which substitutes an instantaneous flash of light for the opening and closing of the camera shutter. This stroboscopic light illuminates the object to be photographed with an intense

flash of short duration, the light being placed in such a position in this picture as to illuminate the droplets with a dark-field effect, so that they stand out sharply even in daylight and give photographic images larger than actual droplet size. The time of exposure was about 1/30,000 of a second.

In such a sneeze as that illustrated here, the droplets are numbered in the thousands, varying with the intensity of the expiratory effort. The number of bacteria dispersed in a sneeze may also be very large. It is stated that most of the droplets are under 2 mm. in diameter and that many are less than 0.1 mm.

The 'muzzle velocity' of some droplets is said to be as great as 150 feet a second, and large droplets may be expelled to a distance of 12 feet, although the majority do not travel more than 2 or 3 feet. The involuntary closing of the mouth near the end of a sneeze tends to form a restricted orifice, resulting in the production of more and smaller droplets, which probably come largely from the saliva in the front of the mouth. Also it is apparent from the photograph that the number of droplets issuing from the nose in an unstified sneeze is insignificant as compared with the number expelled from the mouth. As stated by Jennison and Edgerton, these observations are probably important in relation to infectivity, because of the differences in the microbic flora of the two regions.

Some droplets fall to the floor or ground, while others evaporate, leaving their bacteria suspended in the air,

The expulsion of droplets in an unstified sneeze.

through which they may be disseminated by air currents.

The bacteriologic and epidemiologic aspects of infection of the air were discussed in a recent article by Wells, Wells, and Mudd, who conducted experiments on the concentration of micro-organisms in the air. They state that 'the numbers of streptococci characteristic of the nasopharynx indicate a hazard of respiratory infection and have a sanitary significance comparable with the presence of *Escherichia coli* in drinking water'. They estimate that several thousand nasopharyngeal streptococci per sneeze are contributed to the atmosphere and that 'the sneeze thus almost seems to be a provision of nature for the survival of nasopharyngeal parasites. Even where the manifestations of a disease do not provide for the wide auto-dissemination of the infection through the air it has been observed that an outbreak of colds will be followed by the rapid spread of contagion. Sneezing induced by pollens might conceivably facilitate the spread of nasopharyngeal infection . . .'

Although much is yet to be learned experimentally regarding the physical and other characteristics of expiratory droplets which are factors in determining more accurately the rôle of droplet transmission in those communicable diseases that are spread by nose and mouth discharges, there can be no question that covering the mouth in coughing and sneezing is an important preventive measure with respect to such diseases.

# Anaemia yields readily

Results of experiments devised to determine the potency of Waterbury's Compound as a haemoglobin restorative in nutritional anaemia.

Hæmoglobin count using the Dare Hæmoglobinometer and scale. Sample taken from tail artery.

65th day, period when supplementing with Waterbury's Compound was begun.

## TO WATERBURY'S COMPOUND *PLAIN*

Anæmia is probably the most frequent after-effect of disease, and the most persistent. It will yield readily to intensive treatment with Waterbury's Compound.

This preparation contains fresh liver, spleen and cod liver oil, acted upon by digestive ferments for easy absorption and assimilation.

Waterbury's Compound is also supplied with Creosote and Guaiacol to make it more efficient at those seasons when coughs, colds, and respiratory ills need special attention and care.

May we send you a bottle of each form of this very palatable and dependable hæmatinic and reconstructive to form your own conclusions?

## Fluid for the Surgical Patient

(From the *Lancet*, Vol. II, 17th August, 1940, p. 199)

THE fluid loss of the body in health varies widely, with occupation and environment among other things, but Starling puts the normal loss for the average adult at  $4\frac{1}{2}$  pints a day, of which about  $2\frac{1}{2}$  pints is lost in the urine,  $1\frac{1}{5}$  pint in the faeces, and the remainder by insensible perspiration from the skin or as water vapour from the lungs. The surgical patient often has a big fluid deficit to make up, and during and after operation perspiration is much increased; 6 to  $6\frac{1}{2}$  pints a day is therefore a reasonable allowance for the immediate post-operative period. In addition to water the patient needs salt and glucose, but Avery Jones and Naunton Morgan point out that salt may easily be overdone. They suggest 5 g. daily as a sufficient allowance of salt, and if the 6 to  $6\frac{1}{2}$  pints of fluid are given in the form of normal saline the patient will get over 30 g. of salt, which he may have difficulty in excreting. The retention of salt may then lead to the accumulation of water in the tissues which may produce subcutaneous oedema or water-logging of the lungs and delay the healing of wounds. Normal saline is therefore unsuitable for prolonged administration, but it is useful in replacing electrolytes lost by vomiting or sweating. For rectal infusion Jones and Morgan recommend normal saline diluted with four parts of tap water (0.18 per cent NaCl), though tap water alone is often sufficient and is well tolerated. For continuous intravenous infusion the solution is made up of one part of normal saline and four parts of 5 per cent glucose in distilled water.

This solution contains 0.18 per cent NaCl and 4 per cent glucose, and is isotonic. Hypertonic saline has a strictly limited application in surgery apart from its use as a diuretic and for reducing intracranial pressure, but it is of value in cases of paralytic ileus where there is stagnation of fluid in the dilated intestinal loops. More complicated solutions such as Ringer's and Hartman's have had a certain vogue, but they are unnecessary in most surgical cases.

If the patient can and will drink and there is no other contra-indication the fluid should be given by the mouth. This obvious principle is sometimes forgotten. In comatose or unco-operative patients the fluid can be given by a tube passed into the stomach

through the nose or mouth. After the mouth the rectum is probably the next best route, and up to 10 pints can usually be given daily in this way by a continuous drip delivering not more than 30 to 40 drops a minute, using a small rubber catheter (no. 9) but occasionally a feeble ill patient cannot tolerate the catheter or retain the fluid in his rectum. Nowadays it is the fashion to pour fluid straight into a vein, but this has some serious disadvantages. It is fatally easy to give too much fluid or to give it too quickly, for by this route the blood stream has no choice but to take what is given it. Moreover, as Walthers has remarked, the saline is mixed directly with the blood and thus reduces still further the concentration of plasma proteins which will already be low after an operation, whereas fluid given by the mouth or rectum passes through the liver first, and will be able to pick up protein *en route* before entering the pulmonary circulation. Inserting a needle or cannula into a vein may be difficult for the inexperienced, especially in a collapsed patient, the subsequent infusion needs careful watching, and the needle often needs readjustment or even reinsertion. Hypodermolysis is easy but not much fluid can be given by this route; there is also great danger of infection, and glucose solutions may cause aseptic necrosis. Intraperitoneal infusion is seldom used except in babies, for it is risky and has few advantages.

Lately, Billimoria and Dunlop have described a simple method of administering fluids intramuscularly. The only special instrument required is a long strong needle fitted with a sliding shield. Little skill or time is needed for inserting the needle and setting up the apparatus. If two needles are used—one in each thigh—more than 8 pints of fluid can be given in a day and infusion by this route has been maintained continuously for eight days. If the fluid is given too rapidly it is held up as local oedema, thus safeguarding the pulmonary and systemic circulations against dangerous flooding or dilution. Infection is rarely encountered if strict aseptic precautions are observed. Glucose in 5 per cent solutions may safely be given in this way, but care must be taken that none of the solution collects in the subcutaneous tissues. This method is not new and its soundness is well established; it deserves to be more widely adopted.

## Reviews

**RECENT ADVANCES IN ENDOCRINOLOGY.**—By A. T. Cameron, M.A., D.Sc. (Edin.), F.I.C., F.R.S.C. Fourth Edition. 1940. J. and A. Churchill, Limited, London. Pp. viii plus 432, with 67 figures, including three plates. Price, 18s.

ENDOCRINOLOGY is one of the most virile of the medical sciences, and after a period of four years there are enough 'recent advances' to fill a whole volume. The author has however interpreted the term in the more liberal manner and has interwoven his account of the advances of these four years with that of the advances of the last decade or so. Most of the important sections have been completely rewritten and certain obsolete matter deleted, but the net result is an increase of about 20 per cent in the printed matter. There has been a 25-per-cent increase in the matter on each page without loss to readability; this has allowed an actual reduction in the number of pages.

One of the most important advances in the last four years has been the synthesis of a number of hormones. The physician is liable to accept these chemical triumphs too lightly, but he cannot ignore their practical importance. One example is desoxycorticosterone acetate;

though it has not entirely displaced gland-extracted cortin, which also probably acts by virtue of its impurities, it can at least be used as a substitute for this expensive gland product in a number of occasions, and it may mean that the man of moderate means with Addison's disease will be kept alive as a useful member of society for a considerable time. A reference in this volume is made to a patient who was maintained in almost normal health for at least two years with 25 c.cm. of cortin daily, but, to compensate for the labour involved in preparing this amount of gland extract, the individual would have to be a very valuable member of society. Another advantage of the synthetic preparation is that tablets can be inserted subcutaneously for maintenance dosage.

Equally important advances have been made in the realm of sex hormones and here again synthetic preparations are well established.

The impression that one gains from reading this important review on the present status of endocrinology is that, if the science is not prostituted by adventurer manufacturers and advertisers and the too-easily-victimised polytherapy-practising members of the profession, it has a very bright future.

**DERMATOLOGIC ALLERGY: AN INTRODUCTION IN THE FORM OF A SERIES OF LECTURES.—**

By M. B. Sulzberger, M.D. 1940. Charles C. Thomas, Springfield, Illinois. Pp. xxii plus 540, with 13 coloured plates and 39 illustrations. Price, 47s. Obtainable from Messrs. Ballière, Tindall and Cox, London

THIS book is arranged as a series of fourteen lectures. The first is devoted to definitions and classification of skin allergy, and the second is on the protective nature of the skin and its importance as a possible originator of allergic changes. Lecture three is on the basic phenomena in allergy and lecture four describes how to investigate a suspected case of skin allergy.

These four lectures make an excellent introduction to the study of this difficult subject, and having acquired that knowledge the student is next taken through the principal types of allergic skin reaction in the next nine lectures, and lecture fourteen is an interesting and speculative consideration of the future of allergy in medicine.

At the end of the book there are several appendices one of which is particularly useful as it gives a long alphabetically-arranged list of substances used in patch tests with the strengths of the solutions and the solvents it is best to use for each of them, and another appendix of practical value is one of 30 pages in which the general management of urticarial and eczematous conditions is discussed, apart from their allergic aspect.

The author modestly describes his book in the opening sentence of the preface by saying it is not a book of reference nor an encyclopædic treatise on allergy. On this account it is all the more useful to the average practitioner who is concerned primarily with treating and curing his cases, because he can obtain from its pages more than he will usually need in the treatment of allergic skin diseases, without having to flounder through a welter of irrelevant and often contradictory statements such as a complete reference book on allergy must contain.

It is a book we can heartily recommend to all those who want a working knowledge of allergic dermatitis and how to treat it, and at the same time they will acquire a sufficient insight into the scientific aspect of the subject to show what a fascinating field it offers to those with inquiring minds.

P. A. M.

**ROSE AND CARLESS MANUAL OF SURGERY: FOR STUDENTS AND PRACTITIONERS.—**

By C. P. G. Wakeley, D.Sc., F.R.C.S., F.R.S.E., F.R.S.A., F.A.C.S., F.R.A.C.S., and J. B. Hunter, M.C., M.Chir. (Cantab.), F.R.C.S. (Eng.). Sixteenth Edition. Volumes I and II. 1940. Ballière, Tindall and Cox, London. Pp. xi plus 840 in volume I and pp. from 841 to 1708 and 48 index pages in volume II. Price, 30s. for two volumes

'ROSE AND CARLESS' is too well known to students and teachers to require a lengthy introduction. Except for one gap due to the last war, revisions of this textbook have been made at three-yearly intervals, and it is now in its sixteenth edition. But comparison of this with the two previous editions reveals that very important improvements have been made.

In the first volume, the first eight chapters show considerable alteration and now provide a concise introduction to surgical pathology which it would be hard to equal. For the rest, new descriptions of neurosurgery and much-needed revision in the section on fractures deserve special mention.

There are many new illustrations, and some of the old ones have been redrawn; they are perhaps of greatest value in the chapters on abdominal surgery, and include a coloured plate depicting gastroscopic appearances.

In the chapter on hernia the following passage is to be found: 'The most satisfactory operation of all for inguinal hernia, and that associated with the least number of recurrences, is some modification of Gallie's operation.' This is at variance with the opinion of many teachers, and also with a remark made by the

senior editor in his Hunterian lecture on 31st January, 1940, which reads, 'During the last few years fascial grafts for the repair of an inguinal hernia have come into vogue, and it has been claimed that the results are better than by other methods. I cannot agree that this view . . .' (*vide The Lancet*, 4th May, 1940, p. 822).

As before, the second volume contains chapters on special subjects by various contributors, and the section on tropical surgery has again been written by Sir Frank Connor.

Two new chapters attract special attention. The first is an excellent one on anaesthetics by Dr. Vernon Hall. If anaesthetists in this country would put into practice some of his teachings, the lot of both surgeon and patient would be immeasurably improved. The other chapter, the last in the book, is devoted to war surgery. In it the editors have laid down the general principles of this branch for the guidance of medical officers on active service.

Although larger and more profusely illustrated than before, the price of this book remains the same, so that one has no hesitation in predicting its continued popularity.

W. McN. N.

**SHOCK: BLOOD STUDIES AS A GUIDE TO THERAPY.—**

By John Scudder, M.D., Med., Sc.D., F.A.C.S. 1940. J. B. Lippincott Company, Philadelphia and London. Pp. xvii plus 315, with 55 illustrations, 5 plates—3 of which are in colour. Price, 30s.

THIS book is a record of experimental work on shock. It is also incidentally an historical bibliography of earlier work, and it will always justify its shelf-room on account of its bibliography of 533 references, and its historical record of the developments in our conception and treatment of shock, and in our knowledge of the functions of the adrenal gland and of the physiological effects of potassium. The author's own work could however have been reported more concisely and therefore more usefully in a reasonably-sized article in some journal devoted to experimental medicine.

One of the main contentions of the writer is that careful blood examination in each case is essential as a preliminary to proper treatment. One of the effects of shock is hæmoconcentration, which can be shown by an increase in specific gravity, but this may be associated with an actual loss in the proportion of red cells to the circulating blood, which will be indicated by a cell volume estimation. He might go further and suggest that a total red cell count should always be done, for after hæmorrhage there is an increase in size of the individual red cell, so that an increase in cell volume might cover a loss in numbers of red cells and an actual decrease in cell-plasma interface.

Another point made is the increase in plasma potassium in shock and also in stored blood, so that obviously the latter is unsuitable for use in shocked patients, and plasma separated at an early date would be much better.

The volume is a beautiful example of the best American book production and the writer's style is lucid, though he lapses now and then into the jargon of the careless medical writer, *e.g.*, 'at the time of her operative death'. What would A. P. H. say?

**DISEASES AFFECTING THE VULVA.—**

By Elizabeth Hunt, B.A., M.D., Ch.B. (Liverpool). 1940. Henry Kimpton, London. Pp. xiii plus 215, with 36 illustrations and 18 plates in colour. Price, 21s.

A book such as Dr. Hunt's 'Diseases Affecting the Vulva' is very welcome indeed, and Dr. Hunt may rest assured that it will 'prove of assistance in the treatment of the many women who suffer so seriously and so long', the hope she expresses in her preface.

After an introduction, in which allergy is very clearly explained, the anatomy and development of the vulva are described. There is an excellent chapter on the histology of the vulval tissues and then the author goes on to the description of all those diseases which

# Elastoplast Technique in Modern Surgery

## ABDOMINAL POST-OPERATIVE DRESSING

A sterile dressing is applied to the abdominal wound followed by a piece of an 'Elastoplast' bandage, sufficiently wide to cover completely the sterile dressing and sufficiently long to stretch from one side of the abdomen to the other.

Piece of 'Elastoplast' Bandage showing centre portion rendered NON-adhesive by dabbing with cotton-wool.

Section showing 'Elastoplast' applied over a sterile dressing.

Section showing 'Elastoplast' cut up centre and turned back for examination and re-dressing of wound. Fix with clip or safety-pin

The centre of the 'Elastoplast' is dabbed with cotton wool, thus rendering it non-adhesive, to an extent that will just cover the sterile dressing. This is then applied to the abdomen with the required tension, so that the non-adhesive portion covers the dressing.

When it is desirable to change the dressing the following procedure is necessary:—

The centre is slit up with a pair of dressings scissors; the sterile dressing is changed and the cut ends are folded back over the dressing and fastened with a clip or safety-

pin. For subsequent dressings it is then only necessary to unfasten the clip or safety-pin for the wound to be examined and re-dressed.

Where frequent change of dressing is required, an improved method is illustrated below.

Completed Dressing.

Dressing opened for inspection.

- (1) Rods. (2) Strips of 'Elastoplast' folded round the rods, so that the adhesive surface does not come in contact with dressing. (3) Rubber bands. (4) Dressing.

# Elastoplast

'Elastoplast' Bandages and Dressings are specially prepared for use in the Tropics

# A single teaspoonful of CAL-BIS-MA

The first teaspoonful or the last—there is no difference in the composition of CAL-BIS-MA. In every teaspoonful there is just the right proportion of sodium bicarbonate and magnesium carbonate for quick gastric neutralization ; every single teaspoonful has the proper amount of calcium carbonate and bismuth salts to prolong the neutralization. Ingredients of matched density, incorporated in a colloid base, assure a uniform product throughout. ¶ But Cal-Bis-Ma goes further. With colloidal kaolin it obviates gaseous distension ; with bismuth and colloidal kaolin it soothes and protects the irritated gastric mucous membrane and prevents secondary acid rise. ¶ Descriptive literature and trial supply of Cal-Bis-Ma gladly sent on request.

MARTIN & HARRIS LTD.,

## Chosen by Radiologists Everywhere

ILFORD X-RAY FILM is particularly suited to the requirements of modern radiographic technique. It is coated with an emulsion which combines speed to X-Ray, speed to Intensifying Screens, excellent contrast, freedom from fog, and quick fixing to a degree hitherto unknown.

The same film may be used with or without Intensifying Screens, and radiographs of excellent quality, full of detail, are obtainable.

Ilford X-Ray Film is supplied on both nitrate and acetate bases.

## ILFORD

## X-RAY FILM

*(Double Coated)*

FOR EXTREMITY WORK, the finest results are obtained from

ILFEX Double-Wrapped X-Ray Film.

Supplied only  
on Acetate (Safety) Clear Blue Base.

affect the vulva. Each condition is taken completely under the headings 'Ætiology', 'Clinical Manifestations', 'Diagnosis' and 'Treatment' and where necessary 'Complications', 'Histopathology' and so on are added. The descriptions are clear and concise, and really portray pictures. The author, though not dogmatic, is definite in her opinions on controversial subjects. Treatment is expounded particularly well and includes useful prescriptions for nearly all conditions. Considering the reputation skin diseases have for chronicity a little more space might be devoted to prognosis which is rarely mentioned, except by implication. For example, in discussing the treatment of kraurosis, the author advises the use of vegetable rather than mineral oils 'as these patients may require to use the preparations daily for a prolonged period'. Whether or not a cure is to be hoped for is not mentioned.

The pictures, so clearly described in the text, are supplemented by 28 really beautiful coloured plates and there are, in addition, 36 figures mostly of microscopic sections.

This book, so far as I know the only one of its kind, should be read and kept for reference by all who attempt the treatment of women. This is especially true in India where dermatologists are few and far between and where, unfortunately, skin conditions are often very inadequately treated. Pruritus, the subjective symptom, is more often than not labelled pruritis, a disease, and treated with douches, tampons, and alkaline hip-bath. This may not only fail to relieve the itching but may, as Dr. Hunt emphasizes, do actual harm.

G. B. W. F.

**MEDICAL DISEASES OF WAR.**—By Sir Arthur Hurst, M.A., D.M. (Oxon.), F.R.C.P., Lieut.-Colonel, late R.A.M.C. With the Co-operation of H. W. Barber, M.A., M.B. (Cantab.), F.R.C.P., F. A. Knott, M.D. (Lond.), M.R.C.P., and T. A. Ross, M.D. (Edin.), F.R.C.P. 1940. Edward Arnold and Company, London. Pp. viii plus 327. Illustrated. Price, 16s.

THIS book deals with the medical diseases that are the results of or are encountered during wars, and it is based on the author's varied experience of these diseases during the last great war and the post-war period.

More than half of the book deals with the various aspects of war neurosis. These chapters, which contain numerous illustrative case notes, are the results of original studies that Sir Arthur Hurst carried out among the soldiers of the last great war, and they form a brilliant exposition of the subject. Besides war neurosis, some acute infectious diseases, skin diseases, war nephritis, gas poisoning—the other diseases that are likely to be encountered in an European war—have been adequately discussed. Some of the diseases that are likely to occur in a tropical campaign have not been described in this book. This is unfortunate, for the present war is no longer limited to Europe, but has spread to tropical countries.

The book is written by one of the most eminent men in the medical profession in England and the various chapters written by him bear the stamp of a master of the subject. The author has invited collaboration of well-known specialists in writing some of the special sections. This has further enhanced the usefulness of this single volume dealing with the various diseases of war.

The book will undoubtedly be of help to medical officers called upon to treat soldiers and civilians during the present war.

P. C. S. G.

**A MANUAL OF EMBRYOLOGY: THE DEVELOPMENT OF THE HUMAN BODY.**—By J. Ernest Frazer, D.Sc. (Lond.), F.R.C.S. (Eng.). Second Edition. 1940. Baillière, Tindall and Cox, London. Pp. x plus 523, with 282 Illustrations. Price, 30s.

NINE years ago when Professor Frazer produced the first edition of *Manual of Embryology* he departed

from the traditional method of taking each and every organ separately and describing its development. He introduced the new method of giving as far as possible regional descriptions. This has not only made the book enjoyable to read, but it gives a clear picture of the growth of the body as a whole and not as he says 'a patchy series of discrete descriptions of the formation of organs'.

Another departure was the omission of references and the failure to point it out always when the author's descriptions deviated from those then generally accepted. Since then Professor Frazer's views on development have become universally known and the student will never be far wrong if he accepts them *in toto*.

The drastic cutting down of detail, the author states in his preface, is not pleasant. This is indeed true, more detail would be welcome in every section.

One disadvantage of the regional method—which is really an asset—is that the student swatting for his anatomy examination is unable to turn up the textbook and learn off an embryological note for each organ. This was a very popular method of 'learning embryology'. Actually it is not too much to hope that any student trying to use Frazer's *Embryology* in this manner will become interested in the subject and really learn something; certainly the text is sufficiently interesting to hold the attention of the serious student if once he dips in. Some space devoted to the various abnormalities of development would add to this interest and would be appreciated in the next edition.

The 1940 edition is on the same plan as the first edition though there are minor changes in its arrangement and some additions including seven new diagrams and new accounts of the umbilical cord, foetal circulation, and the sinus venosus.

Few misprints have been carried over into the new edition, for example, on page 169 in the penultimate sentence 'hind-brain' has been written instead of 'mid-brain', and, in figure 7, U.C. has been used to identify two different things, the umbilical cord and the uterine cavity.

The paper and printing in the new edition are distinctly superior.

G. B. W. F.

**FORENSIC CHEMISTRY.**—By Henry T. F. Rhodes, Dip. Inst.C. (Lyon). 1940. Chapman and Hall, Limited, London. Pp. viii plus 214. Price, 12s. 6d.

THIS little book by a worker in France covers remarkably well the ground common to the police and the chemist. It is much more than the toxicology which is usually associated with forensic medicine. References are plentiful and will provide, when necessary, details of procedures.

With a view to increasing the utility of the next edition of this useful book the following suggestions are offered: (i) removal of certain obscurities (p. 13, third para.; p. 95 last para.; p. 175 first para.) and an unnecessary restriction (p. 176, not keeping sulphuric acid in glass bottles); (ii) differentiating between blood *groups* and blood *types*; (iii) clarification of description by rearranging headings and sub-headings and indicating them by the usual system of lettering or numbering (a heading in CAPITAL letters should not be a part of a narrative under a heading in small letters, an instance on p. 129, and items whose relationship is one of genus and species should not be headed alike when following one another, an instance on p. 183); and (iv) inclusion of sweat analysis undertaken for turf clubs (samples from horses suspected to have been drugged have been sent to France for many years from all over the world).

The paper, the printing and the binding are good. Only one printer's error arrests attention (p. 121 last para. 'd oments'). The price perhaps could be lowered in normal times.

The book should be available to all investigators of crime.

S. D. S. G.

1938—a decline of 121 deaths. Of the total number of infantile deaths, 1,461 (46.91 per cent) were amongst the Burmese, 839 (26.94 per cent) amongst the Hindus, 333 (10.69 per cent) amongst the Mohammedans and 247 (7.93 per cent) amongst the Chinese. The important causes of infantile mortality were as usual convulsions, bronchitis and pneumonia, premature birth, malnutrition, dysentery and diarrhoea and enteritis.

Four thousand seven hundred and sixty-five infants were under the care of the Maternity and Child Welfare Scheme of this department and out of these, 634 died giving a mortality rate of 133.05 per 1,000 against 177.51 in the year 1938. The table below gives the infantile mortality rate amongst infants under the care of the Maternity and Child Welfare Scheme in the city during the last 4 years.

1936	..	145.96	1938	..	177.51
1937	..	139.90	1939	..	133.05

The tuberculosis dispensary maintained its popularity, the number of new patients and the total attendance during the year being 4,927 and 38,039 respectively compared with 3,955 and 34,206 during the previous year.

The number of patients treated at the various other dispensaries maintained by the Corporation was 183,691 compared with 172,087. The total attendances at these dispensaries during the year was 435,910 against 403,582 during the previous year.

There is not much to report with regard to any improvement made in the milk supply of the city. Two thousand four hundred and eighty samples of milk, of which 2,394 were taken by the milk inspectors, were examined. Eight hundred and nineteen conformed to the standard.

The water supply, as usual, was chlorinated and kept at a high standard of bacteriological purity. During the year, treatment of water by chloramine was tried. The results were encouraging but in view of the difficulties of obtaining regular supplies of chemicals as a result of the war, further progress could not be made although chloramine treatment is still being continued.

The staff employed for combating the mosquito nuisance in the city continued to do useful work. The public has now become conscious of the mosquito problem and if sustained efforts are made, the day is not distant when the mosquito problem will become practically insignificant.

#### ANNUAL REPORT ON THE WORKING OF THE ASSAM MENTAL HOSPITAL, TEZPUR, FOR THE YEAR 1939

THE superintendent has endeavoured, with considerable success, to introduce the modern 'hospital' outlook into the institution, as opposed to the out-of-date 'Lunatic Asylum' atmosphere. The keeper staff have been taught the ideal that inmates of the institution are sick patients and that the proper attitude towards them is that of a nurse in a children's hospital. According to modern ideas of psychological medicine as much freedom as is compatible with safety is given to the patient and mechanical restraint has been done away with. This has, of course, put considerable strain on the staff, but it seems well justified.

Dr. H. C. Barua, the Superintendent, remarks—

'This institution is a mixture of an asylum, a jail and a mental hospital. The majority of the patients are chronic cases requiring life-long asylum treatment. Those cases, however, in whom there is a prospect of cure react adversely during the recovery process, when they are in association with chronic cases. This is also observed as in the case of criminal mental patients who may, after recovery, have to stay in association with chronic cases sometimes for a considerable period before their discharge. These patients fully realize their position and some relapse. For such cases a separate convalescent home is wanted and it is suggested that the two new blocks proposed as a future extension should be built outside the compound and devoted to this purpose'.

The points raised by the superintendent are important and deserve the consideration of Government.

*Paying patients.*—There were only six patients among the inmates, at the time of submitting the report, who were stated to be capable of paying modest rate of maintenance. This seems an incredibly small proportion.

*Sanitation and hygiene.*—The defects here are outstanding and have been reported repeatedly. It is almost unbelievable that an institution of this kind, the only one in Assam, should have to carry on its work with a totally inadequate water-supply and with an antiquated arrangement for sterilizing clothing and bedding.

The municipal water-supply, in spite of the high tax charged, is, and seems likely to remain, totally insufficient and a separate plant for the hospital with a good tube-well is essential. Insufficient water brings the inevitable sequel of dirt and disease, and nowhere is it more important to guard against these than in a community composed mainly of mental patients.

The 'blanket boiler' can only be described as a relic of the past. It should be abolished and replaced by a modern type of steam sterilizer. Efficient sterilizing and perhaps even more important here—effective—delousing is otherwise impossible.

## Correspondence

### ENTOMOLOGICAL SPECIMENS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—For a number of years, I have made use of the following plan to demonstrate entomological specimens to students:—

A stout test-tube of suitable width is selected. The specimen to be mounted is picked up on a long entomological needle, and absorbent cotton-wool is wrapped round the shaft of the needle till the cotton forms a closely-fitting bung; the whole is then introduced into the test-tube, the insect being foremost. The cotton plug is carefully pushed in till the specimen is very near the dome-shaped bottom of the test-tube. A naphthalene ball is put in, and the proper label

# During the Age of Growth

**A**T no time, throughout the span of life, is the proper and orderly balance of calcium, phosphorus and iron, vitamins and other highly important food elements more readily disturbed than during the period of active growth and development.

The food supply of every child should, therefore, contain an adequate proportion of these important substances, if normal progress is to be maintained. The construction of an entirely correct dietary, to suit the varying requirements of each individual is, however, beyond the possibility of realization in ordinary practice.

Many physicians ensure that the ordinary dietary of the young patient is safe and adequate by advocating the daily addition of 'Ovaltine'. This is a complete, well-balanced food, rich in natural vitamins and in readily assimilable calcium, phosphorus and iron.

'Ovaltine' is composed of ripe barley malt, pure creamy cow's milk together with valuable natural phosphatides and vitamins. Its sugar content is chiefly in the form of maltose, a very readily available source of energy. No cane sugar or chocolate is added to give bulk or to cheapen the cost. 'Ovaltine' is delightful to the taste and readily assimilable even by digestions impaired by disease.

# ST. BARTHOLOMEW'S HOSPITAL OPERATION TABLE

with the  
**Latest Improvements**

including

Easy to operate Release Lever for lowering the table; Trendelenburg position increased to 55° tilt; Foot operated rubber-covered Floor Brake.

The St. Bartholomew's Hospital Operation Table is now manufactured in five different models and thus supplies a range of modern operation tables embodying the latest ideas of well-known surgeons for carrying out surgical operations.

All models can be supplied with either tripod or platform base.

**Model A**

In Trendelenburg position, 55° tilt, showing shoulder rests and instrument tray in position.

**Model AC**

in lateral position, with back elevator and lateral supports.

Over 1075 of these tables are in use at home and abroad.

*A descriptive booklet, fully illustrated, will be sent on request.*

**ALLEN & HANBURY LTD.**

(Incorporated in England)

**CLIVE BUILDINGS, CALCUTTA**  
and at 37 Lombard Street, London, E.C.3

**Model B**  
in chair position,  
with heel supports  
and bladder irriga-  
tion tray.

giving name, details, etc., is then introduced. A cork or rubber stopper completes the mounting.

Thus preserved, the specimens last for years, and each can be examined in detail with a hand-lens.

I have found that this method saves a lot of time and temper, as heads and legs do not drop off so frequently, and the mounting is able to withstand the onslaught of a series of classes.

Yours, etc.,

P. A. DALAL, L.M. & S. (Bom.),  
D.T.M. & H. (Camb.),  
(Late Professor of Bacteriology,  
Grant Medical College, Bombay).

242, PRINCESS STREET,  
BOMBAY,  
24th October, 1910.

## Service Notes

### APPOINTMENTS AND TRANSFERS

COLONEL R. H. CANDY, C.I.E., K.H.S., is appointed to be Surgeon-General with the Government of Bombay, with effect from the 31st October, 1910.

Lieutenant-Colonel R. S. Aspinall, C.I.E., an Agency Surgeon, is appointed as Residency Surgeon, Mysore, with effect from the afternoon of the 15th October, 1910.

Lieutenant-Colonel M. Das, M.C., made over the executive charge of the Alipore Central Jail to Mr. C. Heath on the afternoon of the 4th October, 1910.

Lieutenant-Colonel F. H. Whyte is appointed to the post of Civil Surgeon, New Delhi, with effect from the forenoon of the 15th October, 1910.

Major E. A. R. Ardeshtir made over charge of the office of Superintendent of Rajshahi Central Jail to Dr. Monsural Rahman on the afternoon of 4th October, 1910.

On return from leave Major D. W. B. Read, an officer of the Medical Research Department, is transferred to foreign service under the Indian Research Fund Association, with effect from the 8th July, 1910 (forenoon).

Major G. Milne, an officiating Agency Surgeon, is appointed as Medical Officer in charge of the Crown Representative's Police Force Hospital, Neemuch, with effect from the forenoon of the 16th October, 1910.

The undermentioned officers retire with gratuity and are granted emergency commissions from the dates specified against each:—

#### Short Service Commission

Captain R. Kasliwal. Dated 23rd September, 1910.

#### Permanent Commission

Captain A. S. Rao. Dated 10th October, 1910.

#### To be Captains (on probation)

Tahil Dayaram Chablani. Dated 30th September, 1910, with seniority from 30th September, 1936.

Ram Lal Soota. Dated 10th October, 1910, with seniority, 10th October, 1936.

Motilal Shankhla. Dated 11th October, 1910, with seniority, 11th October, 1936.

#### To be Lieutenants (on probation)

Thomas Jenner Powell. Dated 3rd August, 1910.

J. O'Neill. Dated 23rd April, 1940.

M. K. Bryce. Dated 3rd August, 1940.

J. L. O'Neill. Dated 3rd August, 1940.

W. J. Stewart. Dated 3rd August, 1940.

M. Ata-ullah. Dated 20th October, 1940.

#### RETIREMENT

Lieutenant-Colonel G. C. Maitra. Dated 10th November, 1940.

## Notes

### GLAXO LABORATORIES PRODUCTS

We have just received a very neat catalogue of the products of this laboratory.

The first dozen pages or so are conveniently devoted to indices. The first is an index of their products in alphabetical order: they cover a wide range and include over sixty items. The next is a pharmaceutical index from 'threatened abortion' in which 'viteolin', an extract of wheat germ oil, which is rich in vitamin E,

to 'wounds' for which they recommend 'flavogel', acriflavine jelly. This index refers to well over a hundred diseases in which Glaxo products are useful. There is then a separate list of vitamin products, from A to P, and finally detailed lists of Pharmaceutical Products, 'Glaxo' Injections, Dissolved Vaccines 'Glaxo' and Glaxo Food Products, with full details of indications and dosage.

This is a very handy list for any doctor to keep on his table for quick reference. The agents, H. J. Foster & Co., Ltd., have offices in Calcutta (P. O. Box 2257), Bombay (P. O. Box 202), Madras (P. O. Box 108) and Lahore (P. O. Box 244).

### UREA SULPHAZIDE:—'T'

(U. S. T.)

UNION DRUG Co., Ltd., take pleasure to announce the introduction of their latest chemotherapeutic, UREA SULPHAZIDE:—'T' (U. S. T.), designed for the oral treatment of gonococcal infections. Clinical trials with the preparation have shown that it is equally effective in the treatment of all stages of gonorrhoea and its complications.

Samples of the product and fuller details on dosage and method of administration are supplied to the medical profession on request to the manufacturers at 285, Bowbazar Street, Calcutta.

## Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

*Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.*

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

# HEWLETT'S ORIGINAL PREPARATIONS

## HEWLETT'S MIXTURE

(Mist. Pepsinae Co. c. Bismutho.)

COMPOSITION :—Pepsine, Bismuth, Sol. Opii Purif., Tr. Nuc. Vom., Acid Hydrocyanic Dil., etc.

Over 60 years' reputation as a useful remedy in Dyspepsia especially when Pyrosis is a conspicuous symptom and in Diseases of the Stomach.

DOSE :—One to two drachms, diluted.

Price in England. 4-oz. bottles, 10d. oz. 10, 22, 40, and 90-oz. bottles, 12/6 per lb.

## LIQ. ERGOTAE PURIF. (HEWLETT'S)

Physiologically standardised. This preparation is superior to the ordinary liquid extracts, tinctures and other preparations of Ergot. It has been successfully employed in tedious Labours, Post-Partum Hæmorrhage, Hæmoptysis, Dysmenorrhœa, etc., and also in the treatment of Whooping Cough.

Price in England. 5, 10, 22, 40, and 90-oz. bottles, 25/- per lb.

## MIST. ANTI-ASTHMATIC CONC. (HEWLETT'S) 1 to 7

COMPOSITION :—Potassii Iodid., Sodii Brom., Ext. Euphorb. Pilulif., Nitro-Glycerine, 1/200 gr.; Tinct. Lobeliae, etc., in each fluid ounce.

This mixture is prepared from the recipe of the eminent therapist, Dr. Hare, for the relief of Asthma and its concomitants, dyspnœa, sibilant bronchi, loud wheezing or shrill whistlings.

DOSE :—One fluid ounce of the diluted mixture.

Price in England. 4-oz. bottles, 4d. oz. 10, 22, 40, and 90-oz. bottles, 4/6 per lb.

## "HEPATAGEN" TRADE MARK

(Mist. Hepatica Conc. Hewlett's)

An excellent compound of Cascara, Rhubarb, Jalap, Podophyllin, etc. with 1/20 gr. Cocaine in each drachm.

(Not under the Dangerous Drugs Act.)

An elegant and palatable general Aperient and Cholagogue, especially recommended in cases of so-called "Biliousness", Hepatitis and Chronic Gastritis.

DOSE :—10 to 60 minims, diluted.

Price in England. 4-oz. bottles, 10d. oz. 10, 22, 40, and 90-oz. bottles, 12/6 per lb.

## LIQ. SANTAL FLAV. c. BUCHU et CUBEBA (HEWLETT'S)

The original preparation. Containing three remedies of proved utility and employed with extraordinary success in certain cases.

DOSE :—One to two drachms in peppermint water.

Price in England. 4-oz. bottles, 10d. oz. 10, 22, 40, and 90-oz. bottles, 12/6 per lb.

## MIST. DAMIANAE CO. (HEWLETT'S)

Recommended for Neurasthenia, also in the Dyspepsia of commencing Phthisis. It soothes the stomach and enables the patient to take more food whilst acting as a powerful stimulant in relieving exhaustion.

Price in England. 4-oz. bottles, 10d. oz. 10, 22, 40, and 90-oz. bottles, 12/6 per lb.

# HORLICKS

## IN PNEUMONIA

**H**ORLICKS is fresh, full-cream cows' milk combined with the nutritive extracts of wheat and malted barley.

During pneumonia and other acute fevers of short duration the amount of nourishment taken by the patient is not of primary importance, though liquid food at frequent intervals is of value.

Horlicks is an ideal form of nourishment during these illnesses. It is easily and simply prepared—requiring the addition of water only. Hence, no more than is sufficient for a meal need be made at any one time, and the patient is thus assured of receiving freshly prepared food in an appetising form.

Horlicks is easily digested and readily assimilated; it contains adequate protein and possesses marked protein-sparing qualities. It thus prevents tissue waste, and is a valuable builder during convalescence.

*Available Everywhere*

# TRIMAX

(STEARNS)

*Hydrated Magnesium Trisilicate*

ANTACID • ANTIPEPTIC • ANTITOXIC

A smooth, white, fine powder in which no evidence of grit can be detected by the teeth or tongue. It is tasteless and insoluble, possessing adsorbent and antacid properties of particular value in the treatment of Gastric Hyperacidity and Chronic Peptic Ulceration of the Stomach, Duodenum, and Jejunum.

Available in bottles containing 1½ ounces by weight. Owing to the levity of the powder this is equivalent to 8 ounces by volume.

A. O. is made from Tubercle Bacilli of the human type. It is sterile, consists of the native protoplasm of the bacilli, is absorbed, is completely innocuous, is derived from strongly immunizing strains of bacilli and has a uniform potency. A. O. is indicated in cases of latent tuberculosis, pulmonary tuberculosis (apical catarrh), surgical tuberculosis and urogenital tuberculosis, ophthalmological tuberculosis, dermal tuberculosis, pleurisy and peritonitis, in convalescence, disorderly menstruation due to innate weakness, glandular affections, laryngeal and intestinal tuberculosis. A. O. is used for (1) Therapy, (2) Diagnosis, and (3) Prophylaxis. A. O. is innocuous and has no ill effects.

*Yes*, mathematics is an exact science—but one does not always equal one.

For relief of chronic asthma, one injection of Adrenalin in Oil is frequently equivalent to five of aqueous Adrenalin. Relief with the oil suspension often persists ten hours; the effect of the aqueous solution lasts not more than two hours.

Basic Adrenalin is much less soluble than Adrenalin Chloride, and difference in time of action (between two such pre-

parations) is further increased by the physical dissimilarity between oil and water.

Except in emergencies, where the rapid action of aqueous Adrenalin is desirable, symptomatic therapy of asthma, urticaria, and serum sickness is advantageously carried out with Adrenalin in Oil.

Adrenalin in Oil, a 1:500 suspension of basic Adrenalin in peanut oil, contains 2 milligrams of hormone in each cubic centimeter.

*Supplied in 1-cc. ampoules, boxes of 6.*
